Animals that die after chronic persistent coughing, dyspnea, and weight loss exhibit lesions of chronic suppurative pneumonia. Bronchi and bronchioles are filled with purulent exudate, there are multiple mature lung abscesses, and greatly dilated bronchioles contain malodorous exudate. When bronchiectasis is severe, the lung lobes have a nodular appearance. Pulmonary abscesses and bronchiectasis are common findings in cases of chronic pneumonia and explain poor weight gains.[414]

Although gross necropsy alone can be very helpful in generating an accurate list of differential diagnoses, histopathologic and microbiologic findings often add critical information. Gross necropsy findings are not always definitive; for example, in one study of AIP in feedlot cattle, only 67% of the cases that were diagnosed with AIP based on clinical and gross pathologic findings were confirmed by histopathology.[420] Therefore in outbreaks with relatively high mortality or in cases in which long-term and possibly expensive therapy is not yielding expected results, the cost of full necropsy of two or three typical cases is likely to be well worth the expense.

If full necropsy at a local diagnostic laboratory is to be undertaken, two or more animals showing signs that are typical of the early stages of the disease outbreak should be selected for euthanasia and necropsy. Although the producer may be reluctant to euthanize animals that may recover, and would rather send animals with chronic, nonresponsive disease, the chronic cases are unlikely to yield information relevant to the primary problem.

31.59 MICROBIOLOGIC TESTS

If samples are collected from a necropsy on the farm for testing for viral or bacterial pathogens, proper handling and transport of the specimens is critical to maximize the chance of an accurate diagnosis. The veterinarian is encouraged to contact the diagnostic laboratory if uncertain about proper methods of sample collection and transport; most laboratories now post this information on their websites, making it easy to find for those with Internet access.

628
629

31.59.1 Viruses

A specific viral diagnosis requires laboratory confirmation. Most laboratories direct their diagnostic efforts toward the viruses for which vaccines are available. Diagnosis of other respiratory viruses may require the assistance of specialized laboratories. Because of the time and expense that specific viral diagnosis entails, care must be taken in the collection, storage, and transport of appropriate specimens to a diagnostic facility. The veterinarian is encouraged to contact the diagnostic laboratory if uncertain about the proper methods for collecting and transporting specimens for microbiologic diagnosis.

31.59.1.1 VIRUS ISOLATION

Virus isolation is time-consuming and expensive, but it is a sensitive method for identifying viruses. Virus isolation is performed in cell culture. A variety of specimens can be tested, including nasopharyngeal, conjunctival, and tracheal swabs, TTAs, BALFs, and a variety of respiratory tract tissues that can be obtained at postmortem examination. Fluids, tissues, and swabs may be frozen; alternatively, swabs and tissue specimens may be placed in a viral transport medium and kept refrigerated until arrival at the diagnostic laboratory, preferably within 24 hours. BRSV does not appear to survive freezing or transport well, and it is important that specimens be inoculated onto cell cultures as soon as possible. In general, better success at virus isolation is obtained when specimens are collected in the acute phase of disease. Chances of successful

isolation may be improved by sampling asymptomatic animals that are in close contact with affected animals. These animals may be in an incubation phase of infection. Some viruses appear to be more difficult to isolate than others. For example, BRSV is very difficult to isolate by routine procedures, and other diagnostic procedures (discussed later) should be performed in conjunction with attempts at virus isolation. During isolation procedures, viruses are detected by production of cytopathic changes in cell monolayers. Viral identification is accomplished by a variety of procedures such as neutralization with specific antiserum, FA staining, immunoperoxidase staining, and examination by electron microscopy and immunoelectron microscopy. An immunoperoxidase monolayer assay has been developed for detection of BVDV and is in routine use for screening serum samples for detection of cattle persistently infected with BVDV.

31.59.1.2

DETECTION OF VIRAL ANTIGENS

Immunofluorescence is a rapid method for identification of specific respiratory viruses. Antemortem identification can be made from conjunctival or nasal smears and from cells obtained by tracheal lavage or BAL. Postmortem identification can be made from frozen tissue sections prepared from a variety of respiratory tract tissues.

Another technique that is used to detect viral antigen in tissues is immunoperoxidase staining, which is most often carried out using formalin-fixed tissue. This is a very useful procedure that allows histologic examination of tissues in conjunction with immunologic identification of the causative agent.

Antigen capture enzyme immunoassay (EIA) provides a rapid means for detection of respiratory viruses. These tests can be performed on fluids obtained from the respiratory tract. Commercially available antigen capture EIAs are available for diagnosis of human RSV infections in infants and young children that are also capable of detecting BRSV,[421] and these are in use in some veterinary diagnostic laboratories. The same technique has been developed for the detection of BVDV and is in use for screening serum samples to detect cattle persistently infected with BVDV.

31.59.1.3

DETECTION OF VIRAL NUCLEIC ACIDS

The nucleotide sequence has been determined for the genome or partial genome for many of the ruminant respiratory viruses. Testing for viral nucleic acid by PCR (for DNA viruses) or RT-PCR (for RNA viruses) is increasingly more widely available at veterinary diagnostic laboratories. Although they are not currently in routine use, the possibility exists of using nucleotide probes for the detection of these viruses in tissue samples. One benefit of using nucleic acid detection to identify pathogens is that the pathogen does not have to be alive to be identified; this can be a particular benefit for relatively fragile viruses such as BRSV.

31.59.1.4

SEROLOGIC DIAGNOSIS

Retrospective diagnosis of viral infections can be made by determination of antibody titers in paired sera from individual animals. The first sample is collected in the acute phase of the disease, and the second is collected 2 to 4 weeks later (“convalescent sample”). In a respiratory disease outbreak multiple animals should be tested to achieve a serologic diagnosis; it is typical for seroconversion to be identified in only a subset of animals tested in any outbreak. Serologic diagnosis is made by demonstrating a fourfold increase in antibody titer in the convalescent sample as compared with the acute sample; a fourfold fall in titer also indicates recent infection. Because day-to-day variation in results of tests used for serologic diagnosis is typical, the acute and

convalescent samples should be run by the laboratory on the same day. Thus the acute samples can be stored in the freezer by the local veterinarian and shipped together with the convalescent samples.

Because infections in young ruminants can occur in the presence of passively derived antibodies, seroconversion might not always occur during outbreaks of bronchopneumonia involving young animals.[422] This problem may be overcome by inclusion of older individuals in contact with the younger animals in the population sampled, which are likely to have lost passively derived antibody to these viruses and will be more likely to seroconvert. Also, BRSV antibody levels appear in some instances to peak at the onset of severe disease, and a decreasing antibody level is seen on paired serologic analysis rather than a rising level. Serologic testing of normal appearing, in-contact cattle that may be in early stages of infection may be helpful in demonstrating seroconversion to BRSV. A wide variety of serologic procedures is available for antibody determinations, but most laboratories use a microtiter serum neutralization test (also known as *virus neutralization test*) for IBRV, BVDV, PI3, and BRSV. It is important to remember that serum neutralization tests take several days to run. Some laboratories are beginning to use more rapid procedures such as ELISA for determination of serum antibody titers. Through use of an isotype-specific ELISA, diagnosis of BRSV can be achieved with a single serum sample by measurement of IgM levels[423]; similar tests could be developed for other pathogens, but these are unlikely to be widely available. A hemagglutination-inhibition test can also be used for PI3 and respiratory coronavirus.

31.59.2 Bacteria

A wide variety of bacteria have been isolated from the respiratory tract of ruminants in association with respiratory disease. However, the most frequent and most important isolates are *M. haemolytica, P. multocida, H. somni*, and *M. bovis*. The isolation of *A. pyogenes*, coliforms, or anaerobic bacteria often is indicative of chronic pneumonia or aspiration pneumonia and may be associated with lung abscessation. 629 630

Before bacterial culture is attempted, the status of any recent antibacterial therapy should be determined, and, if possible, specimens from untreated cattle should be collected. It is important to remember that *M. haemolytica, P. multocida, H. somni*, and mycoplasmas are normal inhabitants of the nasal passages of cattle and may be cultured in the absence of respiratory disease. It is important to note that not all laboratories will identify the species of mycoplasmas cultured; thus an isolate may be identified only as "*Mycoplasma* sp." If involvement with *Mycoplasma bovis* is suspected, the laboratory may need to be specifically asked to identify the species of any mycoplasmas they isolate. Specific identification of *M. bovis* is most often done by immunofluorescent assay (available at the diagnostic laboratory at Iowa State University, and possibly others), IHC (available at Iowa State University, the University of Saskatchewan, and possibly others), or PCR (available at the diagnostic laboratory at the University of Georgia in Athens, and possibly others). Some mycoplasmas are more hardy or easier to grow than others; for example, it is not unusual for *Mycoplasma bovis* to overgrow *M. dispar* when both are present in the same sample. Culture of mycoplasmas typically takes at least 1 week, and laboratories often call a sample negative only after the sample has been subcultured at least once.

Although isolates obtained from nasal swabs may reflect the organisms causing pneumonia on a group level, specificity can be increased by obtaining specimens from the lower respiratory tract.[299] Specimens appropriate for bacterial culture are similar to those discussed for viruses, such as nasopharyngeal and tracheal swabs, TTAs, and BAL or lung aspirates. Swabs are acceptable for transferring samples directly to culture medium, but if transport is necessary, the swab must be placed in a transport chamber such as a Culturette (Marion Scientific, Kansas City, Mo.) to ensure adequate moisture for the sample during transport. Contamination of the sample with environmental agents can best be prevented by first searing the lung surface, then making an incision with a

sterile scalpel, followed by sampling with a swab through the incision; but it may not be practical to sear the surface of the lung in the field setting. Specimens of respiratory tract tissues such as lung and bronchial lymph nodes can be placed in sterile containers such as Petri dishes or self-sealing plastic bags and transported to the laboratory on ice.

Chlamydial organisms may be demonstrated by staining smears and sections of lesions with a Gimenez stain or by immunofluorescence techniques. Isolation attempts are done by inoculation of yolk sacs of embryonated chicks. Serologic tests such as complement fixation are also available.

31.59.2.1 DETECTION OF BACTERIAL ANTIGENS OR NUCLEIC ACIDS

It is increasingly common for diagnostic laboratories to use IHC for identification of bacteria in formalin-fixed tissues. This technique offers many advantages, including correlation of the pathogenic organism with the lesion and detection of pathogens not found on bacterial culture because of overgrowth of other organisms such as *A. pyogenes* or *P. multocida*. The use of PCR for identification of bacterial agents in a variety of samples is also increasingly available. The veterinarian is encouraged to contact the diagnostic bacteriologist at the local diagnostic laboratory or check the laboratory website for information regarding which tests are available.

31.59.2.2 SEROLOGIC TESTING FOR BACTERIAL PATHOGENS

Diagnosis of infection with bacterial pathogens can be attempted as described earlier for viral pathogens. However, the use of serologic tests for identification of infection by bacterial respiratory pathogens has mostly been limited to use in research. Thus these tests are not likely to be widely available for clinical use.

31.59.3 Treatment of Undifferentiated Bronchopneumonia

31.59.3.1 ANTIMICROBIAL THERAPY

The basic foundations of antimicrobial therapy for bacterial bronchopneumonia are treat early enough, treat long enough, and treat with the appropriate antimicrobial agent. Because there are currently many effective products marketed for the treatment of important bacterial respiratory pathogens in cattle, treating early enough is perhaps more important than what is used for therapy. It should be remembered that a major reason for treatment failure is the presence of a lesion that is too far advanced for successful therapy. If lesions becomes too far advanced, the antimicrobial agents will have difficulty reaching walled-off areas of necrosis and suppuration; moreover, the regenerative response will not be able to return this tissue to normal lung parenchyma.

Although antibacterial agents for the treatment of bacterial bronchopneumonia may reduce losses caused by fatality and retarded growth, they do not serve as a substitute for preventive management practices. Cattle requiring treatment do not perform as well as those that have not needed treatment. However, cattle requiring only one treatment perform better than those that require two or more treatments[424]; this further emphasizes the need for treating early enough with an effective antimicrobial, because animals with treatment failure will have suboptimal performance.

The precise temperature used to determine whether animals need treatment depends on the balance between the costs of overtreatment (drugs and labor) and undertreatment (treatment failures and mortality.) This

temperature may vary depending on the animal type. The cutoff commonly used for feedlot cattle is 104° F to 104.5° F (40° C to 40.3° C), but 103.5° F (39.7° C) may be more appropriate for calves. This recommendation is based on the long-term effects that ECP has been shown to have on growth rate, age at first calving, culling before calving, and culling after calving, indicating that ECP can have long-lasting effects if not properly treated with early antibiotic therapy. When outbreaks of respiratory disease occur, surveillance of the affected group must be increased to ensure early detection of diseased animals.

Treatment of sufficient duration can be achieved only if the response to therapy is monitored. Therapy should be continued for at least 48 hours after clinical signs of fever, dyspnea, and toxemia have abated. Many of the antimicrobial drugs labeled for use in the treatment of pneumonia in cattle provide multiple days of therapeutic drug concentrations in lung tissue after only a single injection. These products decrease the time and stress associated with daily treatment; they also make it easier for feedlots to return animals to home pens rather than keeping them in hospital pens, which seems to be associated with poorer responses by treated animals.[425] Frequently, antibiotics are evaluated over a 3-day treatment period, with cases failing to demonstrate a normal body temperature after 3 days being classified as nonresponders; a different class of antimicrobial should be administered to nonresponders.

630

Although a 3-day course of antimicrobial therapy for bronchopneumonia was for many years standard operating practice, particularly in the treatment of feedlot cattle, the view is increasingly held that treatment for a longer duration may be more appropriate. This is particularly true for pneumonia caused by *Mycoplasma bovis* in dairy calves or feedlot cattle, which seem to respond better to treatment for at least 7 to 10 days.[359,395] Although treatment for 7 to 10 days would be extralabel for many antibiotics, at least three products currently marketed have been shown to provide therapeutic drug levels for at least 7 days when used at dosages recommended on the label (see Table 31-10). Unfortunately there is little research evaluating the effect of treatment duration on long-term outcome in ruminants with bacterial bronchopneumonia, so it is difficult to make evidence-based recommendations regarding exactly how long antibiotics should be administered. Determination of therapeutic response by evaluation of general appearance without regard to restoration of normal body temperature has been shown to result in high relapse rates. A typical decision tree for treating feedlot cattle with antibiotics is shown in Fig. 31-63, but protocols such as these may be modified as more information about the use of long-acting antimicrobials is obtained from field research.

631

Selection of the appropriate antibiotic tends to be what most veterinarians focus on when treating respiratory disease because this is the aspect of therapy over which they have the greatest control. Factors such as cost, route of administration, treatment interval, drug labeling, necessity of extralabel doses, and withholding times quickly cull a number of antibiotics, leaving a short list of suitable alternatives for use as first-line antimicrobial agents. Antibiotics that are associated with severe injection site reactions such as erythromycin or those associated with complications of administration such as balling gun injuries with oral boluses are often avoided. Only antibiotics that are licensed and effective at label doses should be considered for routine use in food animals. Table 31-10 lists the approved antimicrobials for treating respiratory disease in cattle. If data regarding the MIC of bacteria isolated from animals before treatment with antimicrobials are available, the dose or duration of therapy can be rationally modified, but it is imperative that proper withdrawal times be observed when antimicrobials are used in an extralabel fashion. At the time of this writing, the Food Animal Residue Avoidance Databank (FARAD; www.farad.org or 1–888-USFARAD) is an invaluable resource for veterinarians who need to identify withdrawal times for drugs administered to food animals at extralabel dosages. The use of MIC data requires some understanding of the pharmacokinetics of the drugs in question; published information is available regarding interpretation of MIC data, or veterinarians can contact FARAD or the diagnostic bacteriologist at their local diagnostic laboratory for assistance.

Determining the antimicrobial sensitivity patterns or MIC data for causative agents such as *M. haemolytica* in the case of bacterial bronchopneumonia can be difficult. The best information is that gained from bacterial culture and susceptibility testing of animals subjected to necropsy before receiving any antimicrobial therapy; however, producers may be reluctant to allow necropsy of animals that have never been treated. Once an animal has been treated, any antimicrobials administered can bias the results of susceptibility testing of bacteria later cultured from the animal. Many bacteria, including *M. haemolytica*, can develop plasmid-mediated multiple antimicrobial resistance by bacterial conjugation so that, for example, exposure to oxytetracycline may induce resistance not only to oxytetracycline, but also to penicillin. Therefore, *M. haemolytica* recovered from cattle treated with antibiotics will have a different sensitivity pattern than *M. haemolytica* cultured from untreated cattle. This is especially important when reviewing publications reporting antimicrobial susceptibility of *M. haemolytica* isolates cultured at diagnostic laboratories, because these results will most often be from cases that have been treated with antimicrobial agents before death. The findings of these studies may be looked at as a worst-case scenario demonstrating antimicrobial agents for which acquired resistance is rarely or never a problem, versus those for which acquired antimicrobial resistance occurs commonly. In general, resistance to many drugs used for the treatment of bovine pneumonia has been identified when *M. haemolytica* isolates from cattle treated with antibiotics before death are evaluated.

Sensitivity testing using isolates from clinical cases raises questions regarding the best site for sample collection. Antibacterial sensitivities of isolates cultured from nasal swabs may not represent sensitivities of organisms causing pneumonia. This is surprising, because pneumonia usually is preceded by multiplication of bacteria such as *M. haemolytica* in the upper respiratory tract, and the nasopharynx serves as the source of bacteria colonizing the lungs. Nevertheless, there are discrepancies between antimicrobial sensitivities of bacteria isolated from nasal swabs and clinical outcome. Specimens for sensitivity testing should be collected from pneumonic lung, tracheal swabs, or TTAs collected from cattle before treatment whenever possible.

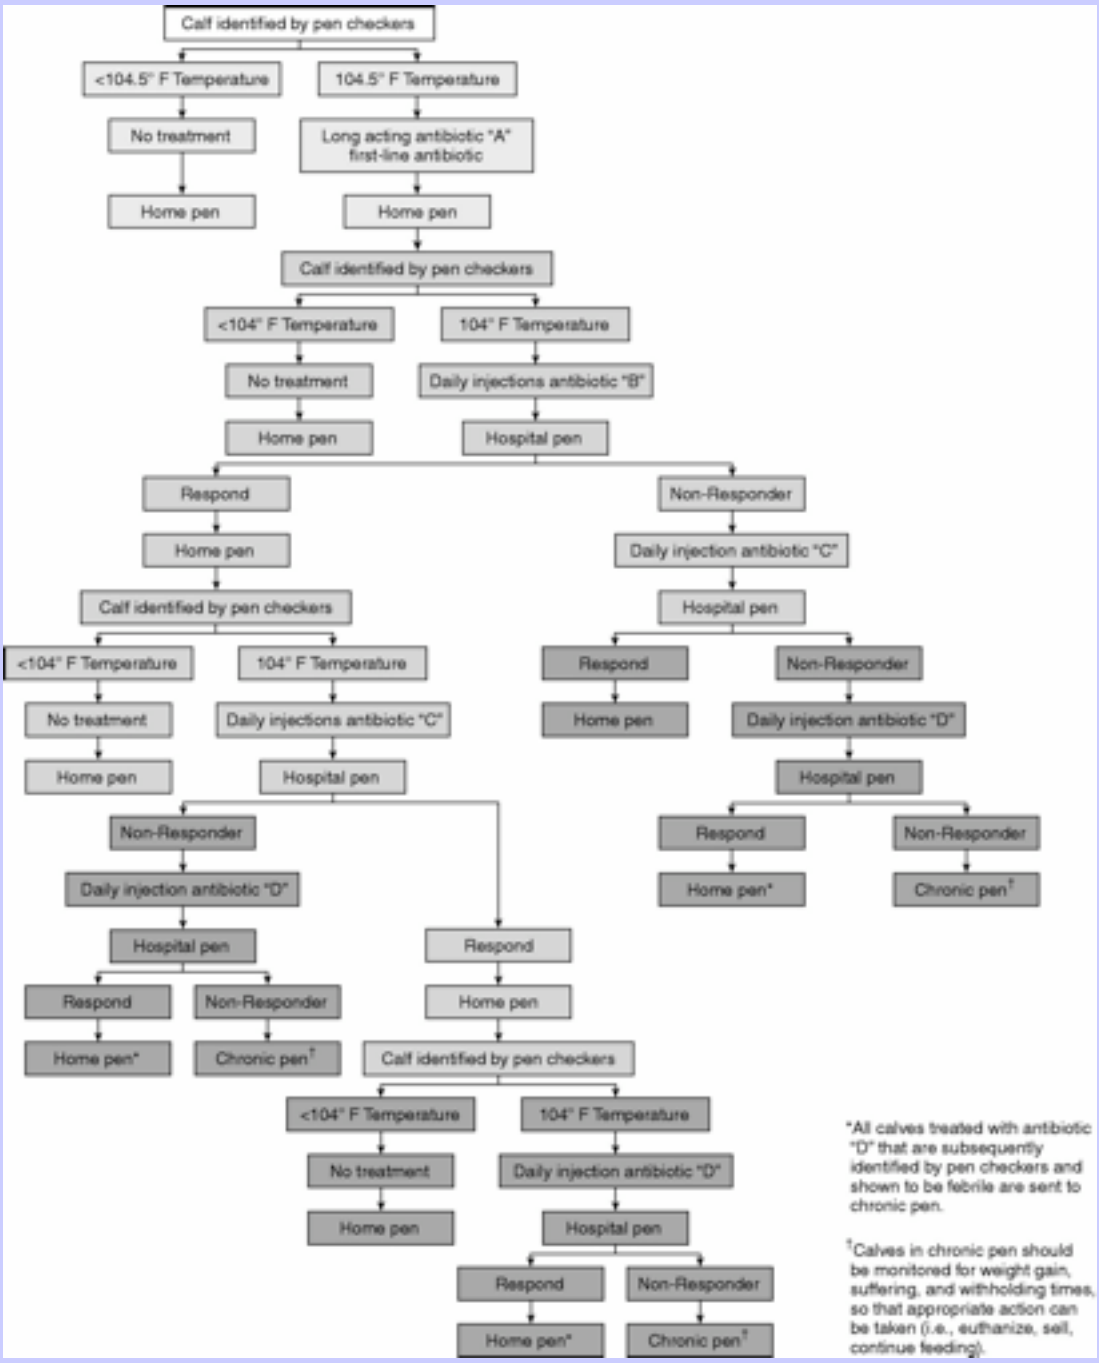
The choice of which drug to use can also be based on records of efficacy for animals treated in the past. Producers who keep accurate records of drugs used, with results of treatment responses, relapses, and chronic cases, may select first-line antibiotics based on historical performance of a drug. This may be the best approach to antimicrobial selection. A final method of choosing a first-line antimicrobial drug is reliance on published treatment trials. Published trials give comparisons between among responses for various antibiotics in cattle with naturally occurring bacterial bronchopneumonia. The outcomes for these trials are often expressed as both health and production values. When evaluating published treatment trials that use cases of naturally occurring bacterial bronchopneumonia, it is important to realize that the results may not be applicable to the cattle and pathogens outside the operation where the trial was carried out, but if the trial was well designed, it should provide useful comparisons. The characteristics of a well-designed field trial are discussed later in the section on vaccination (p. 641).

Mass medication with antibiotics at full therapeutic doses during an outbreak of feedlot cattle pneumonia dramatically curtails the daily number of new cases and improves feed consumption. In the acute stages of an outbreak, whatever drug is chosen should be given by injection; therapeutic levels cannot be reliably maintained by administering drugs in feed or water. Bronchopneumonia cases that occur after administration of mass medication have an increased possibility of being resistant to therapy with the antimicrobial used in mass treatment and have a greater than usual resistance to other antimicrobials. Thus mass medication should not be a standard practice but is warranted to control severe outbreaks of pneumonia. It is important to base a decision to mass medicate on measurable criteria. Some feedlot veterinarians implement mass medication when the pull rate of sick animals is 10% on any 1 day or is 25% over a 3- to 5-day period. A sudden drop in feed consumption, especially in high-risk cattle, is another situation in which mass antibiotic medication

should be cost-effective. Long-acting antibiotics have extended withdrawal times to slaughter. It is of critical importance that animals that receive them are properly identified and that the withdrawal times are observed. 631

632

Fig. 31-63 Decision tree for antibiotic treatment of feedlot cattle.



632

633

The same principles of therapy described previously apply to the treatment of sheep and goats.[220] Unfortunately, fewer drugs are labeled for the treatment of sheep and goats as compared with products used

for cattle. Drugs labeled for use in sheep and goats are listed in Table 31-10. Note that whereas tilmicosin (Micotil 300, Elanco Animal Health) is labeled for use in sheep, fatal reactions to tilmicosin have occurred in goats treated with this drug. Goats should not be treated with tilmicosin. Long-acting tetracycline at 10 mg/kg is very effective against experimental *M. haemolytica* infections in sheep. Administration of tetracycline subcutaneously is effective and less painful than IM injection. It is imperative to ensure that producers are given an appropriate meat and milk withdrawal time when antimicrobials are administered to sheep and goats at extralabel dosages; this is a particular concern in feedlot lambs or goats and in lactating dairy sheep or goats, from which products may enter the food chain in a relatively short time after treatment.

31.59.3.2

ANTIINFLAMMATORY THERAPY

Favorable responses to treatment with corticosteroids and antihistamines have been reported from field outbreaks of BRSV infection. However, corticosteroids should not be used indiscriminately in the treatment of respiratory disease because of the potential for immunosuppression. Corticosteroids may have a place in treatment of respiratory diseases such as necrotic laryngitis or tracheal edema syndrome of feedlot cattle.[90] It is unlikely that a single administration of a glucocorticoid will have a detrimental effect on the immune system of cattle. The dose for dexamethasone in cattle is 0.05 to 0.2 mg/kg IM or IV, and the dose for isoflupredone acetate is 10 to 20 mg IM. Treatment with corticosteroids may cause recrudescence of BHV-1 infections.

NSAIDs such as acetylsalicylic acid (aspirin), flunixin meglumine, and ibuprofen have been reported to be beneficial in the treatment of respiratory disease in ruminants. Aspirin (100 mg/kg every 12 hours) is approved for use in cattle, as is flunixen meglumine (1.1 to 2.2 mg/kg IV either as a single dose or divided into two doses at 12-hour intervals). Flunixin meglumine administered intravenously at 2.2 mg/kg to calves with pneumonia induced by PI3 virus results in a marked improvement in clinical signs and reduction in lung consolidation.[426] However, the use of flunixin meglumine may not be cost-effective in large numbers of animals. It is important to remember that flunixin meglumine is approved only for IV use; administration via the IM or SC route can result in violative residues in tissues if longer withdrawal times are not observed. Phenylbutazone, which has been used in the past for antiinflammatory effect in ruminants, is now illegal to use in lactating dairy cattle, and because of prolonged tissue levels found in treated cattle its use is discouraged in all food animals.

Unlike corticosteroids, NSAIDs do not impair immune function. The clinical responses of calves with either experimental or naturally occurring pneumonic pasteurellosis are markedly improved by adding flunixin meglumine to tetracycline therapy. In contrast, supplementation of antibiotic therapy with corticosteroids usually results in poorer responses, more relapses, and prolonged illness, although there is still some controversy over the use of corticosteroids for treatment of pneumonia. Because of the potential for renal toxicity with NSAIDs, dehydrated animals should be rehydrated before administration of these drugs. Care should also be taken not to overdose with NSAIDs or use them for prolonged periods, because they may also result in abomasal ulceration.

There has been little work done to evaluate the use of antihistamines as an ancillary treatment for bovine respiratory disease. Tripelennamine HCl is labeled for cattle at a dose of 1.1 mg/kg, which can be repeated in 6 to 12 hours if needed.

Tilmicosin has been suggested to have antiinflammatory effects in cattle because of the effect of the drug to induce apoptosis in leukocytes, which could theoretically decrease inflammatory responses in treated animals.[427] However, the concentrations of tilmicosin used in this study were quite high relative to concentrations

obtained in treated animals, and a later study of the effect of tilmicosin on the function of leukocytes taken from treated cattle showed no effect.[428]

31.59.3.3 ANTIVIRAL AND IMMUNOMODULATING THERAPY

Because viral respiratory infections predispose to development of secondary bacterial infections, antibiotic therapy is indicated to prevent or limit the development of bacterial pneumonia in animals with viral respiratory tract disease. Few antiviral drugs are available in human medicine, and none of these is in routine use in veterinary medicine for the treatment of viral respiratory disease in ruminants. Interferon has potential as an immunomodulating and antiviral drug in the prevention and treatment of viral respiratory disease. Human leukocyte interferon has been shown to decrease morbidity associated with shipping fever, but the therapy has not become widely used. Levamisole and isoprinosine have been used in attempts to stimulate the bovine immune system with equivocal success and cannot yet be recommended as supportive treatments.[426] It is important to recognize that the immunostimulatory benefits of levamisole occur at doses in the 2- to 3-mg/kg range, compared with the anthelmintic dose of 6 mg/kg. A decreased immune response has been observed after an 8-mg/kg dose of levamisole. High doses of vitamin C (1 g/45 kg; 1 g/100 lb) have been shown to enhance the activity of bovine neutrophils and reverse dexamethasone-induced suppression of neutrophil activity.[429] Isoprinosine has been evaluated as an immunomodulating drug for treatment of bovine respiratory disease and has shown some potential on the cellular level.[426]

31.59.3.4 SUPPORTIVE THERAPY

Supportive treatment of any kind will relieve stress, thus fostering the resistance of the patient, a very important component of the successful therapy of pneumonia cases. Sick animals should be provided shelter that protects them from rain, cold, wind, and hot sun. They should not be crowded, and the best-quality feed and clean water should be easily accessible. Mineral and vitamin deficiencies should be corrected with the use of injections or oral preparations if necessary. An IM vitamin A injection is considered useful adjunctive therapy by some veterinarians treating ruminants with bronchopneumonia.

31.59.4 Epidemiology of Ruminant Respiratory Disease

31.59.4.1 ENZOOTIC CALF PNEUMONIA

ECP has traditionally been described as affecting calves from 2 to 6 months of age; however, prospective studies examining cohorts of calves have found calves may be affected with ECP as early as 2 weeks of age.[430] Slaughter surveys of dairy calves 4 to 14 days of age have found ECP to be the second most common cause of slaughter condemnation.[431] Virtala and colleagues[430] found that veterinarian-diagnosed ECP occurred at a younger age than did caretaker-diagnosed ECP. As a whole, these studies suggest that ECP may start much earlier than previously recognized.

Pneumonia of dairy calves occurs both as endemic disease and as outbreaks (epizootics) of respiratory disease. Chronic endemic disease is the most common manifestation of this disease, and as a result pneumonia of dairy calves is commonly called *enzootic calf pneumonia*. The distinction between enzootic and epizootic calf pneumonia is important in reference to etiology because different causes are more important in each form of the disease.

633 634

Waltner-Toews, Martin, and Meek[432] determined from producer diagnosis that 15% of Ontario Holstein dairy calves were treated for pneumonia before weaning. Curtis, Erb, and White[433] reported that Holstein calves in New York had a crude incidence risk of 7.4% for respiratory tract illness, as diagnosed by the farmer. Sivula and colleagues[434] found that 7.6% of 845 Minnesota dairy calves were diagnosed by producers as having pneumonia. Van Donkersgoed and colleagues[435] found that the risk of pneumonia in Saskatchewan dairy calves was 39% as diagnosed by the farmer and 29% when the pneumonia was veterinarian diagnosed. Virtala and colleagues[430] found that the risk of pneumonia was 11% in New York dairy calves when diagnosed by producers and 25.6% when diagnosed by a veterinarian.

Mortality rates reported for ECP vary from 1.8%[434,435] to 4.2%.[430] Case fatality rates reported for calves with ECP range from 2.2% to 9.4% and vary with the sensitivity of the initial detection method (veterinarian versus producer).[430]

Pneumonia accounts for a significant proportion of the mortality (proportionate mortality) in dairy calves raised on dairy farms. Pneumonia accounted for 24% of deaths in New York calves[430] and 30% in Minnesota calves.[434] In one study examining Ontario veal calves raised in veal barns, pneumonia accounted for 52% of mortality in 4863 calves on six farms.[436] Producer accuracy in diagnosing causes of mortality was examined by Sivula and colleagues.[434] Producers were found to be moderately accurate but often listed the cause of death as unknown. This emphasizes the importance of laboratory confirmation of cause of death over producer diagnosis.

31.59.4.2

SHIPPING FEVER

Despite the undisputed economic importance of the disease, surprisingly little has been established regarding the behavior of pneumonic mannheimiosis or shipping fever at the population level, and even the question of whether the disease is truly contagious has yet to be answered from the epidemiologic perspective. Reviews of the literature from North American feedlot studies before 1985 found that published measures of morbidity in calves ranged from 0% to 69%, whereas measures of population mortality ranged from 0% to 15%. Incidence of disease was found to peak within 3 weeks of calves arriving at the feedlot. In view of the lack of uniformity in methods used to define cases of respiratory disease and calculate disease incidence, however, these data may not be reliable. In most of the studies the crude measures of total morbidity and total mortality were used as outcomes, and case definitions for these were often highly variable or absent. This lack of uniformity with respect to case definition and nomenclature, along with the inherently subjective nature of morbidity assessment, makes it difficult to draw legitimate comparisons among reports. One observational study specifically addressing epidemiology of fibrinous pneumonia (the classic lesion of shipping fever caused by *M. haemolytica*) was conducted by Ribble and colleagues.[305] Because of the difficulty and expense inherent in making definitive diagnoses of the causes of illness and death among feedlot cattle, most epidemiologic studies have used crude (total) mortality as an estimate of death losses caused by shipping fever, and treatment rate as a measure of respiratory morbidity. The results of several necropsy surveys and the previously cited epidemiologic study, however, indicate that crude mortality is unreliable as a surrogate measure of fibrinous pneumonia mortality and may lead to erroneous conclusions regarding risk factors contributing to this important disease.

In the observational study of fatal fibrinous pneumonia conducted by Ribble and colleagues in 1995,[305] risk factors specifically associated with shipping fever mortality in western Canadian feedlot calves were

investigated. Data were collected on all 58,885 spring-born calves entering a single feedlot in southwestern Alberta between September 1 and December 31 over a 4-year period (1985 to 1988). The vast majority of calves were purchased from auction marts throughout western Canada and transported to the feedlot by truck. A complete necropsy was performed on all dead cattle within 24 hours of death, and a gross diagnosis recorded. Cases were assigned a diagnosis of fatal fibrinous pneumonia on the basis of pathologic evidence of acute fulminating lobar bronchopneumonia with fibrinous exudate, and data from each year were analyzed separately. Crude mortality ranged from 2.44% to 4.78%, whereas the mortality caused specifically by fibrinous pneumonia varied more than tenfold (0.25% to 2.73%) between years. Proportionate mortality caused by fibrinous pneumonia ranged from 10% to 57%, and this large annual variation was interpreted as evidence that crude mortality should not be used as a measure of fibrinous pneumonia mortality in epidemiologic studies. Epidemic curves constructed for each of the 4 years showed that peak mortality occurred approximately 16 days after arrival at the feedlot and that at least 50% of fibrinous pneumonia mortalities occurred within 3 weeks of arrival. Epidemic curves using the time of first treatment for all cases that eventually died of fibrinous pneumonia revealed that peak fatal disease onset occurred within 8 days of arrival and that 75% of fibrinous pneumonia mortalities were already sick within 2 weeks of arrival. The consistent onset of fatal disease in calves within days of their arrival at the feedlot indicates that the disease process may have been well underway in affected calves before their installation in a home pen, and that preventive measures should be implemented at the time of arrival, or possibly even before. In one of the study's most important findings Ribble and colleagues[305] demonstrated that when the incidence of fatal shipping fever was high (greater than 2%), the disease clustered within truckload groups of calves and also, in 1 year, within pens. This was contrary to the conclusions of other studies and lends credence to anecdotal reports from feedlot owners that shipping fever mortality is not randomly distributed in calves throughout the feedlot, but may often be abnormally high in individual truckloads or pens, indicating a contagious nature to the disease.

Although *H. somni* can also cause fibrinous bronchopneumonia in feedlot cattle, epidemiologic curves evaluating the day of first treatment of calves ultimately dying of disease caused by *H. somni* are distinct from epidemic curves of cattle dying of fibrinous pneumonia caused by *M. haemolytica*. The median days after arrival for the onset of fatal disease caused by *H. somni* is 28, as opposed to 8 days after arrival for fatal fibrinous pneumonia.[345,346]

31.59.4.3

BRONCHOPNEUMONIA OF ADULT CATTLE

Although anecdotal reports indicate that adult beef or dairy cows can experience outbreaks of bronchopneumonia that can have high morbidity and an important impact on milk production (in dairy herds), very little is published in the veterinary research literature regarding the problem. Outbreaks of significant respiratory disease with notable mortality caused by BRSV infection have been described in individual herds of adult dairy cattle.[149,150] Respiratory disease and decreased milk production in adult dairy cows was associated with seroconversion to influenza virus and BRSV,[253] but the authors could not confirm that influenza was contributing to clinical disease in the affected cows. The lack of research on respiratory disease in adult cows is likely a result of the fact that other diseases that affect reproductive performance and milk yield are of greater economic significance in this class of cattle, but the few published descriptions of respiratory disease outbreaks confirm that the problem can on occasion be of major importance to individual herds. Little research has investigated the effects of infectious respiratory disease in adult cattle on productivity.

634
635

31.59.4.4 BRONCHOPNEUMONIA OF SHEEP AND GOATS

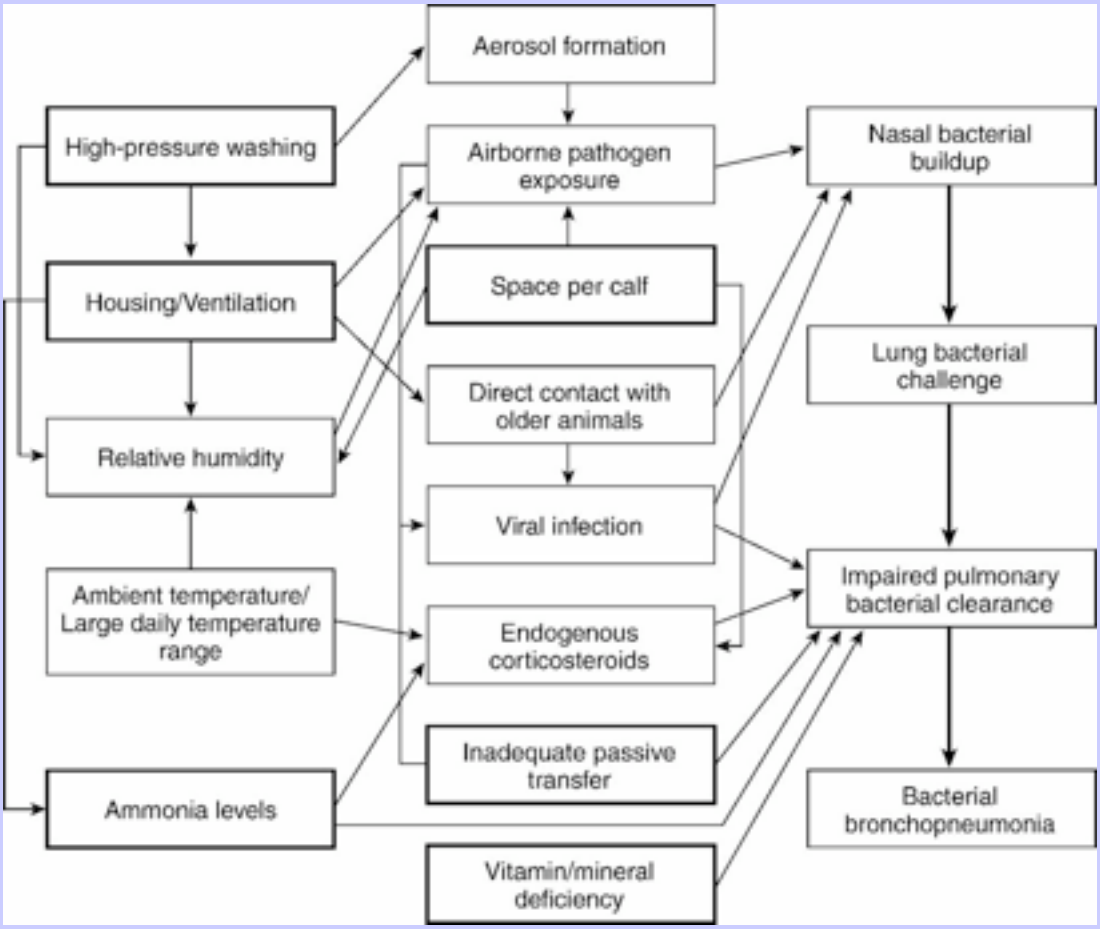
Little information has been published regarding the epidemiology of bronchopneumonia in sheep and goats. The 2001 National Animal Health Monitoring System (NAHMS) survey of producers indicated that 7% of death in adult sheep were due to respiratory disease, whereas 12% of lamb deaths were due to respiratory disease.[437] Feedlots reported that shipping fever pneumonia accounted for 13% of feedlot lamb deaths, and other respiratory disorders accounted for 29% of lamb deaths.[438]

31.59.5 Host and Environmental Risk Factors for Respiratory Disease

31.59.5.1 ENZOOTIC CALF PNEUMONIA

The documented host and environmental risk factors of dairy and veal calf bronchopneumonia involve inadequate passive transfer of immunoglobulins, nutritional deficiencies, and adverse environmental conditions (Fig. 31-64). Calves are generally affected at less than 2 months of age. Successful passive transfer is the foundation of protection against pneumonia at this age and older and is effective except in situations in which the other risk factors are so severe that even calves with high concentrations of passively acquired immunoglobulins are at high risk. Successful passive transfer requires good-quality colostrum and adequate volume (4 L in the first 12 hours for 45-kg calves). In addition, regular herd vaccination, especially in dry cows, should increase the levels of specific antibody in calves, provided passive transfer is accomplished. Vaccination of calves may produce a protective immune response in calves that prevents or limits the severity of ECP from certain infectious agents. Historically it has been recommended that vaccination be delayed until maternal immunity has waned, but recent research indicates that calves can be primed for a protective immune response by vaccination in the face of maternal antibodies in at least some cases (see further discussion on p. 640).

Fig. 31-64 Path model for risk factors for enzootic calf pneumonia. *Note:* Risk factors in bold-faced rectangles indicate those that may be altered by management.



Nutritional problems that predispose to calf pneumonia include deficiencies of energy, protein, vitamins, or the minerals necessary for the immune response. Deficiencies of copper, selenium, zinc, manganese, iron, and vitamins A and E are of special concern. Dairy managers sometimes create energy and protein deficiencies by feeding calves a low volume of milk during the first few weeks of life to minimize the incidence of neonatal diarrhea.

The calf's immediate environment affects the calf in a number of ways. Ambient temperature is an important factor affecting dairy calf health.[439] Cold weather is especially detrimental to young calves, which have little body insulation. Increased humidity or precipitation in the calf's environment worsens the calf's ability to maintain thermal neutrality. Warm weather can also be undesirable, because young calves are capable of greater perspiration per pound of body weight than adults, and warm weather may predispose young calves to dehydration.[439]

The bacterial content of air in cattle barns can be as high as 10^6 organisms per cubic meter.[440] Disease incidence can be affected by length of pathogen survival time as an aerosol and the concentration of the pathogen in the air space. Humidity is an important limiting factor affecting pathogen survival. The optimum zone for limiting survival time of bovine pathogens is 55% to 75% relative humidity. Adequate fresh airflow into the calf's environment is important in limiting humidity and reducing the concentration of noxious gases and pathogens. The flow of air should be from younger, more susceptible cattle to older, less susceptible cattle to limit moving pathogens from older cattle to younger cattle. Adequate fresh airflow and proper directional movement of air are important goals of ventilation.

635

636

Calf housing with overcrowding of calves or excessive stocking densities results in increased transmission of pathogens, especially if there is mixing of age-groups. Overcrowding also puts additional stress on the building ventilation through buildup of noxious gases and pathogens. Cleaning of calf crates with high-pressure water sprayers is associated with new cases of pneumonia several days later. Bates and Anderson[441] have recommended standards for ventilation, including building location, fan capacity and location, intake location and design, temperature regulation, air space needed and airflow directions, and acceptable humidity levels. Individual calf hutches that are properly located provide the calf with adequate fresh air free of pathogens and noxious gases and overcome many of the problems found with calf barns. Calves moved out of hutches can then be put into small groups (seven or eight calves) separated from older cattle through use of super hutches. Like the calf hutch the super hutch also serves to limit pathogen transmission and buildup of noxious gases in this susceptible group of calves. Alternatively, calves can be moved out of hutches and placed in pens in pole sheds provided groups are small (7 to 10 calves), air quality is good, and proper segregation from older age-groups is maintained. Standards of housing for calves are shown in Table 31-11.

Sivula and colleagues[434] found that 80% of calf barns provided housing that failed to meet adequate standards of ventilation and housing[441] regardless of whether calves were housed individually or in groups. In addition, calf housing in which calves shared the same air space as adults never met the adequate standards of ventilation and housing.[434] A much higher percentage of calf housing that used calf hutches met these adequate standards of ventilation and housing, and virtually 100% would have been adequate housing if the hutches had been positioned correctly.[434] Calves raised in inadequate housing have significantly poorer growth rates than do calves raised in housing that is considered adequate,[434] which emphasizes the importance of adequate housing. The percentage of producers who use calf hutches continues to increase, as the benefits of their use are documented and published.

Table 31-11 Standards for Adequacy of Ventilation of CalfHousing[434,441]

Housing Type	Ventilation Standards
Calf hutch	One calf per hutch
	Minimum of 4 ft between hutches
	Hutches further than 50 ft from exhaust outlets of other buildings
	Hutches 10 ft from fenced enclosure with older cattle
Mechanically ventilated calf barn	200 ft^3 of air space per calf Barrier walls to separate age-groups of cattle housed in building
	Fan capacity to achieve four air changes per hour in winter, 15 air changes per hour in spring and fall, and 40 air changes per hour in summer
	Humidity levels between 50% and 80%
	Ammonia levels less than 10 ppm
	Intake velocity for fresh air intakes of 200 to 800 feet/sec
Naturally ventilated calf housing	Adjustable opening on sidewalls Open ridge for dual slope (2 in/10 ft of building width)
	Eve opening for monoslope buildings (2 in/10 ft of width)
	Barrier walls between age-groups (especially first postweaning age-group and older animals)
	Separate waterer for first postweaning age-group

Veal calves are at greatest risk because they are reared in rooms that are filled to high stocking density with calves from multiple dairies that put minimal effort into ensuring that the calves are fed adequate amounts of high-quality colostrum. Similar problems occur on “calf ranches,” where hundreds to thousands of very young dairy calves are raised to the point at which they are old enough to be returned to dairies or sent on to feedlots. A high proportion of calves that enter calf ranches have FPT. Also, the accumulation of a large number of calves with a variety of histories and from a variety of sources causes problems similar to those encountered with older animals in feedlots. The respiratory defenses of the calf lung include aerodynamic filtration, particle removal, adhesion resistance, secretory defenses, and cellular defenses. The physical respiratory defenses (filtration, removal, adhesion resistance) can be compromised by inhaled noxious gases, temperature extremes, dehydration, and viral infections causing impairment through damage to the mucosal lining of the upper respiratory tract, or by increased viscosity of respiratory secretions. Noxious gases, such as ammonia, methane, hydrogen sulfide, and carbon dioxide, which become increased from inadequate manure handling or poor ventilation, can also impair secretory defenses via damage to the mucosal lining and impair cellular defenses by direct effect on alveolar macrophages. Viral infection may also damage the mucosal lining and impair production of secretory defenses, such as lysozymes, lactoferrin, complement, or secretory immunoglobulin. Viral infections can also have a direct effect on cellular defenses, including alveolar macrophages, and for some viruses, the neutrophils. Stress caused by overcrowding, temperature extremes,

commingling, surgical procedures, or vaccination may impair cellular defenses and immunoglobulin production and enhance bacterial adherence.

Calves that have neonatal diarrhea are at greater risk of pneumonia.[435] Thus risk factors that are unique to neonatal diarrhea, such as poor sanitation in the calving area, must be added to those outlined in Fig. 31-64 as possible risk factors for dairy calf bronchopneumonia. Calves born in loose housing have a higher risk of illness than those born in individual maternity pens. Treatments at birth can affect subsequent calf health. All dairy calves should have the navel treated. Injections of vitamin A and iron at birth may increase the disease resistance of dairy calves, which can be deficient in these nutrients at birth.

Other risk factors associated with ECP include large herd size, weather extremes (hot and cold), birth to a heifer, and low antibody titers to certain respiratory pathogens.[430,435] Pneumonia of beef calves on the farm has the greatest incidence after weaning. The occasional outbreaks of pneumonia in suckling beef calves may be associated with adverse weather, parasitism, or nutritional deficiencies.

31.59.5.2 SHIPPING FEVER PNEUMONIA

Risk factors of feedlot calf bronchopneumonia are active in three areas: (1) at the farm of origin, (2) during transit, and (3) in the feedlot[305,442,443] (Fig. 31-65).

636

637

Fig. 31-65 Path model for risk factors of feedlot cattle pneumonia. *Note:* Risk factors in *bold-faced rectangles* indicate those that may be altered by management.

Several on-farm management practices have a large impact on feedlot cattle pneumonia. Weaning, creep feeding, and performance of routine surgeries at least 3 weeks before shipment have been shown to reduce morbidity rate 20% to 25%.[443] Vaccination on the farm against respiratory pathogens would be expected to reduce the incidence of feedlot cattle pneumonia but has not always been beneficial. Other farm factors are deficiencies of nutrients necessary for normal immune responses. Pneumonia has a higher incidence in young calves, and severe outbreaks sometimes occur in early weaned calves that enter feedlots.

Risk factors that are active during transport from the farm to the feedlot include sale through auctions, feeding of low-energy diets before shipping, and prolonged time in market channels (sales barns, transport vehicles). Excessive dehydration or "shrink" from transport has been shown to account for significant morbidity and mortality in the feedlot. Movement through multiple auctions greatly increases the risk of pneumonia.

Feedlot risk factors that influence morbidity and mortality rates include processing procedures, numbers of calves and number of different origins of calves per pen, diet, on-arrival surgeries (e.g., dehorning), and environmental conditions. Calves that arrive in the feedlot with moderate levels of antibodies against the respiratory viruses have been shown to have a decreased incidence of pneumonia, indicating that natural exposure or vaccination at the ranch, rather than the feedlot, is protective. Mixing of calves from different origins and filling of feedlot pens with calves over a prolonged period increase mortality and morbidity rates because infectious agents spread more readily in large populations. Starting calves on diets containing 75% concentrate or greater or feeding corn silage as a major dietary component during the first month is associated with higher mortality and morbidity rates, probably because of an inhibition of alveolar macrophage function caused by acidosis. Nonprotein nitrogen, such as urea, fed to stocker calves at any time or to feedlot calves on arrival is associated with increased levels of pneumonia. The addition of antibiotics to the drinking water of newly arrived feedlot cattle has been shown to be detrimental to their health, possibly because of decreased water consumption.

As mentioned in the earlier discussion of respiratory defenses of dairy calves, endogenous corticosteroid release caused by physical stressors (overcrowding, mixing of calves, surgical procedures, starvation, dehydration), environmental stressors (weather extremes), and damage to respiratory defenses (vehicle exhaust, environmental dust, noxious fumes, acidosis, dehydration, and viral infections) may also weaken or overwhelm the respiratory defenses of feedlot calves.

31.59.5.3 BRONCHOPNEUMONIA OF ADULT CATTLE

Studies confirming risk factors for bronchopneumonia of adult cattle in modern North American production systems are lacking, but it is assumed that factors are similar to those described previously for calves and for cattle entering feedlots.

31.59.5.4 BRONCHOPNEUMONIA OF SHEEP AND GOATS

Many of the risk factors that have been found to predispose to bronchopneumonias of sheep and goats are similar to those affecting cattle.[220] Pneumonia is more common in younger animals, after shipping or storms, and under crowded conditions. In addition, cold stress is an important risk factor for pneumonia in young lambs and recently shorn adult sheep and goats. In contrast, heat stress may predispose to pneumonia in unshorn sheep that do not have access to shade. Pneumonia also is associated with semiconfinement or total confinement of sheep in poorly ventilated barns.

31.59.6 Prevention and Control of Ruminant Respiratory Disease

31.59.6.1 MANAGEMENT PRACTICES TO MINIMIZE ENZOOTIC CALF PNEUMONIA

Bronchopneumonia of dairy and veal calves is prevented by eliminating or altering as many predisposing risk factors as possible. Control is based on healthy, well-vaccinated dams giving birth in maternity facilities that limit pathogen exposure. Good colostral management is needed to ensure adequate passive transfer. The calves must have their navels disinfected and be moved to calf housing that limits pathogen exposure by overcrowding and direct contact, provides good-quality air, and protects the calf from environmental extremes.

Evaluation of the microclimate of housed calves is of critical importance in the control and prevention of pneumonia. Equipment useful for evaluating mechanically ventilated buildings includes a smoke generator to visualize airflow patterns, an anemometer to measure air velocity, a psychrometer to determine air temperature and relative humidity, and a gas detector kit to measure ammonia concentrations in the air. Agricultural engineers from animal science departments at regional universities can be often be contacted for guidance in the use of these tools. Naturally ventilated buildings should also be evaluated for adequate sidewall and ridge openings, adequate segregation of age-groups, and stocking densities. Calf hutches that are managed properly provide most, if not all, housing needs required to minimize calf pneumonia. Hutches should be evaluated for proper placement in relation to other hutches, other buildings, prevailing winds, exposure to sun, bedding and draining, and ventilation of the hutch.

After weaning, calves need to move to housing that allows small groups to be segregated from older age-groups. Sharing air space or having direct contact with older calves or adult cattle is an important risk factor for calf respiratory disease. Super hutches or pens in pole sheds separated by barrier walls can effectively provide this postweaning housing. Calves should be fed proper nutrition for protein, energy, minerals, and vitamins and should be vaccinated appropriately. Vaccination programs are often used in dairy calves beginning at 1 to 2 months of age in situations where housing or mixing of calves results in a high incidence of ECP. More information regarding the use of vaccines for preventing infectious respiratory disease is presented in the following sections.

31.59.6.2 MANAGEMENT PRACTICES TO MINIMIZE FEEDLOT PNEUMONIA

31.59.6.2.1 Preconditioning

Preconditioning of calves is an attempt to eliminate certain risk factors that influence the occurrence of feedlot cattle pneumonia. Preconditioned calves are weaned well in advance of shipment to feedlots. They are trained to eat some grain from feed bunks and drink water from tanks (this is especially important for calves raised on rangeland where feed bunks or water tank may not be seen). Calves are castrated and dehorned, treated for internal and external parasites, and vaccinated against respiratory pathogens, with one dose of vaccine administered before weaning and the second dose administered 2 to 4 weeks after weaning. The exact details of a preconditioning program can be tailored to the needs and characteristics of the individual herd of cattle. A variety of preconditioning protocols have been described, and most of the major companies that sell vaccines have recommended standardized preconditioning programs. Also, in many areas of the United States and Canada, state, provincial, or regional groups have become established that offer a standardized preconditioning program for local cattle producers. Typically some sort of validation

that calves have received preconditioning is available through these organizations. Some of these groups also help the participating producers market the preconditioned calves in large, relatively uniform groups, which helps the calves bring better prices. In some cases, producers can retain ownership of their cattle after they enter the feedlot, and they receive data regarding health and performance of their animals throughout the feeding period and at slaughter. Information about local preconditioning programs can usually be obtained from agricultural extension agents or from faculty who specialize in beef cattle management and health at colleges of animal science or veterinary medicine.

The value of preconditioning has been debated over the decades. A summary of eight studies comparing the health of preconditioned calves with that of control calves indicated that, on average, preconditioning reduced morbidity rate by 23% and mortality rate by 50% in the feedlot.[443] However, preconditioned cattle do not always escape disease once they enter feedlots, and they sometimes experience outbreaks of high morbidity and mortality not unlike those seen in high-risk calves that are not preconditioned. Moreover, even when preconditioned calves experience less disease, their performance in the feedlot is not always better than that of nonpreconditioned calves,[444] or they may not always perform well enough that a profit is returned that is greater than the cost of preconditioning.[445] An evaluation of data collected over 8 years by the Texas A&M Ranch to Rail program showed that preconditioned cattle returned on average $90 more per head than nonpreconditioned cattle. However, in some years the return was better for preconditioned cattle than in other years.[306] These data emphasize that preconditioning is likely to pay in the long run, but it may not always pay for individual groups of cattle in a single given year. Because of year-to-year uncertainty in the economic advantage of preconditioned cattle, producers who sell preconditioned calves may not always be able to sell calves at a price that provides a profit over the cost of preconditioning. Marketing preconditioned calves through state or provincial organizations that have gained the respect of cattle buyers and that allow the marketing of large numbers of uniform cattle may be the best way for the producer to realize a profit from preconditioned calves. Retaining ownership of calves sent to feedlots may also allow the producer to realize better profits, but this requires a relationship with a feedlot that will manage the calves in ways that will continue to optimize health once the calves enter the feedlot.

31.59.6.2.2

Backgrounding

Another practice similar to preconditioning is the practice of backgrounding. In backgrounding, weaned beef calves from a variety of sources (often purchased from multiple sale barns) are accumulated and processed in a manner similar to that carried out for high-risk calves at feedlot entry (Box 31-5). Calves are then sorted by size and type and sold to feedlots, usually within a few days of arriving at the backgrounding operations. A variation of the backgrounding operation is the stocker operation; in stocker operations calves are processed and then “stocked” onto pastures, often with supplemental concentrate feeding, to graze and grow for a few weeks to months before shipment to feedlots. The difference between preconditioning and backgrounding is that preconditioning occurs on the farm where the calf is born, or at least before the calf is mixed with other calves from different sources, with some aspects of treatment such as the first dose of vaccines ideally being administered before weaning. Calves that enter backgrounding or stocker operations often have uncertain health histories and have often been weaned immediately before purchase. Because of this, disease outbreaks of high morbidity and mortality are not uncommon on some backgrounding operations. The backgrounder or stocker operator is thus taking on some of the risk of high-risk calves and is theoretically providing the feedlot with animals more likely to grow well with minimal disease than if they entered the feedlot straight from the auction market.

638
639

31.59.6.2.2.1

Box 31-5 Examples of Processing Protocols for High- and Low-Risk Cattle Entering Feedlots

31.59.6.2.2.1.1

PROCESSING PROTOCOL FOR HIGH-RISK, FALL-WEANED, AUCTION MARKET CALVES

1. Modified live IBR, BVD, BRSV, and PI3 vaccines
2. Eight-way clostridial bacterin
3. Ivermectin type "pour-on" antiparasitical
4. *Mannheimia haemolytica* ± *Pasteurella multocida* vaccine
5. *Haemophilus somnus* vaccine (if significant problem in past)
6. Implant
7. Ear tag identification
8. Bulls castrated (if needed)
9. Tip dehorning (if needed)
10. "Temp" all incoming cattle and sort by temperature (e.g., >105° F (40.5° C)—treat with tilmicosin; all others treat with long-acting oxytetracycline)

31.59.6.2.2.1.2

PROCESSING PROTOCOL FOR HEALTHY YEARLINGS PREVIOUSLY FED IN BACKGROUNDING OPERATIONS

1. Modified live IBR, BVD, BRSV, and PI3 vaccines
2. Eight-way clostridial vaccine
3. Ear tag identification
4. Implant
5. Ivermectin type "pour-on" if days on feed will allow for withholding times needed

BRSV, Bovine respiratory syncytial virus; *BVD*, bovine virus diarrhea; *IBR*, infectious bovine rhinotracheitis; *PI3*, bovine parainfluenza virus type 3.

31.59.6.2.3

Management at Feedlot Entry

It is not surprising that preconditioning does not always influence the occurrence of pneumonia in cattle after they enter the feedlot, because it has no effect on many risk factors active during transit and in the feedlot. Therefore optimal control of feedlot pneumonia should begin with preconditioning and continue

with avoidance of auction yards, minimization of transport time to the feedlot, limited mixing of calves from different sources, limited number of calves per pen, control of dust, and careful diet management in the feedlot. Correction of vitamin and/or mineral deficiencies if known or detected, using vitamin injections in entering calves, may be a very important aspect of prevention of feedlot pneumonias that are associated with immunodeficiencies of nutritional origin.

Processing procedures on arrival at the feedlot affect the incidence of pneumonia. General recommendations for handling incoming cattle can be made that are appropriate for any category of animals. In a receiving program, rest, rehydration, and ruminal restoration need to be addressed because cattle are physically and psychologically stressed by the marketing and transportation processes. It is useful for these cattle to be rested for 12 to 24 hours before processing to allow the immune system to overcome the effects of stress. Prolonged holding before processing is associated with increased illness, and holding times over 48 hours should be avoided. Holding pens should be clean and dry or have dry bedding (if pens are wet from excessive precipitation), because this allows all cattle to lie down and rest. Shelter from wind, sun, rain, and dust should also be present in the receiving pen.

Holding pens should have 150 to 200 square feet of pen space per animal and 12 to 16 inches of bunk space per animal and should be located close to the processing facility. Excess mixing of cattle in the receiving pens should also be avoided.

It is important that incoming cattle have access to clean, fresh water. Raised spigots have been suggested as a way to teach incoming cattle to drink out of automatic watering devices because cattle will be attracted to the sound of splashing water. Incoming cattle should also be offered good-quality, long grass hay on arrival. This is the most similar to what cattle are used to on range. Hay is the best foodstuff for restoring or refilling the rumen. Hay can be put in the feed bunks as well as in feeders in the pen as a way of teaching cattle to eat out of bunks. Hay feeders may also be put along the pen perimeter to decrease walking the fence line and encourage eating. The starter ration is an important source of energy and should be highly palatable. The proportion of the starter ration dry matter that is forage is not usually less than 50% to prevent problems of acidosis. Starter rations often contain a coccidiostat, because coccidiosis can occur in calves after commingling.

Processing protocols may be tailored to the category of the incoming cattle. Pharmaceutical processing options include vaccination (respiratory and nonrespiratory), vitamin injections, implanting, deworming for internal parasites and acaricides for external parasites (may be the same product for both), long-acting antibiotic therapy, drugs for aborting pregnant heifers, and probiotic administration. Management procedures for processing include ear tagging, branding, tail trimming, castration, tip dehorning, and temperature sorting. Some management procedures such as castration and dehorning could be left for a later time—for example, at reimplanting at 70 to 90 days on feed (if cattle are expected to be on feed for more than 150 days). “Temping” on arrival can be very useful, because even cattle that look bright can have very high temperatures and thus can be identified as “sick” by this procedure. Examples of processing protocols for high- and low-risk cattle are shown in Box 31-5.

31.59.6.2.4

Metaphylactic Antimicrobial Therapy

The term *metaphylaxis* refers to the administration of an antimicrobial to a group of animals that may be in the early stages of bacterial pneumonia or that are at significant risk of developing bacterial pneumonia. Thus the antimicrobial drug administered may have either therapeutic or prophylactic effect, depending on the state of each animal treated. Metaphylactic administration of antibiotics to feedlot cattle on arrival in

order to prevent bacterial bronchopneumonia in feedlot cattle has been shown in many studies to decrease morbidity and mortality in groups of high risk cattle.[446,447] It is useful to consider the theoretic mechanisms by which metaphylactic administration of antimicrobials may limit disease. Soon after cattle are shipped, *M. haemolytica* A1 can proliferate in large numbers in the upper respiratory tract. This period of replication is a crucial phase because large numbers of bacteria can be inhaled into the lung, allowing colonization, proliferation, and production of virulence factors. There appears to be a short time after arrival in the feedlot when cattle that will subsequently develop bacterial bronchopneumonia have large numbers of *M. haemolytica* A1 present in their upper respiratory tract. Antimicrobial therapy timed to coincide with this pathologic event and designed to provide therapeutic levels in respiratory tissues is aimed at reducing the number of *M. haemolytica* A1 present in the upper respiratory tract of calves, which should also limit colonization of the lung and prevent horizontal transmission of *M. haemolytica* from calf to calf. Long-acting antibiotics have been reported to significantly alter the number of calves from which *M. haemolytica* can be cultured.[270,448] An additional rationale for metaphylaxis on arrival is based on the epidemic curve of fatal disease onset for bacterial bronchopneumonia, which shows that feedlot calves dying from fatal fibrinous pneumonia are already sick on arrival or become ill within days of arrival. Although metaphylaxis through feed and water was used in the past, it is currently recommended that metaphylaxis be administered by use of injectable antimicrobial agents. The ability of these drugs to reach therapeutic levels quickly in all animals gives them a clear advantage given the previously discussed rationale for bacterial bronchopneumonia metaphylaxis.

639

640

A number of trials have been published that examine various antimicrobial agents and their effectiveness for bacterial bronchopneumonia metaphylaxis. Most of these studies have examined both health and production values, and a variety of products have been shown to be efficacious in decreasing respiratory morbidity and mortality and sometimes in improving production parameters.[449–451] Tilmicosin or long acting oxytetracycline, both of which provide therapeutic levels of drug for 3 days, are most commonly used for metaphylaxis in feedlot cattle.

Similar use of long-acting antimicrobials in dairy calves may also be of value. The disease process does not have the same narrow windows of therapeutic intervention that occur in calves entering the feedlot. Dairy calves properly managed in maternity facilities and raised in hutches rarely experience any respiratory disease until they are moved to postweaning housing. Injectable mass medication is often used at the time calves are moved and then again at some time later (7 to 10 days after entering the postweaning housing) as a means of controlling postweaning ECP.

31.59.6.3

MANAGEMENT PRACTICES FOR PREVENTING SHEEP AND GOAT PNEUMONIA

Prevention of pneumonia in sheep and goats is also based on altering the risk factors that predispose to pneumonia. Minimizing cold and heat stress, providing properly ventilated housing, avoiding overcrowding, and avoiding long transports in adverse weather aid in prevention. Mass medication can be used to control outbreaks of pneumonia in flocks. Injectable long-acting oxytetracycline is often used subcutaneously at 10 mg/kg. Tilmicosin can also be used for mass medication therapy for sheep, but tilmicosin should never be administered to goats, as it can result in fatal reactions. Feedlot lambs are sometimes administered metaphylactic therapy (long-acting oxytetracycline) on arrival.

31.59.6.3.1

Vaccination To Prevent Respiratory Disease

31.59.6.3.1.1

Factors That Affect Success of Vaccination

Many factors can affect the success of vaccination. For a vaccine to successfully prevent disease, the vaccine must induce a protective immune response against a pathogen to which the host will be exposed. Apparent vaccine failure is often blamed on the product or the manufacturer, but in many cases other factors may have led to vaccine failure. Possible causes of apparent vaccine failure that must be also be considered when vaccinated animals contract disease are related to the administration of the vaccine, the ability of the host to respond to vaccination, and to the nature of pathogen exposure. Examples are listed in Box 31-6. Although the points listed may be obvious, it is important to carefully consider and rule out these problems when a vaccine has failed to prevent respiratory disease before making a quick switch to another brand or type of vaccine.

In addition to the factors just discussed, vaccine characteristics can also affect the success of a vaccination program. Once the decision has been made regarding choice of pathogens to be included in the vaccine, the use of a live versus killed vaccine must be considered. Much research has evaluated the immune response of animals to modified live versus killed (inactivated) vaccines, and the subject has been the focus of much discussion. To summarize:

31.59.6.3.1.1.1

Box 31-6 Reasons for Apparent Vaccine Failure

31.59.6.3.1.1.1.1

FACTORS RELATED TO ADMINISTRATION OF THE VACCINE

Improper storage of live vaccines

Residual chemical disinfectant in reusable syringes

Using live vaccine reconstituted days or weeks previously

Administration into wrong anatomic location

Administration of antibiotics with live bacterial vaccines

Incorrect timing of vaccine administration

Animals already incubating disease

Failure to allow time for immune response to occur

Administering booster too early, too late, or not at all

31.59.6.3.1.1.1.2

FACTORS RELATED TO ABILITY OF HOST TO RESPOND TO VACCINATION

Age (very young or very old animals)

High levels of maternal antibody

Immunocompromise resulting from concurrent disease or stress

Genetic factors

Poor air quality or other environmental insults

31.59.6.3.1.1.1.3

FACTORS RELATED TO PATHOGEN EXPOSURE

Disease caused by pathogens not included in vaccines

Antigenic variation (strain variation) of naturally occurring pathogens

Overwhelming pathogen exposure

- Modified live virus (MLV) vaccines in general stimulate cell-mediated immunity, important for an effective immune response to most viral pathogens, as well as effective humoral immunity.
- Live vaccines can sometimes elicit protective immunity with only a single dose of vaccine.
- Live vaccines contain a smaller dose of organisms, because the organisms in the vaccine are expected to replicate at least minimally.
- Live vaccines generally do not require adjuvants, which are often a major cause of adverse reactions after vaccination (however, some MLV vaccines do contain adjuvants to improve the immune response).
- Live vaccines are generally cheaper.
- Disadvantages of live vaccines include the possibility of causing abortion in pregnant animals, transmission to nonvaccinated animals, exacerbation of morbidity in sick or immunocompromised animals, and reversion to a more virulent form with disease possibly occurring.
- Another disadvantage of live vaccines is that they can be inactivated in a short time by exposure to heat or light.

- In contrast, inactivated vaccines do not generally stimulate effective cell-mediated immunity, although certain adjuvants can overcome this.
- Inactivated vaccines often stimulate high levels of antibody.
- Inactivated viral vaccines require at least two doses at a 14–28 day interval to induce an effective anamnestic response to subsequent challenge.
- Adjuvants in killed vaccines can cause adverse reactions.
- Inactivated vaccines are safe in pregnant or immunocompromised animals, and storage requirements are not as rigorous for inactivated vaccines as for MLV vaccines.

640

641

Much of the above has been determined using viral vaccines; the situation with bacterial vaccines is less well characterized. Modified live bacterial vaccines may stimulate both humoral and cell-mediated arms of the immune response better than inactivated products (bacterins). However, for extracellular bacterial pathogens such as *M. haemolytica*, humoral immunity is the most critical component of an effective immune response. Past evidence has suggested that live *M. haemolytica* vaccines are superior to inactivated products; however, recent comparisons have shown some nonliving products to provide superior resistance to experimental challenge. Live bacterial vaccines can be inactivated if animals are given antibiotics at or near vaccination.

It is important to note that all vaccines for a given disease are not necessarily equal. If a vaccine is inactivated, the means by which it is inactivated can influence antigenicity. Moreover, a wide variety of adjuvants exist, and the adjuvant included in a vaccine can greatly influence the type and duration of immune response elicited. Adjuvants are included in inactivated and some modified live products. The choice of adjuvant to include in a vaccine is the subject of much creative thinking and research effort by manufacturers; this is emphasized by the fact that it is often very difficult to obtain detailed information about the adjuvant contained in a vaccine.

31.59.6.3.1.2

Impact of Maternal Antibody on the Response to Vaccination

For many decades veterinarians have been taught that young animals cannot be effectively vaccinated when they have moderate levels of maternal antibodies obtained through passive transfer after birth. This was based on numerous research studies that showed that vaccination of young animals with maternal antibodies did not lead to the expected increase in serum antibodies to the agent in the vaccine. However, an important finding is that some vaccines appear to prime calves for an improved response to subsequent challenge, even when vaccination occurs in the presence of maternal antibodies. In such cases vaccination does not induce an increase in serum antibody titer within 2 weeks of vaccination, but when calves are vaccinated or challenged at a later date, they respond with what appears to be an anamnestic response as measured by increased serum antibodies, or protection against disease resulting from experimental or natural challenge, as compared with unvaccinated calves.[351,352,452,453] In general, a response was induced most reliably when modified live vaccines were administered and when the calves received at least two doses of vaccine at an appropriate (2- to 4-week) interval. Similarly, calves exposed to live pathogens in the face of maternal antibody can develop a protective immune response, even though they do not seroconvert after exposure.[454,455] It has been shown that a cell-mediated immune response can be measured even when there is no evidence of humoral response in calves infected in the

face of maternal antibodies.[455] Although multiple studies show that calves can be primed for an anamnestic immune response in the face of maternal antibodies, if very high titers of maternal antibody are present, priming by the vaccine can be blocked, as traditionally understood.[453]

This information suggests that at least in some cases a protective immune response can be initiated in calves when the first dose of vaccine is given in the face of maternal antibodies; a cell-mediated response may occur even if calves do not have an increase in serum antibody titer after vaccination. This is particularly useful in the context of pneumonia in nursing dairy or beef calves, as it supports the concept that vaccination can improve the immune response to challenge even if calves have some level of maternal antibodies at the time of vaccination. More research is needed to confirm which vaccines have this effect and to determine how this information should be used to guide vaccination recommendations for calves. It is also not known if this information can be extrapolated to sheep and goats.

31.59.6.3.1.3

Efficacy of Vaccines for Preventing Ruminant Respiratory Disease

Information regarding the use of vaccines for individual agents that cause ruminant respiratory disease was presented earlier in the section describing the individual infectious agents. There has been considerable debate over the years regarding whether vaccines have any impact on ruminant respiratory disease.[456] The literature on the subject is extensive, and interpretation of the data is complicated by the fact that there is much variation among research studies in the type and number of animals studied, the nature of animal management, and the outcomes measured as evidence of efficacy. There are three major types of research studies by which vaccine efficacy can be measured: studies that measure production of antibodies or in vitro cell-mediated immune responses in vaccinated animals; studies that measure the resistance of vaccinated animals to experimental challenge with viral or bacterial pathogens; and studies that measure the impact of vaccination on health and productivity of animals in a conventional field setting (field trials). Of the three methods, field trials are the most meaningful, but they are also the most expensive and difficult to undertake. When they are undertaken, it is often in small numbers of animals under management practices that may not be representative of practices in other regions. Moreover, they rely on the natural occurrence of the disease in question in the animals under study. A well-designed field trial can be very expensive and time-consuming, and the results can be useless if no animals in the study contract the disease naturally.

In spite of these limitations the results of some field trials testing the efficacy of respiratory disease vaccines have been published. For some important pathogens (e.g., BVDV), there are still no large-scale field trials published that show evidence of efficacy in preventing respiratory disease. One trial showed an economic advantage to administering a modified live vaccine containing BHV-1, BVDV, PI3, and BRSV over the use of a modified live vaccine containing only BHV-1 in feedlot cattle,[457] but it was not possible to determine which component of the multivalent vaccine was responsible for efficacy. Multiple field trials have been published that tested currently available vaccines against *M. haemolytica*[311–314] and BRSV[193–196]; these are discussed further in the earlier sections on these specific pathogens. In general, some of these studies found that vaccination could prevent disease and sometimes improve productivity, and some of these studies could not find a beneficial effect of vaccination. It is important to remember that in nearly all of these field trials, the effect of vaccination to decrease *all* respiratory disease was measured. That is, in most cases, no effort was made to determine whether disease specifically caused by the agent included in the vaccine was affected by vaccination. Therefore the apparent lack of efficacy of

vaccines in some studies may have been because animals developed disease caused by other respiratory pathogens.

Occasionally, in addition to evaluating the impact of vaccination on morbidity, mortality, and measures of productivity, investigators calculate the economic advantage or disadvantage of vaccination. When such calculations are made, it is important that the reader assess the assumptions made and determine whether they are appropriate. It has been noted that when the economic advantage of using a given vaccine is calculated, various scenarios should be considered that may prove the vaccine to be economically advantageous in some situations and disadvantageous in others.[458]

641
642

The mixed results of clinical trials published to date indicate that vaccines decrease respiratory disease, improve animal productivity, and save money for the producer in some cases, and in some cases they do not. This should not be a surprise when the multitude of factors that can converge to cause an outbreak of respiratory disease is considered. Vaccination should be seen as one component of a multifactorial approach to minimize animal disease; it should not be seen as a guarantee against all disease, all the time. Thus, the value of vaccination will depend on the risk of disease in the population in question, and the risk of disease will depend on the likelihood of pathogen exposure and the likelihood that other host and management factors can be modified to maximize the ability of the host to respond to vaccination and resist disease.

No single, simple recommendation for vaccination of ruminants for the control of respiratory disease can be made. The veterinarian must individualize each vaccination program to the situation at hand. Many factors need to be considered in formulating recommendations for vaccination, including type of production unit, age of animals, system of management, housing facilities, amount of stress imposed on animals, open or closed herd, type of ration, and level of sanitation. In addition, some infectious agents such as BHV-1, BVDV, and *H. somni* can cause other disease problems not associated with the respiratory tract. Thus the complete spectrum of disease caused by these agents must be considered in formulation of a vaccination program. Examples of respiratory vaccination protocols that could be used in a cow-calf operation and in a dairy are presented in Boxes 31-7 and 31-8.

31.59.6.3.1.4

Evaluating Reports of Vaccine Efficacy

Vaccines approved for sale in the United States must be proven by the manufacturer to be safe, potent, stable, and efficacious. Duration of immunity is an additional parameter that manufacturers are beginning to be required to address. Efficacy is usually determined by experimental challenge, using defined methods or methods approved on a case-by-case basis. For many bovine respiratory pathogens (e.g., BHV-1, *M. haemolytica*), experimental challenge protocols have been developed that can induce disease of reasonable severity. To be approved for sale, vaccines need to prevent to a significant degree clinical signs associated with such experimental challenge. However, whereas protection against experimental challenge is a useful indication of the possible efficacy of a vaccine under field conditions, few experimental challenge protocols closely model the field situation in terms of simultaneous occurrence of other stresses and concurrent infection with other pathogens. Thus, it is ideal to evaluate vaccine efficacy through evaluation of an appropriately designed field trial. The design of field trials has generally improved greatly in recent years, but in the case of many vaccines, no high-quality published field trials evaluating the efficacy of vaccination for prevention of BRD exist.

COWS

Modified live BHV-1/PI3/BRSV/BVD prior to breeding

Consider boost with killed **or approved modified live*** BHV-1/PI3/BRSV/BVD at dry off

Consider *M. haemolytica/P. multocida* vaccine at 2 months prior to calving, with boost one month later, in herds with history of problems with pneumonia in nursing calves

31.59.6.3.1.4.2.3

CALVES

In herds with significant calf pneumonia prior to weaning, consider modified live† BHV-1/PI3/BRSV/BVD and *M. haemolytica/P. multocida* vaccine at 1–4 months of age with boost 2–4 weeks later, timed so that boost occurs 2–4 weeks prior to expected onset of calf pneumonia.

31.59.6.3.1.4.2.3.1

To Minimize Pneumonia In Calves Postweaning

Modified live BHV-1/PI3/BRSV/BVD one month prior to weaning with boost at weaning

Consider *M. haemolytica/P. multocida* vaccine one month prior to weaning with boost at weaning in herds with a history of post weaning pneumonia, or if required for participants in defined preconditioning programs

* Certain modified live BHV-1/PI3/BRSV/BVD vaccines are approved for use in pregnant cattle **when administered in accordance with label directions**.

† Modified live BHV-1 and BVD vaccines can induce disease in very young (<1 month of age) or debilitated calves. In such calves, intranasal MLV BHV-1 vaccines or inactivated vaccines may be safer.

Veterinarians can arm themselves with useful information by evaluating published studies of vaccine efficacy in a critical manner. In some studies animals are vaccinated but never exposed to the pathogen. Serum and/or mucosal antibody levels may be measured, and markers of cell-mediated activity, such as

lymphocyte blastogenesis, cytokine production, or cytotoxic T cell activity, may be assayed. Such studies can indicate the antigenicity of a vaccine, but one must consider whether the parameters measured are known to correlate strongly with protection against disease. More information can be gained when measurements of immune function are evaluated in light of natural or experimental challenge. In experimental challenge studies, relatively small groups of animals are vaccinated and later challenged with the pathogen contained in the vaccine. Although experimental challenge studies are rather artificial compared with the situation animals experience in the field, a high-quality experimental study has certain characteristics. Some questions to ask include the following: Was a nonvaccinated control group, identical to the vaccine group in all ways except vaccination status, included? Were control animals tested at the same time as vaccinated animals? If factors that could affect vaccination were present (e.g., maternal antibody), were affected animals divided equally between control and vaccine groups? Did experimental challenge result in disease in the control group? If not, it is impossible to say if vaccination had an effect on challenge. Were investigators who evaluated clinical or pathologic signs of disease blinded to the treatment status of the animals? This removes an important source of bias that otherwise can make data, particularly subjective data such as "depression" or "dyspnea," suspect. Were statistical tests used to compare results of vaccine and control groups, and was the *P* value given to indicate likelihood that differences were due to chance alone? Other questions that can help determine the relevance of the experimental study to the field situation include the following: Was disease resulting from challenge clinically and/or pathologically similar to that seen in field cases? Was the vaccination regimen similar to that used in the field? How soon after vaccination were animals challenged? Did the time between vaccination and exposure mimic the field situation?

642

643

Field trials are characterized by allocation of animals in a natural "field" situation to either vaccine or control groups. Animals are treated accordingly and then followed for variable periods of time to determine whether disease occurs in vaccinated animals and, if so, whether vaccinated animals have disease less often, have disease that is less severe, or have improved production characteristics (e.g., average daily gain) after vaccination. When evaluating a field trial, consider the following questions to determine the value of the study: Were animals randomly allocated to control or treatment groups? This is critical; if there is no mention of randomization, it is difficult to gain useful information from the study because of the many types of bias that can affect the outcome. Were concurrent controls used, as opposed to historical controls? Historical controls are of much less value in determining vaccine efficacy, as many factors can affect disease outcome in a group of animals from year to year. How many animals were included in the study, and for how long did the study run? In general, trials with larger numbers of animals are more likely to reveal differences between vaccine and control groups. Were evaluators of disease blinded to the treatment groups to remove their bias in interpreting outcomes? Did disease occur in the control animals? One weakness of field trials is that natural disease must occur in the animals under study to determine the effect of vaccination on disease; the investigators have no control over this aspect of the study. If disease did not occur in at least the control animals, the vaccine cannot be evaluated for protection against the disease. Also, ask what outcomes were measured as evidence of protection against disease. In most cases of feedlot trials, fibrinous pneumonia morbidity and mortality are measured. If this was the case, identify how cases were identified, and determine if the definition is accurate. In many trials, total morbidity and mortality is also measured as an outcome. This may be considered a less reasonable outcome; for example, it may not be reasonable to expect BHV-1 vaccination to decrease deaths caused by ruminal acidosis. Production characteristics, such as rate of gain or feed efficiency, are also often evaluated, and net cost of vaccination, including estimated losses due to disease or loss of production, may be calculated. In these cases, evaluate how costs were estimated, and determine if estimates appear to be accurate and reasonable. Finally, veterinarians may want to consider

whether the field trial was conducted under conditions similar to that seen in their practice; if so, the results may be more relevant to the needs of their clients (adapted in part from Ribble).[459]

31.60 THE INTERSTITIAL PNEUMONIAS

AMELIA R. WOOLUMS

DANIEL L. GROOMS

JOHN A. SMITH

Understanding of the interstitial pneumonias of ruminants has undergone considerable evolution in the past 30 years. Unfortunately, confusion still exists, particularly with regard to terminology. Terms such as *acute bovine pulmonary emphysema, atypical interstitial pneumonia* or AIP, *fog fever, pulmonary adenomatosis, farmer's lung*, and *ARDS* have been used interchangeably for all of the conditions that follow. This text uses a classification presented by Breeze,[460] which places the interstitial pneumonias into four groups: (1) ARDS, (2) hypersensitivity diseases, (3) chronic conditions that may be sequelae of ARDS or hypersensitivity diseases, and (4) parasitic diseases. BRSV infection can also cause AIP; this disease was discussed in relation to the respiratory disease complex of cattle, sheep, and goats earlier in this chapter.

31.61 ACUTE RESPIRATORY DISTRESS SYNDROMES

ARDS is any respiratory condition characterized clinically by a sudden onset of (usually severe) dyspnea (Fig. 31-66) with gross and histopathologic findings consistent with AIP. The characteristic gross findings of AIP are lungs that fail to collapse when the thorax is opened (Fig. 31-67) and that are heavy and have a firm, rubbery texture on palpation. Interlobular or bullous emphysema is usually present (see Fig. 31-54), and sometimes the cut surface of the lung has a shiny or wet appearance because of edema. In some cases affected lobules, which are dark red to purple, or sometimes grayish, are interspersed with normal-looking lobules, giving the lung a “patchwork” appearance. Although the gross findings are suggestive and often characteristic, other lung diseases can cause similar changes, so a diagnosis of AIP can be confirmed only by histopathologic evaluation. The histopathologic changes that confirm a diagnosis of AIP include alveolar hyaline membrane formation and fibrin deposition, alveolar and interstitial edema, and type 2 pneumocyte proliferation. Hemorrhage, emphysema, and interstitial inflammatory cell infiltrate can also be seen.

643

644

Fig. 31-67 Postmortem photograph of lung from heifer with ARDS caused by feedlot acute interstitial pneumonia (AIP). Note expanded dorsocaudal lung, and dark, collapsed lobules interspersed with pale, hyperinflated lobules. Photograph contributed by Dr. Amelia Woolums, University of Georgia, Athens, Ga.

The term *atypical interstitial pneumonia* has often been applied to describe the changes characteristic of AIP, but it has been pointed out that the clinical and pathologic changes in affected cattle are not "atypical" but are rather "typical" of ALI.[460,461] Use of the term "acute interstitial pneumonia" to describe the characteristic pathologic changes, and the term *acute respiratory distress syndrome* to describe the clinical picture in an animal with AIP of as-yet undetermined cause, is both accurate and all-encompassing. A diagnosis of AIP should be understood as a pathologic diagnosis rather than an etiologic diagnosis, because a variety of insults can lead to the same lung lesion of AIP.[460,461]

31.61.1 Acute Bovine Pulmonary Edema and Emphysema

31.61.1.1 Definition and Etiology

Acute bovine pulmonary edema and emphysema (ABPEE), classically known as *fog fever*, is an ARDS of adult (over 2 years old) cattle that are changed from dry, sparse forages to lush green pastures. It is caused by the conversion of L-tryptophan ingested in the lush forages to a pneumotoxic compound (3-methylindole [3-MI]), which leads to the development of pulmonary edema, alveolar epithelial hyperplasia, hyaline membranes, and emphysema.[460]

31.61.1.2 Clinical Signs

Adult brood cows are most commonly affected because this is the type of animal most likely to be subjected to the abrupt pasture change required to produce the condition. No breed is resistant.[460] The type of pasture appears to be unimportant, as long as it is lush; ABPEE has been reported on a wide variety of grasses, alfalfa, rape, kale, and turnip tops.[462] Signs usually occur within 2 weeks of the pasture change.[460] In severe cases there is an acute onset of very severe dyspnea with a loud expiratory grunt, frothing at the mouth, mouth breathing, and tachypnea (35 to 75 breaths/min).[462] The animals are obviously distressed (as opposed to exhibiting the typical depression that occurs with infectious diseases) and stand with the head and neck extended and elevated and the nostrils dilated.[463] Temperature and heart rate may be elevated secondary to the severe dyspnea and hypoxia.[463] On auscultation the breath sounds are usually surprisingly soft in view of the gross dyspnea and tachypnea; a few crackles may be heard.[462] Even mild exercise increases the dyspnea and may precipitate collapse and death. As many as 30% of severely affected patients may die, usually within 2 days.[462] Those that survive typically show a dramatic improvement after 3 days.[462] Recovering patients and those that are less severely affected exhibit tachypnea (50 to 80 breaths/min), hyperpnea, harsh breath sounds, and crackles and wheezes, particularly in the caudal lung fields.[462] SC emphysema may develop. The demeanor of the entire group tends to become more tranquil.[462] In cattle that have repeated episodes of nonfatal ABPEE, a chronic respiratory condition characterized by diffuse pulmonary fibrosis and alveolitis may develop.[464] For purposes of differential diagnosis, it is important to note that coughing is not prominent in the individual or the group.[462] The main differential diagnoses are those diseases that cause ARDS in pastured adult cattle, usually in outbreak form. The association of ABPEE with typical management conditions (e.g., changes of pasture) and the absence of coughing, signs of sepsis, and adventitious lung sounds in early cases are also very important features. Primary considerations should include the other plant toxicities (moldy sweet potatoes, perilla mint, and possibly others) that can be differentiated only by identifying the source. An outbreak of BRSV infection or parasitic bronchitis could cause similar clinical signs and pathology, but these are characterized by more coughing, signs of depression, and more prominent adventitious sounds; fever is common in animals with acute BRSV infection.

31.61.1.3 Pathophysiology

L-Tryptophan in lush forages is converted by ruminal microorganisms to indole acetic acid and eventually to 3-MI, which is rapidly absorbed from the rumen into the blood. Metabolism of 3-MI by the cytochrome P-450 mixed function oxidase system in the nonciliated bronchiolar epithelial (Clara) cells and type 1 pneumocytes

results in one or more highly reactive intermediates that bind to intracellular proteins or other macromolecules. It is thought that these intermediates produce the damage to these cells. These intermediates are detoxified by conjugation with glutathione.[465] Cellular damage results in degeneration, necrosis, exfoliation of type 1 pneumocytes and Clara cells, and edema. These lesions in turn cause hyaline membrane formation, proliferation of type 2 pneumocytes, and, to a lesser extent, proliferation of Clara cells.[465] The proliferation of type 2 cells is also known as *adenomatosis*. Emphysema is probably secondary to the severe dyspnea.[465]

31.61.1.4 Epidemiology

As indicated, ABPEE is consistently related to management practices in which hungry adult cattle are suddenly moved from sparse, dry grazing to lush green pastures. The British name "fog fever" arose from the association of the disease with "fog" pastures, which are the lush green regrowth pastures after hay or silage has been cut. The problem usually occurs in the fall. In the typical pattern in the western United States, cattle are moved from dry summer range onto irrigated or fertilized aftermath pastures.[460] The disease usually appears as a herd outbreak, but individuals may be affected to widely varying degrees; morbidity rate commonly approaches 50%, with a case fatality rate as high as 30%.[466,467] Nursing calves are apparently not at risk, and yearlings are less susceptible than adults.[468]

644

645

31.61.1.5 Necropsy Findings

In animals that die of ABPEE, ecchymotic to petechial hemorrhages occur in the larynx, trachea, and bronchi, and frothy fluid is present in the airways. The gross and histopathologic lung lesions are consistent with AIP. Congestion, edema, and hyaline membranes cause deep red-to-purple coloration of the cranial lung lobes and a smooth, glistening appearance to the cut surface. Interstitial emphysema with large bullae and gelatinous yellow interlobular edema is common. Histologically, eosinophilic hyaline membranes line alveoli and alveolar ducts, and there edema and proliferation of type 2 alveolar epithelial cells are present.[460] In animals that are killed after 3 to 4 days, emphysema and edema are less obvious, and the lungs tend to be light brown, firm, heavy, and rubbery. There is severe diffuse alveolar epithelial hyperplasia ("adenomatosis"), and large mononuclear cells, multinucleated giant cells, and hyaline membranes are present in alveolar spaces. Edema, eosinophils, and inflammatory cells occupy the septa.[460]

31.61.1.6 Diagnosis

Diagnosis is made based on the history of recent exposure to lush green forage and typical clinical signs and pathology in fatal cases. Thoracic radiographs could be used to identify changes consistent with interstitial pneumonia in valuable individual animals. The results of TTA or BAL cytology have not been reported for cattle with ABPEE, but a nonseptic mixed inflammatory cell response would be expected. There are no unique hematologic or biochemical changes.[463] A stress leukogram is often seen.

31.61.1.7 Treatment and Prevention

The stress of handling cattle can precipitate further losses. Some authors maintain that most cases in an outbreak occur within 4 days, that removing the herd from the pasture does not prevent additional cases, and that leaving the herd on the pasture does not result in additional cases; consequently the recommendation has been to handle severely affected cattle only if necessary to remove them to shade or to slaughter.[467]

Others[460,468] recommend careful removal from the offending pasture. Antihistamines, corticosteroids, epinephrine, atropine, diethylcarbamazine, and diuretics are alleged to be of palliative value,[460,470] but none of these has been properly tested.[460] Pretreatment with antagonists to postulated mediators of inflammation, including acetylsalicylic acid, mepyramine, sodium meclofenamate, diethylcarbamazine citrate, and betamethasone, did not influence the clinical course or lesions of experimental 3-MI toxicity. Likewise, pretreatment with chloramphenicol or disodium cromoglycate failed to alter signs or lesions.[469] However, in one small trial, flunixin meglumine at 1.1 mg/kg IV daily given after the onset of 3-MI–induced disease in calves was effective in lessening signs and lesions.[470] Recovery often occurs without therapy in the less severe cases. In view of the dangers of handling affected cattle, the questionable efficacy of medical treatment, the probable irreversible nature of severe lesions, and the probability of spontaneous recovery in less severe cases, the best treatment may be no treatment. If treatment must be attempted, affected cattle should be handled very cautiously, and furosemide (0.5 to 1 mg/kg IM or IV once or twice daily)[463] and flunixin meglumine (1.1 to 2.2 mg/kg IV daily or divided twice daily) or steroids (dexamethasone at 0.05 to 0.2 mg/kg IM or IV once daily) may be given. Most fatalities occur in the first 2 days. Severely affected animals that survive may develop chronic emphysema or heart failure secondary to cor pulmonale.[467] Moderate to mild cases often show marked improvement after day 3, with recovery over about 10 days; relapses do not occur.

Prevention is based on management and prophylactic drugs. Management strategies that prevent the exposure of susceptible cattle to potentially toxic pastures include the following:

1 Place the cattle in a drylot, feed palatable hay for several days, and turn them onto the lush pasture for 2 hours the first day. Gradually decrease the amount of hay fed and increase the time on pasture over a period of 10 to 12 days.[467]

2 Delay use of lush pastures until after a hard frost.[468]

3 Cut and windrow the pasture before turning cattle out.[469]

4 Use the pasture for young stock (less than 15 months old) or sheep or other livestock[468]; turn adult cattle out only after the pasture has been thoroughly grazed over.

5 Use the pasture before it becomes particularly lush.[465]

6 Use continuous strip-grazing.[467]

Because such management changes are frequently not feasible, prophylactic medication is a promising alternative. Monensin or lasalocid at 200 mg/head/day PO reduces the conversion of tryptophan to 3-MI.[462] Treatment with monensin should be started at least 1 day before pasture change and should be continued an additional 10 days, whereas lasalocid requires a longer pretreatment period of 6 days.[471] For example, 1 kg/head/day of a protein or energy supplement containing 0.15% Rumensin 60 supplies 200 mg of monensin.[460] Monensin or lasalocid is not expected to be beneficial after the onset of signs. Future possibilities include blockers of the mixed function oxidase system and enhancers of intracellular glutathione levels.

31.61.2 Feedlot Acute Interstitial Pneumonia

31.61.2.1 Definition and Etiology

In feedlot cattle an ARDS occurs that is commonly referred to as *feedlot AIP*. The exact cause of this syndrome is unknown, and it is probably multifactorial. Feedlot management practices typically do not include exposure of cattle to lush forages similar to those that cause ABPEE, and the feeding of moldy sweet potatoes has not been associated with feedlot AIP.[472] A variety of causes have been proposed[473,474]; unfortunately, the amount of research to confirm or refute the various hypotheses ranges from small to nonexistent. The most commonly suggested possible causes or predisposing factors are (1) feed-associated pneumotoxins such as 3-MI[475–477] or dietary factors related to protein metabolism[478]; (2) chronic bacterial pneumonia[479–481]; (3) gender[475,476] and hormonal influences[482,483]; (4) chronic small airway injury[480,481,484]; (5) BRSV infection[481,485]; (6) heat or dust exposure[484,486]; and (7) hypersensitivity reactions.[484,487,488] These possible causes could also work together in various combinations to cause feedlot AIP.[477,481]

Support for 3-MI as a cause of feedlot AIP comes from research that showed that levels of a stable metabolite of 3-MI, 3-methyleneindolenine (3-MEIN), were significantly higher in the blood of cattle with AIP than in control cattle.[475,476] Increased levels of 3-MEIN may be a result of decreased clearance of the toxin.[475] Loneragan and colleagues also found that 3-MEIN levels were higher in lung tissue of AIP cases as compared with animals without lung disease, but they were not higher than 3-MEIN levels in the lung tissue of cattle with bronchopneumonia; this suggested that 3-MI may contribute to the pathogenesis of both AIP and bronchopneumonia.[476] The mechanism by which 3-MI is generated and leads to lung damage was discussed earlier in the section describing ABPEE. If 3-MI does contribute to the pathogenesis of feedlot AIP, it is not clear what about the feedlot diet predisposes cattle to produce high levels of 3-MI. Normal cattle produce some 3-MI through metabolism of dietary proteins. It may be that the protein composition (e.g., the tryptophan concentration) of feedstuffs sometimes added to feedlot rations can lead to spikes in 3-MI production. Cattle with feedlot AIP have been found to have higher ruminal pH values than expected for cattle adapted to a high concentrated diet. Ruminal pH in AIP cases ranged from 5.6 to 7.2 in one study[481] and from 4.9 to 7.4 in another,[489] whereas the ruminal pH of cattle adapted to a high concentrate diet is typically about 5.5 to 5.6.[490] Many proteins are relatively basic; therefore the high ruminal pH could be related to abnormal protein metabolism. However, the relatively high ruminal pH could also be caused by anorexia. The concept that abnormal ruminal protein metabolism could contribute to feedlot AIP was also supported by a small study that found increased ammonia levels in the ruminal gas cap of cattle with AIP.[491] An interaction between digestive health and AIP was also suggested by the finding that in feedlot pens in which at least one animal had died from digestive disease, the incidence of AIP was approximately 70% greater than in pens in which digestive disease deaths did not occur.[478]

The hypothesis that bacterial bronchopneumonia contributes to feedlot AIP is supported by the finding by multiple authors that cattle with AIP frequently have superimposed gross and histopathologic lesions consistent with bacterial bronchopneumonia.[479–481] In a study evaluating the bacteria isolated from the lungs of cattle with feedlot AIP that had not received antimicrobial therapy, *P. multocida* and *Mycoplasma* species were significantly more likely to be isolated from the lungs of cattle with AIP than from the lungs of normal penmates.[481] An earlier study found that bacterial respiratory pathogens were not more likely to be isolated from cases of AIP as compared with controls, but the samples in this study were collected at necropsy of

animals that received antimicrobial treatment before death in at least some cases.[492] It should be noted that no study has yet been able to confirm whether in cases with both lesions the bacterial bronchopneumonia was present before AIP occurred or the bacterial bronchopneumonia developed after the animals had AIP. If bacterial bronchopneumonia leads to the development of AIP, it is not clear how this happens. In humans with ARDS, bacterial infection is often a predisposing factor that appears to lead to ARDS through the induction of high local or systemic levels of proinflammatory cytokines.[493,494] The role of proinflammatory cytokines in cattle with feedlot AIP has not been investigated.

A role for gender and/or hormonal influences in the pathogenesis of feedlot AIP is related to the frequent (although not inevitable)[480] finding that the majority of affected animals are heifers.[475,478,481,495] Feeding of melengestrol acetate (MGA), which is fed to heifers to control estrus, has been suggested to contribute to AIP by some authors,[473,482] but others have not found evidence of any association between MGA and AIP.[478,495] Although one research study indicated that MGA could exacerbate experimentally induced AIP in sheep,[482] a well-controlled experimental study to determine the effect of MGA on AIP in cattle in the field is needed to clarify the involvement of MGA with AIP. It has also been suggested that growth hormone implants may contribute to development of feedlot AIP, although a survey of feedlot managers did not find data to support this.[495]

Infection with BRSV was linked to feedlot AIP in an early study.[485] Because BRSV infection can sometimes cause AIP, the possibility that a ruminant with lesions of AIP is simply a case of BRSV infection must always be considered. However, cattle with feedlot AIP do not always have a fever,[481] which is expected in animals with acute BRSV infection. Moreover, feedlot AIP can occur in outbreaks, but cases often occur sporadically, which would be less consistent with BRSV infection. Neither Sorden and colleagues nor Loneragan and colleagues found BRSV significantly more often in animals with feedlot AIP than in controls.[480,492] In another study the difference in frequency of identification of BRSV in feedlot AIP cases as compared with normal penmates approached significance ($P = .07$).[481] It is interesting to note that in this study BRSV antigen was not found in airway epithelial cells, as is characteristic of acute BRSV infection,[496] but rather was found in cells, possibly macrophages, that were surrounding airways. The significance of this was not clear; perhaps the BRSV antigen found in these cases was residual antigen in phagocytic cells that was engulfed during BRSV infection in the recent past.

Although AIP is by definition “acute,” it is interesting that several authors have reported histopathologic evidence of chronic airway injury (particularly, bronchiolitis fibrosa obliterans) in the lungs of animals with AIP.[480,481,484] In one study, the presence of bronchiolitis fibrosa obliterans was identified significantly more often in cattle with AIP than in penmates with no history of treatment for respiratory disease; this was in spite of the fact that AIP cases in the study also had no history of previous treatment for respiratory disease.[481] It is not known how past airway injury is related to the development of AIP, although chronic airway injury could be linked to the occurrence of chronic bacterial pneumonia, which has also been associated with feedlot AIP, as described previously. It may be that the chronic airway injury is related to dust exposure, although it is not clear why animals with AIP would be more likely to have airway injury caused by dust exposure than other penmates. Dust exposure has been anecdotally related to AIP,[484,486] and feedlot managers often report that efforts to control dust, such as spraying water lightly onto the surface of pens, decreases AIP occurrence when the disease is a problem. However, repeated exposure to feedlot dust or to fungal organisms from feedlot dust did not induce AIP in sheep or goats in experimental studies.[497,498] One study of the effect of dust on feedlot respiratory disease found only a weak association between airborne dust particles and respiratory disease.[499]

High ambient temperatures are thought to contribute to feedlot AIP because several investigators have found that the majority of cases occur in the summer,[478,484] but no mechanism by which hot weather might exacerbate AIP has been researched. Hypersensitivity reactions are often suggested to cause AIP.[502,503] It is true that anaphylaxis can cause pulmonary edema, hemorrhage, and emphysema, with microscopic evidence of hyaline membrane formation.[500] However, animals that survive longer than a few hours after an episode of anaphylaxis do not have lung changes consistent with AIP, such as type 2 pneumocytic proliferation and interstitial inflammatory cell infiltrate.[501] Therefore an anaphylactic reaction may cause an occasional case of sudden death with lung changes typical of AIP, but anaphylaxis does not explain the majority of feedlot AIP cases. Other types of hypersensitivity-mediated lung disease have pathology that is unlike that seen in feedlot AIP, also making other types of hypersensitivity an unlikely cause of the majority of feedlot AIP cases.[460,473]

646

647

In summary, the cause of feedlot AIP is unknown, but the strongest support currently exists for some role for (1) factors related to feed, or ruminal metabolism, including 3-MI; (2) infectious respiratory disease, especially chronic bacterial pneumonia, and possibly BRSV; (3) gender and/or other hormonal influences; and (4) chronic airway injury, which may be related to infectious respiratory disease. It seems likely that multiple factors can contribute to the development of feedlot AIP, and the factors may act in some as-yet unidentified combination in at least some cases. It is also possible that some causes predominate in some feedlots or individual cases, whereas other causes predominate in other feedlots or individual cases. A study evaluating the occurrence of bacterial respiratory pathogens in cattle with feedlot AIP found bacterial respiratory pathogens in the lungs of the majority of cases in one feedlot, and in almost none of the cases in a second feedlot,[481] suggesting that bacterial infection played a role in the development of AIP cases in the first feedlot but not the second.

31.61.2.2 Clinical Signs

Feedlot cattle with AIP may be found dead in the pen.[504] Clinical presentation includes rapid onset of expiratory dyspnea and tachypnea, although if the respiratory effort is great, the actual respiratory rate may not be greatly elevated. Cattle typically stand with their heads extended and front legs spread apart, and exhibit open-mouth breathing (see Fig. 31-66). Frothing from the mouth may also be observed. Rectal temperatures are variable, ranging from normal to elevated.[481] Physical examination may reveal cyanosis, tachycardia, and SC emphysema that extends from the cervical to dorsal thoracic area.[505] Auscultation of lungs reveals dull areas throughout the lungs, along with some crackles. Differential diagnoses of bronchopneumonia, tracheal edema, tracheal obstruction, and hypersensitivity pneumonitis should be considered.

31.61.2.3 Pathogenesis

Because the cause of feedlot AIP is unknown, the pathogenesis is also uncertain. If feed-related pneumotoxins cause at least a subset of cases with AIP, the pathogenesis will be similar to that described for ABPEE, 4-ipomeanol toxicity, and perilla ketone toxicity. If bacterial infection is a cause of some cases of feedlot AIP, as is true for some human cases of ARDS, then proinflammatory cytokine production and the resultant inflammatory cascades they initiate are likely involved. More research is necessary to determine the cause and the pathogenesis of feedlot AIP.

31.61.2.4

Epidemiology

In the 1999 NAHMS survey of feedlots, AIP was identified as the second leading cause of feedlot mortality, behind bronchopneumonia (shipping fever).[502] Mortality rates resulting from AIP of 0.03% to 0.15% have been reported.[478,479,484,495] An important feature of AIP is the tendency of the disease to occur most often in cattle on feed more than 60 days,[475,481,484,492,495] as opposed to shipping fever, in which mortality peaks by 45 days after feedlot entry.[506] This means that losses due to AIP deaths are amplified by the fact that relatively more resources in feed and labor have been invested in cattle that die of AIP, as compared with cattle that die of shipping fever. Most cases of feedlot AIP occur in the summer,[478,484,495] but the disease can occur in any season of the year; and most studies report that heifers are disproportionately affected.[475,476,495] One survey found the odds of an animal with AIP being a heifer were 3.1 times greater than the odds of the animal being a steer.[476] In feedlot pens in which an animal died from a digestive disorder, the relative risk of AIP occurring was about 1.7, indicating that pens with a digestive disorder death were about 70% more likely to also have an AIP death, as compared with pens with no digestive disorder deaths.[478]

A survey of feedlot managers was undertaken to determine risk factors for feedlot AIP.[495,503] Although the response rate was relatively poor (12%), the responding managers oversaw just under 2.5 million cattle, which represented about 10% of the U.S. feedlot inventory the year the survey was undertaken.[503] Feedlots in northern states were significantly less likely to recognize AIP as a cause of morbidity or mortality as compared with feedlots elsewhere, whereas larger feedlots and feedlots placing a higher proportion of yearlings were more likely to recognize AIP as a cause of morbidity or mortality. Feedlots that vaccinated less than 95% of placements for *M. haemolytica* ± *P. multocida* were more likely to recognize AIP as a cause of disease, and these feedlots recognized AIP as a cause of a larger proportion of deaths, as compared with feedlots that vaccinated more than 95% of cattle for these pathogens.[495] If the data reported by the feedlot managers are representative of a true association between *Mannheimia* and *Pasteurella* vaccination and AIP, the reason for the link is not clear. It may simply be related to the association between placement of a high proportion of yearling cattle and AIP, as yearlings are less likely to be vaccinated for *Mannheimia* and *Pasteurella* than younger cattle. It may also be related to the finding that AIP cases have increased likelihood of having concurrent bacterial pneumonia in some feedlots, but more research is necessary before any definite conclusions can be made.

31.61.2.5

Necropsy Findings

The gross pathology of feedlot AIP is essentially the same as that described for ABPEE. If there is concurrent bacterial bronchopneumonia, there may be cranioventral consolidation, with fibrin deposition on the pleura, but in cases with no concurrent bacterial pneumonia, the pleura is free of fibrin. Grossly it is common to see a “patchwork” appearance of dark and light colored lobules interspersed, and the lobules are freely movable[473,481] (see Fig. 31-67). Histologically, the most acute cases will have only hyaline membrane formation and alveolar edema, possibly with hemorrhage in the alveoli or interstitium; cases that have been going on longer will have proliferation of type 2 alveolar epithelial cells and inflammatory cell infiltrate into the interstitial space (septa). It is not unusual to find evidence of chronic airway injury, such as peribronchiolar lymphoid cuffing, peribronchiolar vascular fibrosis, and bronchiolitis fibrosa obliterans.[480,481] Whether the chronic airway injury is related to the pathogenesis of AIP or whether it is an incidental finding is unknown,

but in one study bronchiolitis fibrosa obliterans was significantly more common in AIP cases than in penmates with no history of lung disease.[481]

31.61.2.6 Diagnosis

Diagnosis of feedlot AIP can be confirmed only by histopathologic evaluation of lung from animals that die or are euthanized because of the disease. Clinical signs and even gross pathology are not definitive; only 65% to 80% of cases identified based on clinical signs were confirmed by histopathologic evaluation to have AIP in two studies.[475,481]

647

648

31.61.2.7 Treatment and Prevention

Treatments recommended are similar to those recommended for ABPEE. However, feeding monensin does not preclude development of feedlot AIP, as cattle that die of AIP are often consuming feed including monensin when they contract AIP.[481] Treatment is supportive and typically includes administration of antiinflammatory drugs such as steroids (dexamethasone at 0.05 to 0.2 mg/kg once or twice) or flunixin meglumine (1.1 to 2.2 mg/kg IV q24h), and diuretics such as furosemide (1 mg/kg IM or IV q12-24h). Antimicrobial drugs are appropriate given the fact that cases often have superimposed bacterial pneumonia (see Table 31-10). There are no studies evaluating the response of cattle with AIP to any treatment, and such studies would be difficult because there is no perfect method of making an antemortem diagnosis of the disease. However, anecdotal reports indicate that the prognosis is guarded even with treatment. It is important to note that simply moving cattle out of the pen could lead to death from severe respiratory compromise. Because of the risks and uncertainties of treatment and the expected high case fatality rate, immediate salvage slaughter may be the most economic course to take[507]; if salvage slaughter is attempted, remember to observe proper drug withdrawal times.

Because the cause of feedlot AIP is unknown, it is difficult to recommend control measures. Administration of aspirin and of vitamin E have been suggested as rational preventative strategies to counteract inflammatory pathways suspected to be involved in feedlot AIP; however, two trials showed no clear effect of these therapies on levels of 3-MI in treated cattle.[508,509] No cattle in these trials developed AIP, so an effect on disease could not be identified. The risk factors identified suggest that management strategies to minimize abrupt dietary changes and to control infectious respiratory disease may be helpful; anecdotal reports also suggest that efforts to control feedlot dust may be helpful.

31.61.3 4-Ipomeanol (Moldy Sweet Potato) Toxicity

31.61.3.1 Definition and Etiology

Moldy sweet potato toxicity is caused by the ingestion of a furanoterpenoid toxin produced by sweet potatoes *(Ipomoea batatas)* in response to infestation with the fungus *Fusarium solani (javanicum)*. It should be emphasized that this disease is an intoxication and not an allergic response to the fungus.[460]

31.61.3.2 Clinical Signs

There is an acute onset of tachypnea, tachycardia, hyperpnea, and dyspnea, with loud expiratory grunting, frothing at the mouth, extension of the head and neck, flaring of the nostrils, and frequent deep coughing. Crackles and harsh bronchial sounds are heard on auscultation.[510] Signs usually occur within 1 day of exposure, and deaths may occur 2 to 5 days later.[460] Differential diagnoses are as for ABPEE (see earlier discussion), which this condition closely resembles, except for the history of exposure and the more prominent cough and adventitious lung sounds.

31.61.3.3 Pathogenesis

When *F. solani* (or closely related species) grows on sweet potatoes, the potato produces several 3-substituted furans, including 4-hydroxymyoporone, which is hepatotoxic. This is converted by the fungus to a series of pneumotoxins, the most abundant of which is 4-ipomeanol. When ingested by cattle in sufficient amounts, this toxin is absorbed, carried to the lungs in the blood, and converted to a highly reactive metabolite by a cytochrome P-450–dependent mixed function oxidase system.[460] From this point the pathogenesis is similar to that of ABPEE—that is, the toxin binds to intracellular macromolecules in the cell, causing cellular damage, particularly in Clara cells, type I pneumocytes, and endothelium; edema, hemorrhage, cellular necrosis, hyaline membrane formation, and proliferation of cuboidal epithelium result, with secondary emphysema.

31.61.3.4 Epidemiology

The disease usually occurs in outbreak form when groups of cattle are fed damaged sweet potatoes. Morbidity and case fatality rates are high. Calves nursing affected cows are unaffected.[511]

31.61.3.5 Necropsy Findings

The lungs are wet, firm, and large and fail to collapse. Hemorrhages, yellow gelatinous edema fluid, and emphysema with bullae occur throughout. Lobules are dark red and firm.[510,511] Microscopic lesions include edema, emphysema, hyaline membranes, hemorrhage, mixed interstitial infiltrates, alveolar epithelial hyperplasia, peribronchiolar fibrosis, and bronchiolitis obliterans.[511]

31.61.3.6 Diagnosis

Diagnosis is made based on history of feeding sweet potatoes and identification of clinical signs and pathology consistent with AIP. Other diagnostic tests as described for ABPEE could also be attempted in valuable individual animals.

31.61.3.7 Treatment and Prevention

Treatment has not been investigated. Because the pathophysiologic mechanisms are similar to those of ABPEE, similar recommendations are offered here: handle affected animals with extreme care; if treatment is attempted, furosemide (0.5 to 1 mg/kg IM or IV q12-24h) and flunixin meglumine (1.1 to 2.2 mg/kg IV daily or divided twice daily) or dexamethasone (0.05 to 0.2 mg/kg IV or IM q24h) may be given. The prognosis for

moderate to severe cases is grave, regardless of management. Because toxicity is difficult to predict and is usually severe and irreversible when it occurs, the feeding of mold-damaged sweet potatoes should be strictly prevented.

31.61.4 Perilla (*Perilla Frutescens*) Ketone Toxicity

31.61.4.1 Definition and Etiology

Perilla ketone toxicity is an ARDS caused by ingestion of a pneumotoxin found in the leaves and seeds of *Perilla frutescens*, a common weed in the southeastern United States. This plant is also known as purple mint, perilla mint, wild coleus, and beefsteak plant.[512] It is an erect herbaceous annual about 2 m high, with characteristic square stems, an aromatic odor, and opposite, coarsely serrated ovate leaves 5 to 10 cm long and 4 to 8 cm wide, with a purplish tint at maturity. The seed and flower stage, which occurs in August to October, appears to be most toxic.[512] The flowers are small, white to purple blooms on a long raceme.[512] The plant prefers semishade, such as damp, open wooded areas.

31.61.4.2 Clinical Signs

Animals are often found dead.[512] Signs observed include a sudden onset of moderate to severe dyspnea, wheezing, frothing at the mouth, and an expiratory heave or grunt.[512,513] In less severe cases the cow may pant.[513] Exertion worsens the signs and may precipitate death. Mature cows are most often affected, but deaths have been reported in yearlings and calves.[512] Death occurs in 3 to 7 days in experimental toxicity.[512] Differential diagnoses are as for ABPEE (see earlier discussion), which this condition closely resembles and from which it can be differentiated only by history of exposure.

648

649

31.61.4.3 Pathogenesis

The volatile oils of *P. frutescens* contain a number of 3-substituted furans that are chemically similar to 4-ipomeanol, the moldy sweet potato toxin. One of these, perilla ketone, predominates in the later growing season (when most toxicities occur) and has been shown to be pneumotoxic when given parenterally to mice, hamsters, goats, calves, and sheep.[512] The toxin is absorbed from the rumen, carried to the lungs through the blood, and probably metabolized to the toxic form by the mixed function oxidase system, as for 4-ipomeanol and 3-MI (see earlier). The pathogenesis from this point parallels that of ABPEE or moldy sweet potato toxicity.

31.61.4.4 Epidemiology

P. frutescens seems to thrive in late summer, when pastures in the southeastern United States are frequently dry and dormant.[513] This also corresponds with the more toxic stage of the plant.[512] Cattle normally avoid the plant when other pasture is available but may be forced to consume it during this critical period.[513] However, under experimental conditions calves were noted to prefer the mint.[512] The preseed stage appears to be of relatively low toxicity; the green seed-stage plant is most toxic, especially the seed parts; dried hay from seed-stage plants is less toxic than green plants but is still potentially lethal; and frosted plants appear to have

relatively low toxicity.[512] The exact toxic dose is unknown, but 2.3 kg of green seed-stage plant and 11.2 kg of hay were lethal for cattle in one trial.[512]

31.61.4.5 Necropsy Findings

The lungs are distended (often bearing the impressions of the ribs), fail to collapse, and are moist, heavy, edematous, and emphysematous. There are often bullae, pleural effusions, and froth in the airways. Histologic characteristics are edema, extensive alveolar epithelial hyperplasia, emphysema, and congestion.

31.61.4.6 Diagnosis

Diagnosis is based on history of exposure to perilla mint and characteristic clinical signs and lung pathology. Other diagnostic tests as described for ABPEE could also be attempted in valuable individual animals.

31.61.4.7 Treatment and Control

Treatment has not been investigated. On the basis of the similar pathophysiologic mechanisms, the recommendations for ABPEE should be followed (see earlier discussion). The prognosis for severe cases is grave, regardless of management. Cattle should be provided sufficient forage that they do not seek out perilla mint; once they have begun to eat it, they should be fenced away from stands of the plant, and other forage should be provided.

31.61.5 Other Toxic Plants

Zieria arborescens (stinkwood) leaves cause a fatal ARDS in Tasmanian and Eastern Australian cattle after ingestion of 15 to 30 kg over 2 to 4 weeks. An oil isolated from the leaves has produced the same lung lesion in rabbits. The signs are as for the other ARDS: acute tachypnea, grunting, extension of the head, mouth breathing, abdominal respiration, tachycardia, and fever secondary to the respiratory effort. Death occurs in 1 to 21 days; some animals survive. Lesions include massive pulmonary edema and emphysema.[514] Treatment has not been investigated, and recommendations as for ABPEE (see earlier discussion) are suggested. As mentioned in relation to ABPEE, *Brassica* species (rape, kale, turnip tops) are currently regarded as one of the types of pasture that can precipitate the 3-MI–associated disease. The possibility that other specific toxins may be identified in these species has not been excluded. Morbidity and mortality rates appear to be much higher on *Brassica* species pastures than on other lush forages.[460] The hepatotoxic effects of pyrrolizine alkaloids are well known, but they also cause lung lesions. Lung lesions develop only in animals with chronic liver lesions, and the minimum dose necessary to produce lung lesions is never less than that which is hepatotoxic; therefore signs of liver disease usually predominate. *Crotalaria* and *Trichoderma* species are the most common offenders; to a lesser extent, *Senecio* species are a cause. Horses, sheep, cattle, and pigs have been affected. Pulmonary lesions include edema, congestion, hemorrhage, proliferation of bronchiolar and alveolar epithelial cells with megalocytosis, and interstitial fibrosis and cellular infiltration. As with 3-MI, 4-ipomeanol, and perilla ketone, the toxicity of the pyrrolizine alkaloids depends on activation by the mixed function oxidase system; in this case, however, the toxin is probably formed in the liver and spills over into the blood to reach the lungs. Vascular endothelium is probably the primary target for injury (vs. the Clara cells and type 1 pneumocytes in the other ARDS).[515]

31.61.6 Toxic Gases

Food animals may be exposed to a variety of toxic gases in the environment. The most important are ammonia, hydrogen sulfide, carbon dioxide, and methane from excreta and respiration; these can be especially important when excreta is collected in pits or tanks. Other gases include nitrogen dioxide from silos; carbon monoxide from machinery exhausts and heaters; zinc oxide from welding of galvanized metal in barns; chlorine, formaldehyde, insecticides, and other fumes from agricultural chemicals and cleaners; and smoke from fires. In most cases concentrations usually remain below overtly toxic levels, and effects are very subtle. Such chronic low-level exposure may result in decreased disease resistance and depression of growth rates.[516] Slightly higher levels of chronic exposure may cause clinically vague syndromes of lethargy, mild dyspnea, anorexia, depressed growth, excessive lacrimation and salivation, low incidence of sudden deaths over weeks or months, and stillbirths.[516] Acute, severe outbreaks usually occur in tightly enclosed facilities and are related to accidents, power outages, agitation or pumping of manure pits, or other combinations of unusual circumstances. Such outbreaks are characterized by an ARDS of variable morbidity and frequently a high case fatality rate.

31.61.6.1 NITROGEN DIOXIDE

Nitrogen dioxide (NO_2) is a yellow-orange to brown gas with an acrid odor that is produced by anaerobic fermentation of green plant material. It is a major component of “silo gas.” Acute exposure of farm workers to high concentrations of NO_2 causes a respiratory condition known as “silo-filler's disease,” characterized by severe acute edema and congestion and followed by bronchiolitis obliterans and progressive interstitial pulmonary fibrosis. A similar condition has been induced experimentally in cattle,[517] and apparent (although unproved) spontaneous field cases have been reported.[518,519] Clinical signs in experimental and apparent field cases include cough, tachycardia, tachypnea, respiratory grunting, depression, anorexia, hypogalactia, extension of the head, open-mouth breathing, fever, salivation, lacrimation, and SC emphysema. Auscultation reveals decreased breath sounds and crackles.[518,519] The primary differential diagnoses should include other ARDSs of housed cattle that occur in outbreak form, especially exposure to other toxic gases (manure pit gases, zinc oxide, chlorine, carbon monoxide), and hypersensitivity pneumonitis from moldy hay. Nitrate toxicity should also be considered. Clinical pathologic evaluation is of limited benefit. Leukocyte counts remained normal in experimental cases; methemoglobin levels increased to a peak at 30 minutes after exposure and returned to normal in 12 to 24 hours.[517] The pathophysiologic mechanism probably involves the dissolution of the NO_2 in the water of the respiratory tract to form nitric acid. Nitrates and nitrites are also formed; these are irritating, and the nitrites cause methemoglobinemia.[519] Nitrogen dioxide is also an oxidant itself and may contribute directly to the injury. The disease occurs as an outbreak, usually in housed cattle in proximity to a silo chute in a tight or poorly ventilated barn.[518,519] Nitrogen dioxide is heavier than air and layers on the top of silage or spills out around the bottom of the silo. Corn silage produces more gas than hay, and a high nitrate content increases the danger. The levels are highest in the first 48 hours after filling the silo but may remain dangerous for 2 to 3 weeks.

649

650

Necropsy findings in experimental disease include hyperemia of the upper airways; hemorrhages, fibrinous membranes, and froth in the trachea; distended, noncollapsing lungs with rib imprints; a mottled appearance caused by consolidated lobules alternating with emphysematous lobules; and bullae. Microscopic lesions include alveolar epithelial hyperplasia, large foamy alveolar macrophages, hyaline membranes, hyperemia, hemorrhage, and edema.

Treatment involves the establishment of adequate ventilation; cows should be completely removed from closed buildings if necessary. Corticosteroids have apparently been beneficial in field cases,[518,519] but no controlled studies have been performed. Because of the obvious differences in pathophysiologic characteristics, it would be unwise to extrapolate treatment regimens from those of ABPEE. Suggested empiric therapy might include corticosteroids (dexamethasone at 0.05 to 0.2 mg/kg IM or IV daily), furosemide (0.5 to 1.1 mg/kg IM or IV daily or twice daily), and appropriate antibiotics to prevent secondary bacterial infections.

31.61.6.2

ZINC OXIDE

Zinc oxide (ZnO) fumes have been associated with an ARDS in cattle.[520] Oxyacetylene cutting or arc welding of galvanized pipe results in production of white fumes of zinc oxide containing colloidal particles 0.3 to 0.4 mm in diameter, which can reach the terminal alveoli when inhaled.[520] Construction activities in closed barns containing animals may result in toxicity in animals in close proximity or in the path of ventilation. All ages may be affected.

Clinical signs in severe cases include acute onset of anorexia, frothing at the mouth, anxiety, extension of the head and neck, mouth breathing, expiratory grunting, tachypnea, tachycardia, mild fever, SC emphysema, and crackles on auscultation of the lungs. Death may occur within 12 hours. Less severely affected animals exhibit depression, mild fever, and tachypnea.[520] Differential diagnoses include other ARDS of housed cattle that occur in outbreak form such as exposure to other toxic gases (nitrogen dioxide, manure pit gases) or hypersensitivity pneumonitis. The pathophysiologic process presumably involves direct damage to cells by the ZnO and its products dissolved in the fluid lining the respiratory tract. Necropsy findings include purulent conjunctivitis; SC emphysema; congestion of the airways; tracheal hemorrhages; stiff, noncollapsing lungs; and pulmonary congestion, edema, and emphysema with bullae.[520] Histologic lesions include pulmonary congestion, emphysema, edema, and mixed cellular infiltrates with a prominent eosinophil component. Treatment of severe cases with epinephrine, antihistamine, atropine, and corticosteroids had no effect in one outbreak,[520] whereas mild cases recover spontaneously. Suggested empiric therapy could include ventilation of the area, dexamethasone (0.05 to 0.2 mg/kg IM or IV daily), furosemide (0.5 to 1.1 mg/kg IM or IV daily or twice), and appropriate antibiotics to control secondary bacterial invaders.

31.61.6.3

CHLORINE

Chlorine is a greenish yellow gas widely used in manufacturing. Animal exposure is usually the result of industrial accidents. Exposed animals may be found dead. Signs include depression, profuse nasal discharge, lacrimation, and dyspnea; crackles may be heard on auscultation.[521] The toxic effects are the result of the formation of hydrochloric and hypochlorous acids; the latter breaks down to hydrochloric acid and oxygen, both of which are toxic to tissues. Necropsy findings include congestion of the nasal mucosa, tracheitis, and pulmonary edema, hemorrhage, and emphysema. Histologic lung lesions include edema, emphysema, hemorrhage, atelectasis, hyaline membrane formation, and lymphocytic bronchitis.[521] Treatment is empiric; suggestions include corticosteroids (dexamethasone at 0.05 to 0.2 mg/kg IM or IV daily), furosemide (0.5 to 1.1 mg/kg IM or IV daily to twice daily), and appropriate antibiotics to prevent secondary bacterial infection.

31.61.6.4 MANURE GASES

Manure gases include mixtures of hydrogen sulfide, ammonia, carbon dioxide, methane, and carbon monoxide.[460] Accumulation of these gases can result in asphyxiation of animals in enclosed barns over manure pits.

31.61.6.5 SMOKE INHALATION

Smoke inhalation injury may occur in animals that survive barn fires. Many clinical changes may not become evident for 24 to 48 hours after the fire. It is important to assess the degree of damage as early as possible and to attempt to anticipate sequelae so that early aggressive therapy can be instituted.[522] Common problems for which to check include oral burns, conjunctivitis, and laryngospasm. Hoarseness, expiratory wheezes, and carbonaceous sputum indicate potentially serious sequelae. Crackles and wheezes on auscultation may occur very early or may be delayed for hours. Cough, stridor, and tachypnea may also occur. Bright red mucous membranes may indicate CO poisoning or burns and may mask cyanosis.[522] Carboxyhemoglobin determinations on iced venous blood (often available at human hospitals), serial arterial blood gas determinations, transtracheal wash, and bronchoscopy are useful in delineating the extent of damage and prognosis.[522]

The pathophysiology of smoke inhalation is complex and involves two main mechanisms: CO toxicity and smoke toxicity. CO toxicity results in tissue hypoxia in all organs, especially the brain; O_2 consumption in the fire and the pulmonary effects of smoke may aggravate this hypoxia. Heat damage in animals is usually limited to the upper airways. Smoke toxicity is related to the inhalation of soot, superheated particles, and a variety of noxious gases (e.g., aldehydes, oxides of sulfur and nitrogen, benzene from plastics), which results in the formation of dissolved acids, alkaloids, and other direct irritants in pulmonary fluids. These mechanisms eventually (usually 2 to 24 hours after inhalation) result in alveolar damage, interstitial edema, hypoxia, and secondary bronchopneumonia.[522]

650

651

Treatment involves establishing a patent airway with intubation or tracheostomy if necessary. Oxygen, up to 100% for short periods, is indicated[522]; care must be exercised because 100% oxygen can also cause pulmonary damage. IV fluids should be given, with careful monitoring for pulmonary edema. The use of corticosteroids is controversial.[522] Antibiotics are indicated to prevent secondary bronchopneumonia. Bronchodilators such as aminophylline at 6 to 10 mg/kg IV or PO three times daily may help relieve soot-induced bronchospasm.

31.62 HYPERSENSITIVITY PNEUMONITIS

31.62.1 Definition and Etiology

Hypersensitivity pneumonitis, also known as *extrinsic allergic alveolitis* (EAA) or “bovine farmer's lung,” is an allergic respiratory disease caused by inhalation of organic dusts. Several such conditions are recognized in humans, differing only in the nature of the antigen and the circumstances under which exposure occurs. The classic example, of which the bovine disease is probably the counterpart, is “farmer's lung.” EAA is caused by exposure to the dust from moldy hay, grain, or other plant matter containing spores and products of thermophilic

actinomycetes such as *S. rectivirgula* (formerly *M. faeni*) and *T. vulgaris*.[523,524] Other unidentified forms of hypersensitivity pneumonitis probably occur in cattle.

31.62.2 Clinical Signs

EAA is a disease of confined adult cattle; consequently it is more common in dairy than in beef breeds. Typically a succession of acute cases occurs during the winter housing period, so the clinician is presented with a group problem in which animals are in varying stages of the disease. The acute form is indicative of recent exposure and is characterized by a sudden onset of dullness, decreased appetite, hypogalactia, coughing, expiratory tachypnea, dyspnea, and cranial-ventral crackles on auscultation of the lungs.[523–525] There is a moderate transient fever, which is frequently missed.[524] The chronic form is insidious at onset and may not be detected until there is considerable fibrosis. Animals with the chronic disease may have acute exacerbations as a result of heavy antigen exposure; some may not be detected until turned out in the spring, when increased exercise causes an acute crisis. There is a history of weight loss and coughing for several winters, with remission in the grazing season. Chronic signs include hypogalactia, weight loss, productive coughing, tachypnea, obvious hyperpnea, and widespread crackles and wheezes on auscultation of the lungs, especially in the rostral-ventral areas.[524] Differential diagnoses should include respiratory diseases affecting groups of housed adult cattle in winter. Infectious diseases (viral and bacterial pneumonias) can usually be differentiated from farmer's lung by careful evaluation of factors such as clinical signs of fever and pulmonary consolidation. Therefore the main differential diagnoses are the toxic gases. It should be emphasized that hypersensitivity pneumonitis is not considered an ARDS and that no evidence exists for the involvement of hypersensitivity in the pathogenesis of the ARDS described previously. However, severe cases of EAA with prominent dyspnea and moderate, nonfatal cases of gas intoxication may appear clinically similar. If the group outbreak aspect of EAA is ignored, the clinician who examines one individual may be unable to distinguish this condition from fibrosing alveolitis.

31.62.3 Pathogenesis

The spores of the thermophilic actinomycetes are 0.7 to 1.3 mm in diameter and can easily reach the alveoli, where they induce both humoral (precipitating) and cellular immune responses. It is thought that repeated exposure results in the activation of a number of immunologically specific and nonspecific cellular and humoral effector mechanisms at the alveolar level, which results in tissue damage.[523,524]

31.62.4 Epidemiology

EAA is a problem in areas with wet summers and severe winters, a situation characterized by the combination of moldy hay and housing of cattle in winter. In North America, EAA occurs primarily in the Great Lakes region of the United States and the eastern provinces of Canada.[525] Baling and stacking of hay with a high moisture content (over 30%) results in overheating of the stacks. Thermophilic molds become dominant and produce billions of spores, which are released when the hay is distributed for feeding. A similar situation can occur in stored grains. Affected hay is usually dry, friable, discolored, and dusty; however, it is not necessary for hay to be grossly dusty and poor in quality to release large numbers of spores.[524]

31.62.5 Necropsy Findings

In acute cases the lungs are superficially grossly normal. Closer inspection reveals small gray spots in many lobules, which represent interstitial and peribronchiolar accumulations of lymphocytes. Other lobules exhibit dark red centers of atelectasis surrounded by pale pink raised edges of trapped air that are caused by narrowing of airways with lymphocytic infiltrates. Histologic evaluation confirms the presence of these lymphocytic infiltrates and aggregations, as well as epithelial granulomas, bronchiolitis, and bronchiolitis obliterans. The gross appearance in chronic cases is similar, with the addition of focal areas of interalveolar fibrosis and epithelial hyperplasia; epithelioid granulomas are absent unless a recent acute exposure has occurred.[523,524]

31.62.6 Diagnosis

Precipitating antibodies to *M. faeni* are found in the serum in most cases.[523,524] However, two precautions are necessary. First, the presence of precipitating antibodies only indicates exposure to the antigen; many normal animals also have antibodies. Second, it is possible that other as yet unidentified antigens may cause allergic respiratory disease in cattle. The presence or absence of titers is therefore not necessarily diagnostic of the clinical status of the animal, and the magnitude of the titer does not reflect the extent of disease.[460]

31.62.7 Treatment and Prevention

Treatment and control center around removal of the offending antigen, which is frequently difficult from an economic and management standpoint. Corticosteroids (dexamethasone at 0.05 to 0.2 mg/kg IV or IM daily) may be beneficial in acute cases. Suggestions to decrease the molding of hay or degree of exposure include making silage instead of hay, ensuring proper drying before baling, and feeding hay outside. If the condition can be arrested before significant fibrosis occurs, the prognosis is good.

651

652

31.62.7.1 Anaphylaxis

In ruminants the lung is the major target organ in immediate (type I) hypersensitivity reactions. Precipitating antigens include vaccines, drugs, blood, *Hypoderma bovis* or *Hypoderma lineatum* larvae, insect bites, and bee stings. Signs of anaphylaxis usually develop in 10 to 20 minutes and include severe acute dyspnea, with flaring of the nostrils, extension of the head and neck, open-mouth breathing, frothing of the mouth, hyperpnea, and abduction of the elbows. Pharyngeal and laryngeal edema cause stertor and inspiratory dyspnea. Urticaria may occur in some cases, such as milk allergy in Jersey cows. Shivering, salivation, lacrimation, pruritus, diarrhea, fever, edema (eyes, muzzle, anus, and vulva), collapse, nystagmus, cyanosis, and discharge of froth from the nostrils also may occur. On auscultation there are harsh breath sounds, large airway sounds, and crackles. The primary differential diagnosis is peracute interstitial pneumonia. The pathogenesis involves an initial exposure to the antigen, which results in a genetically determined production of homocytotropic antibodies. In humans and dogs, this is immunoglobulin E (IgE); in ruminants various classes may be involved.[526] This antibody attaches to receptors on mast cells and basophils. On subsequent exposure to the antigen, bridging of the Fab parts of the antibody on these cells results in degranulation, with release of a variety of mediators such as histamine, bradykinin, 5-hydroxytryptamine, serotonin, slow-reacting substance-anaphylaxis (SRS-A), eosinophil chemotactic factor A, platelet activating factor, kinins, and prostaglandins.[526–528] These mediators result in a cascade of vascular events, notably increased vascular permeability, which in turn results in acute severe edema. Pulmonary venous constriction, pulmonary artery

hypertension, splanchnic pooling, increased mucus secretion, and bronchospasm also occur. Ruminants that die of anaphylaxis have severe pulmonary congestion and edema, laryngeal edema, and froth in the airways. Lung lesions of ARDS may be present.

The treatment of choice is epinephrine, 4 to 8 mg (4 to 8 mL of 1:1000 solution) IV or SC or 1 to 5 mg IV for an average 500-kg cow and 1 to 3 mg IV or SC for an average adult sheep or goat. Epinephrine has a short half-life, and animals should be observed closely for relapse. Ancillary therapy includes corticosteroids (dexamethasone, 0.1 mg/kg IM or IV; prednisolone, 2.2 mg/kg IM or IV daily). Other supportive therapies include shock doses of IV fluids (40 mL/kg/hr); aminophylline; diuretics such as furosemide; oxygen therapy; and tracheostomy if necessary.

31.63 MISCELLANEOUS CHRONIC PNEUMONIAS

At least two chronic interstitial pneumonias of uncertain cause have been identified in cattle: fibrosing alveolitis and bronchiolitis obliterans. These are typically chronic diseases of individual animals.

31.63.1 Fibrosing Alveolitis

Fibrosing alveolitis is, by definition, a chronic disease of unknown and possibly multiple causes, characterized by diffuse inflammation of the lung beyond the terminal bronchiole. Approximately 50% of cases produce positive results for precipitating antibody to *M. faeni*, and it is possible that these cases represent chronic farmer's lung whereas others (that have negative *M. faeni* results) may be the chronic stage of hypersensitivity to other unidentified antigens.[460] Field investigations have failed to substantiate any connection between fibrosing alveolitis and repeated episodes of ARDS such as ABPEE. Furthermore, recovery from a single dose of 3-MI does not result in lesions typical of fibrosing alveolitis. However, repeated doses of 3-MI at weekly intervals experimentally cause fibrosing alveolitis—like lesions.[460] Fibrosing alveolitis occurs in individual adult cattle (usually over 6 years of age) in both housing and pasture conditions. The history is usually that of a chronic progressive respiratory disease several weeks to 2 years in duration. Affected cattle remain bright and alert and continue to eat until the terminal stages of cor pulmonale and heart failure intervene. Signs include marked weight loss; consistent coughing; tachypnea (40 to 70 breaths/min); very marked hyperpnea, even at rest; and dyspnea after mild exertion. Auscultation may reveal crackles in the rostral-ventral lung field and widespread wheezes. Fever is not apparent. The primary differential diagnoses to consider are other chronic respiratory conditions of individual adult cattle. Chronic suppurative pneumonia and metastatic pneumonia can usually be differentiated from fibrosing alveolitis by careful physical examination and detection of depression, anorexia, shallow respiration, thoracic pain, and hemoptysis. ARDS caused by feed-associated pneumotoxins and lungworms are typically group problems, with at least some severe cases in the group. Differentiation from EAA may be impossible if the group outbreak nature of farmer's lung is not apparent; in fact, at least some cases of fibrosing alveolitis may represent chronic farmer's lung. At necropsy the lungs are very pale, firm, and heavy throughout. Scattered lobules are gray-red, slightly collapsed, and edematous. Thick mucus may be found in the airways, and there is frequently right ventricular hypertrophy as a result of cor pulmonale. Histologic changes are diffuse and include interalveolar fibrosis and infiltration with plasma cells, lymphocytes, mast cells, and interstitial cells; obliteration of alveolar spaces; mononuclear exudates in alveoli; alveolar epithelial hyperplasia; bronchitis; and bronchiolitis. The epithelioid granulomas characteristic of acute farmer's lung are absent.[460] No treatment exists, and the lesions are irreversible.

31.63.2 Bronchiolitis Obliterans

Bronchiolitis obliterans is a chronic respiratory condition of yearling or young adult cattle characterized by a deep infrequent cough, tachypnea, hyperpnea, and an exaggerated expiratory effort. There is no fever. The cause is unknown; the condition is speculated to be a sequela to viruses (RSV, PI3, IBR), parasites such as *Dictyocaulus viviparus*, or hypersensitivity pneumonitis. The lungs appear grossly normal at necropsy, except that they do not collapse. Histologic examination reveals extensive bronchiolitis and bronchiolitis obliterans, with epithelium-covered polyps with a connective tissue core projecting into and obstructing the lumen.[460]

31.64 PARASITIC BRONCHITIS AND PNEUMONIA

ANNE M. ZAJAC

Two parasites in cattle (*D. viviparus* and aberrant migration of *Ascaris suum* larvae) and three in sheep and goats *(Dictyocaulus filaria, Protostrongylus rufescens*, and *Muellerius capillaris)* may cause respiratory disease characterized by alveolar and interstitial pneumonia. Other species of lungworms also parasitize small ruminants but are less widely distributed throughout the world.

652

653

31.64.1 Lungworms of Cattle

31.64.1.1 Dictyocaulus Viviparus

31.64.1.1.1 Definition and Etiology

D. viviparus is a trichostrongylid nematode parasitizing the bovine trachea and bronchi. Adult worms may reach 8 cm in length. The lifecycle of *D. viviparus* is direct. Adult female worms in the trachea and bronchi lay eggs that hatch almost immediately. First-stage larvae are coughed up, swallowed, and passed in the feces. Larvae develop in a minimum of 5 days (usually longer under normal environmental conditions) to the infective third stage, migrate onto grass, are ingested, penetrate the intestine, and move to the mesenteric lymph nodes, where they molt. Fourth-stage larvae travel through lymph and blood to the lungs and tend to lodge in the pulmonary capillaries of the ventral parts of the caudal lobes. Approximately 7 days after ingestion, they enter the alveoli and molt to the fifth (final) stage in the bronchioles several days later. Egg-laying adults are present in the bronchi 21 to 28 days after ingestion of larvae. Clinically evident infection with *D. viviparus* typically occurs in young, nonimmune stock (less than 12 months old) or in previously unexposed yearling or adult cattle. A reinfection syndrome can also occur when previously infected (and therefore immune) adults are subjected to massive challenge with infective larvae.[529,530]

31.64.1.1.2 Clinical Signs and Differential Diagnosis

Primary infection with *D. viviparus* can be broken down clinically into a prepatent phase, a patent phase, and a postpatent phase.[531] No signs are associated with the initial penetration of larvae until they reach the alveoli, where they provoke an eosinophilic exudate that blocks small airways. During the prepatent phase (approximately 7 to 25 days after ingestion), there is a gradual onset of coughing and tachypnea (35 to 60 breaths/min), which becomes increasingly apparent from day 14 to day 25. The severity of signs in this

stage is proportional to the number of larvae ingested, the rate of ingestion, and the proportion reaching the lungs. Severe illness and death can occur in cases of heavy infection. In the patent phase (approximately 25 to 55 days after ingestion), a parasitic pneumonia with consolidation develops in the ventral areas of the caudal lung lobes as a result of aspiration of eggs and larvae into these areas. Tracheitis and bronchitis associated with the adult worms also develop. Clinical signs vary in severity and range from intermittent to marked coughing, tachypnea (respiratory rate may increase to more than 70 breaths/min), dyspnea, anorexia, and weight loss. Fever may develop with secondary bacterial infection. Auscultation reveals harsh breath sounds and widespread crackles and wheezes. In severe cases animals may exhibit open-mouth breathing, extended head and neck, protrusion of the tongue, and an expiratory grunt. Death is common in untreated, heavily infected animals.[530,531]

Recovery begins in the late patent phase, and the signs gradually resolve, sometimes over several months. During the postpatent phase (about days 55 to 90), adult parasites are expelled by a self-cure phenomenon. In approximately 25% of severe cases the postpatent phase is characterized by a sudden exacerbation of dyspnea at days 45 to 60 that is often fatal, after secondary bacterial infection or alveolar epithelialization.[529,531] The reinfection syndrome occurs 14 to 16 days after adult cattle are placed on heavily contaminated pastures. Signs include acute hypogalactia; severe, frequent coughing; marked tachypnea; and depression. Auscultation reveals only harsh breath sounds with no crackles or wheezes.[529,531]

Differential diagnosis should be straightforward if both the clinical signs and epidemiologic characteristics of the disease are taken into account, especially in endemic areas. This is a disease of groups of cattle at pasture, typically in late summer or fall in northern temperate climates; the situation thus resembles ABPEE, which differs in clinical signs (i.e., less coughing and fewer adventitious lung sounds). The signs associated with lungworm infection are reminiscent of those of farmer's lung, which occurs in quite different circumstances. In typically nonendemic areas, outbreaks associated with climatic changes are frequently mistaken for acute bacterial bronchopneumonia.[529]

31.64.1.1.3

Diagnosis

Larvae of *D. viviparus* are large (390 to 450 µm × 25 µm) and slow moving and contain dark food granules. They are best detected by the Baermann test[532] and may also be seen on a transtracheal wash. It is best to check several animals in the herd. Rectal fecal samples are preferred for parasite examination because samples picked up off the ground may contain free-living nematodes that can be difficult to differentiate from lungworm larvae. Recovery of larvae from fecal samples is substantially diminished if the sample is stored at room temperature for more than a few hours. If the Baermann test cannot be set up soon after fecal collection, the sample can be safely refrigerated for 24 to 48 hours without serious larval loss.[533] No larvae are detected in the reinfection syndrome. In some European countries an ELISA technique that can detect adult infection is also available[534] (Cypress Diagnostics, Langdorp, Belgium). An increase in eosinophils in the peripheral blood may also occur approximately 2 weeks after infection, peaking at 4 to 7 weeks after infection.[535]

31.64.1.1.4

Pathophysiology

Once the fourth-stage larvae enter the alveoli, they incite an eosinophilic exudate that blocks small bronchi and bronchioles, resulting in atelectasis and causing the cough and tachypnea of the prepatent phase. As these larvae mature and migrate up the airways, these lesions may resolve. However, the adult worms

produce an inflammatory response in the larger airways, and aspirated eggs and larvae cause a marked macrophage and giant cell response, with consolidation of the ventral caudal lobes; these lesions are the cause of the signs in the patent phase. At any point in the pathogenesis (prepatent, patent, or postpatent stage), complications may occur that account for acute exacerbation and death. These complications are as follows:

- Development of pulmonary edema caused either by heart failure or by extensive alveolar epithelial damage and hyaline membrane formation
- Severe interstitial emphysema from the severe dyspnea
- Alveolar epithelial hyperplasia
- Secondary bacterial infection, which is actually relatively uncommon

In the reinfection syndrome the immune response cannot completely overcome a massive challenge, and a small number of larvae reach the lungs. The signs are caused by the immune reaction to the migrating larvae. Lymphoid nodules develop around dead larvae in the bronchioles.[529–531]

31.64.1.1.5

Epidemiology

Parasitic bronchitis and pneumonia in cattle occur most often in temperate areas with high rainfall or intense irrigation. In the United States, lungworm infection is widely distributed, but disease outbreaks are uncommon, probably because periods of dry summer weather limit larval survival and accumulation on pasture.[530] In the southern United States, lungworm transmission is probably greatest in the cool winter months,[536] whereas autumn is probably the season of most intense transmission in the northern United States.[537,538]

653

654

Dictyocaulus infections have been studied extensively in Europe, where the parasite is an important pathogen. Disease outbreaks occur most frequently in first season grazing animals. If large numbers of larvae are present on pasture at spring turnout of calves, disease may develop at that time. Often, however, levels of pasture larvae are too low to cause disease, but lead to low-level primary infections in calves that result in the accumulation of additional larvae on pasture. This second wave of infection may lead to clinical lungworm disease when the primary infection did not produce adequate levels of immunity. If infection levels remain low, disease may not be observed until a third generation of parasites occurs. Immunity develops beginning about 10 days after heavy infection, and patent infections usually persist for only a few months. In the absence of continued exposure to parasites, immunity to reinfection will begin to decline after several months.[530,539]

Older animals without immunity also develop lungworm disease when exposed to high levels of pasture contamination with larvae. This can occur when animals from a nonendemic area are moved to an endemic area. In recent years outbreaks of primary parasitic bronchitis have become an important cause of respiratory disease in adult dairy cows in Europe. The increased prevalence of disease in this older age-group is likely the result of decreased levels of immunity after the widespread use of powerful suppressive anthelmintic regimens in first and second season grazing animals. Other management factors, such as isolation of calves from adult carrier animals and increased movement of livestock, may also contribute to a decline in levels of immunity.[534,540] Beef animals are less often affected than dairy cattle because

management practices are more extensive and levels of infective larvae on pastures are generally lower.[530] The reinfection syndrome occurs in immune adult animals when, for example, immune cows are placed on a pasture previously contaminated very heavily by calves with patent disease.[529,530]

In northern temperate climates, the infection is carried from year to year by overwintering of larvae on pasture in some areas, by spreading of manure from infected housed calves in the spring, and by carrier cattle. Lungworm larvae also may be inhibited in the lungs of calves in winter (as with *Ostertagia* species in the abomasum) and mature in the spring.[529,531]

31.64.1.1.6

Necropsy Findings

In the prepatent phase the lungs are largely normal, with a few atelectatic lobules in the ventral caudal lobes; adult worms are not present until late in this phase, but larvae may be detectable by microscopic examination of smears of bronchial exudate. In the patent phase there is usually bilaterally symmetric red consolidation of the ventral caudal lobes. Adult worms can be recognized on necropsy by their relatively large size and location in the trachea and bronchi. The lesions of the postpatent phase are similar, but no adult worms or larvae are present. In those patients that die of an acute exacerbation, there is extensive pulmonary edema and emphysema, with hyaline membranes and alveolar epithelial hyperplasia.

Table 31-12 Anthelmintics Approved for Treatment of *Dictyocaulus viviparus* in the United States

Anthelmintic	Formulation	Residual Efficacy of a Single Treatment	Approved for Dairy Cattle of Breeding Age
Levamisole	Drench, bolus, injection		
Fenbendazole	Paste, suspension, medicated feed, mineral		+
Oxfendazole	Suspension		
Albendazole	Paste, suspension		
Ivermectin	Injection, pour-on	28 days	
Eprinomectin	Pour-on	28 days	+
Doramectin	Injection, pour-on	Injection: 28 days Pour-on: 21 days	
Moxidectin	Pour-on, injection	42 days	+ Pour-on only

In the reinfection syndrome the pulmonary lymphoid nodules may be 3 to 4 mm in diameter and thus grossly visible as raised, gray-red to greenish yellow nodules under the pleura. Initially these are composed of a core of eosinophilic parasitic debris surrounded by macrophages, multinucleated giant cells, hyperplastic bronchiolar epithelium, eosinophils, and plasma cells. The lesions eventually mature to lymphoreticular nodules with a germinal center. There is also greenish mucus in the airways and a greenish discoloration to the tissues, both caused by eosinophil infiltration. There is no edema or emphysema, and the rare lungworms that may be found are small and stunted.[529]

31.64.1.1.7

Treatment, Prognosis, Prevention, and Control

D. viviparus infection can be treated with a number of bovine anthelmintics available in the United States and other countries (Table 31-12). Macrocyclic lactone products also have residual efficacy against *D. viviparus*.[541] Animals with only cough and tachypnea respond well, whereas those with dyspnea, fever, anorexia, and depression have a more guarded prognosis; some of these can be expected to die or remain chronically unthrifty.[529] Control (see also Chapter 49) involves appropriate pasture management and the strategic use of anthelmintics to prevent buildup of infection in the herd and on pastures. Several strategic deworming programs have been developed in Europe, which effectively suppress lungworm infection throughout the grazing season. These programs include use of ivermectin at 3, 8, and 13 weeks after turnout and use of doramectin or eprinomectin at 0 and 8 weeks. Use of an oxfendazole pulse release bolus (not available in the United States) also provides strategic treatments. Alternatively, use of a continuous-release ivermectin or fenbendazole bolus (not available in the United States) will prevent development of lungworm infection during its period of efficacy.[540] A long-acting moxidectin injection product that provides protection from lungworm infection for 120 days is also now available in some countries.[542] Anthelmintic treatment with moxidectin or fenbendazole followed by movement of calves to safe pasture 9 weeks after turnout was also effective in controlling lungworm.[543] None of these control programs have been extensively tested under the variety of grazing conditions found in the United States.

654

655

Despite concern that suppressive programs may limit exposure to larvae and interfere with the development of immunity to lungworm, several studies conducted in Europe have shown that stimulation of the immune response still occurs, although relative levels of immunity may vary with different management systems and annual variation in the intensity of lungworm challenge.[534,544–546] In Europe, methods of control also include an effective irradiated larval vaccine, although use of the vaccine has diminished with the introduction of suppressive anthelmintic programs. Delay of spring turnout is an adjunct to control but should not be relied on as the sole means of control.[545] A targeted selective deworming program was successful in controlling lungworm infection in a dairy herd in Sweden. Only cattle testing positive for lungworm by the commercial ELISA test were treated at each sampling date.[547]

31.64.1.1.7.1

ASCARIS SUUM

Cattle exposed to large numbers of *A. suum* eggs in areas contaminated by swine may have an interstitial pneumonia. Animals are typically affected approximately 10 days after exposure. Signs include depression, anorexia, fever, tachycardia, tachypnea, dyspnea with an expiratory grunt, variable coughing, ruminal stasis, and bloat. Auscultation of the lungs reveals increased breath sounds without adventitious sounds. Some deaths may occur. Differential diagnosis is difficult. Differentiation from the other interstitial pneumonias depends more on history of exposure to the causative agents (e.g., lush pastures, moldy sweet potatoes, *P. frutescens*, toxic gases, moldy hay). Differentiation from viral pneumonia (such as that caused by RSV) and *D. viviparus* reinfection syndrome requires necropsy and demonstration of larvae. Ascarid larvae have characteristic lateral alae in histologic sections. Patent *D. viviparus* infection can be differentiated by Baermann examination of the feces. In fatal cases the lung lobes are firm and mottled blue, red, and gray. The cut surface oozes thin yellow exudate. There is emphysema in the dorsal diaphragmatic lobes and subpleural hemorrhage with neutrophil infiltration and necrosis of bronchiolar and alveolar epithelium. In chronic cases the cellular infiltrate is lymphocytic, and there are proliferation of bronchiolar epithelium and peribronchial fibrosis. Recommended treatments include corticosteroids

(dexamethasone, 0.04 mg/kg IM or IV, or prednisolone 1 mg/kg IM or IV daily) and antibiotics to control secondary bacterial infection.[548] Clinical signs resolved after treatment with oxfendazole in one outbreak of suspected *A. suum* migration.[549] Cattle should not be exposed to areas heavily contaminated by swine.

31.64.1.2

Lungworms of Sheep and Goats

Three species of lungworms are of primary importance in sheep and goats: *D. filaria* and the two metastrongylid nematodes, *M. capillaris* and *P. rufescens*. Other genera of metastrongylid lungworms of minor pathogenic importance in sheep and goats include *Cystocaulus, Spiculocaulus*, and *Neostrongylus*. These parasites are rare or absent in North America.[550]

31.64.1.2.1

DICTYOCAULUS FILARIA

D. filaria has a lifecycle essentially identical to that of *D. viviparus;* the time from ingestion to the appearance of larvae in the feces is about 4 weeks. Mainly young animals are affected, but disease can also occur in adults. Dyspnea, tachypnea and coughing, and loss of condition occur in clinical cases.[550,551] Differential diagnosis includes the progressive viral pneumonias. Diagnosis is made by finding larvae in fresh feces by the Baermann test.[532] Samples should be tested soon after collection because larval recovery is significantly reduced in stored samples.[533] Larvae of *D. filaria* are similar in size and appearance to those of *D. viviparus* but also have a distinctive knob on the anterior end. The pathogenesis is similar to that of *D. viviparus* (see earlier discussion). The adults are found largely in the dorsal-caudal regions of the diaphragmatic lobes. Bronchitis and peribronchitis, along with cone-shaped areas of pneumonia and atelectasis, and emphysema are present. Secondary bacterial infections may also occur.[550,551] Levamisole (8 mg/kg), fenbendazole (5 to 10 mg/kg), ivermectin (0.2 mg/kg PO),[551] and moxidectin (0.2 mg/kg, PO or SC)[552–554] can be used for treatment. When outbreaks occur, all animals should be treated and moved to fresh pasture when possible. Clinical *D. filaria* infections seem to occur most frequently in areas with warm climates. In temperate areas the parasite overwinters either as arrested larvae in ewes or as larvae on pasture.[550]

31.64.1.2.2

MUELLERIUS CAPILLARIS

M. capillaris is probably the most common of the lungworms of sheep and goats. Infection is more pathogenic in goats than in sheep. Surveys in Maryland and Georgia detected the parasite in 64% and 68% of goats, respectively.[555,556] The lifecycle is indirect. First-stage larvae are coughed up, swallowed, and passed in the feces. These larvae are relatively resistant and may survive for several months in the environment. After penetration of an appropriate molluscan intermediate host, the infective third stage develops in a minimum of about 12 days, is ingested with the snail, and passes to the mesenteric lymph nodes. The fourth stage larva proceeds to the lungs, where adults develop in the alveoli. The prepatent period of *M. capillaris* infection is about 6 weeks.[557] Although many infections are subclinical, clinical disease may develop. Goats appear to be more likely than sheep to develop unthriftiness, coughing, and dyspnea. Infection may also predispose to secondary bacterial infection.[551,558] The difference in clinical signs between sheep and goats probably results from a difference in the pathogenesis of infection. The adult worms live in the pulmonary parenchyma, particularly the subpleural tissue. In sheep they produce grayish nodules typically 2 to 3 mm in diameter. On palpation at necropsy, these nodules have been described as

feeling like "lead shot."[557] Each nodule contains a worm and necrotic leukocytes and pulmonary tissue surrounded by a connective tissue wall and giant cells.[550] They may calcify or become secondarily infected with bacteria. Reports of lesions in goats indicate that *M. capillaris* causes an interstitial pneumonia. The lungs are resilient and firm, fail to collapse, and have tan, yellow, or gray patches located especially in the dorsal diaphragmatic lobes. The histologic lesion in goats is a diffuse thickening of alveolar septa, with a mononuclear cell infiltrate and alveolar epithelial hyperplasia that extends far beyond the area immediately around the parasite. The local reaction around the worm is quite variable and does not appear to produce the nodules seen in sheep.[558] Diagnosis is made by Baermann examination of the feces. The larvae are smaller than those of *D. filaria* and have a kink at the end of the tail with a characteristic subterminal accessory spine.[532]

Several anthelmintics have been used in the treatment of *M. capillaris* infections. Moxidectin (0.2 mg/kg in oral or injectable formulation) is effective in treating sheep infected with *M. capillaris* and other small lungworms *(Cystocaulus ocreatus, Neostrongylus linearis*, and *P. rufescens)* and may be equally effective in goats.[559] Although larvae may initially disappear in the feces after treatment, they often reappear in fecal samples again after 1 to 2 months, either because anthelmintics are ineffective against immature worms and/or because of resumption of development by inhibited larvae.[559] Treatments that appear to eliminate adult parasites in goats include fenbendazole (15 to 30 mg/kg),[557,558,560–562] albendazole (10 mg/kg),[562] oxfendazole (7.5 to 10 mg/kg),[563] and ivermectin (0.3 mg/kg).[560,564] *M. capillaris* is largely resistant to levamisole.[551] Better control of immature or inhibited larvae with fenbendazole was achieved by administering the drug (1.25 to 5 mg/kg) for 7 to 14 days, although a regimen of 1 week on/1 week off/1 week on appeared to provide the most effective treatment. Albendazole (1 mg/kg) PO daily for 7 to 14 days was also effective.[562] Possible teratogenic effects of extended benzimidazole treatment in goats have not been thoroughly investigated, and albendazole should be used cautiously in the first 35 days of pregnancy.[560] Administration of ivermectin (0.3 mg/kg) or fenbendazole (15 mg/kg) two or three times at 35-day intervals has also been suggested for treatment.[551] Control methods include avoiding wet pastures and treating animals before the start of the grazing season to reduce infection levels in the intermediate host.[551]

655

656

31.64.1.2.3

PROTOSTRONGYLUS RUFESCENS

P. rufescens also uses molluscan intermediate hosts, and adults develop in the small bronchioles of sheep and goats.[557] Most infections are probably subclinical or produce only mild signs of chronic bronchitis or bronchopneumonia with nasal discharge and cough. Occasionally *P. rufescens* may produce severe or even fatal disease.[565] The diagnosis of *Protostrongylus* species infection is made by finding larvae in the feces with the Baermann technique. The larvae are similar to those of *Muellerius* except *Protostrongylus* larvae lack the subterminal accessory spine on the tail.[532] Fenbendazole, levamisole,[565] and moxidectin[559] can be used for treatment at the dosages used for *Dictyocaulus*. Other macrocyclic lactone products may also be effective but have not been tested. Control strategies are identical to those for *M. capillaris*. Few cases of infection have been reported in the United States, but nonspecific clinical signs, presence of subclinical carriers, and need for a special diagnostic technique may produce an underestimation of the prevalence of *P. rufescens* infection in sheep and goats.[565]

31.65 PROGRESSIVE BACTERIAL AND VIRAL PNEUMONIAS OF SHEEP AND GOATS

JEANNE LOFSTEDT

Chronic progressive pneumonias are diagnosed with some frequency in mature small ruminants. In sheep, OPP and *C. pseudotuberculosis*–induced mediastinal lymph node and lung abscesses are the chief causes of chronic progressive pneumonia. Chronic progressive pneumonia in goats is commonly associated with the pneumonic form of CLA, and less frequently with CAE virus (CAEV)–induced lung lesions. Differential diagnoses that should be entertained in sheep and goats exhibiting signs of chronic pneumonia include OPA, chronic suppurative pneumonia, verminous pneumonia, mycotic pneumonia, tuberculosis, and pulmonary neoplasia.

31.66 OVINE PROGRESSIVE PNEUMONIA (MAEDI-VISNA)

31.66.1 Definition and Etiology

OPP and maedi-visna (MV) are North American and European names for slow viral diseases of sheep characterized by chronic, progressive, debilitating pneumonia, wasting, and indurative mastitis.[566–568] Synonyms are Marsh's progressive pneumonia, zwoegerziekte, la bouhite, and Graaff-Reinet disease.[566,567] The OPP virus (OPPV) and MV virus (MVV) are nononcogenic exogenous retroviruses that belong to the subfamily Lentiviridae.[569] These enveloped, single-stranded RNA viruses contain the enzyme RNA-dependent DNA polymerase (RT). With this enzyme they use cellular machinery to transcribe a segment of DNA from a template of single-stranded viral RNA; the DNA strand or provirus is then incorporated into the host genome. Close similarity of causal viruses, clinical signs, and lesions produced in tissues permits discussion of OPP and MV as a single disease entity.[567] The ovine lentiviruses (OvLVs) are also related to the CAEV of goats, but differences have been demonstrated through nucleic acid hybridization studies.[570]

31.66.2 Clinical Signs and Differential Diagnosis

Conditions in sheep attributed to infection with OvLV include progressive emaciation (“thin ewe syndrome”), progressive respiratory failure, indurative lymphocytic mastitis (“hard bag”), posterior paresis, chronic nonsuppurative arthritis, and vasculitis.[566–571] In North America progressive pneumonia and aseptic mastitis are the most common clinical manifestations.[567] Natural disease is usually observed in 2- to 3-year-old sheep, but adult sheep of any age can be affected.[567,568,570] Emaciation despite a good appetite is one of the earliest symptoms. Clinical signs of progressive pneumonia include exercise intolerance, tachypnea, expiratory dyspnea, open-mouth breathing, and occasionally a nonproductive cough. Thoracic auscultation reveals increased breath sounds, but crackles and wheezes are inapparent. Pyrexia and purulent nasal discharge usually indicate the presence of secondary bacterial pneumonia. Affected ewes give birth to small, weak lambs. Death from anoxia or secondary bacterial infection occurs within 6 to 12 months of first appearance of signs.

Chronic pneumonias of sheep that have to be differentiated from OPP include chronic bronchopneumonia caused by *M. (Pasteurella) haemolytica*, OPA, verminous pneumonia, and pulmonary and lymph node abscesses caused by *C. pseudotuberculosis*.[566,569] Thoracic radiographs, culture of tracheal wash material, and fecal examination by the Baermann technique are useful for antemortem differentiation. Gross and histopathologic evaluations of pulmonary tissues obtained at necropsy are useful for diagnosis of a flock problem.

31.66.3 Diagnosis

Hematologic changes in sheep with OPP are nonspecific and may include lymphocytosis early in the course of disease and mild hypochromic anemia and hypergammaglobulinemia in advanced disease.[570] A presumptive diagnosis of OPP can be made on the basis of clinical signs, lack of response to treatment, and serologic test results. Currently available serologic tests are run by different laboratories using different techniques, making comparisons difficult. The serologic tests commonly used to detect antibodies to OvLV in serum are the AGID test and ELISAs.[566–568] The simplicity and low cost of the AGID test makes it the test of choice for eradication programs.[566,572] Several authors have suggested that ELISA tests are more sensitive than the AGID test.[566,572,573] However, in a study comparing the AGID test with 2 recombinant ELISA tests the AGID test was found to have a specificity of 100% and a sensitivity of 11% 2 weeks postinfection, and 100% 5 weeks postinfection.[566] In comparison, ELISA tests directed against the OvLV core protein or the OvLV transmembrane protein had mean sensitivities of 88% and 86%, respectively, and mean specificities of 95%.[566] ELISA tests may produce false-negative results in recently infected animals as they detect IgG rather than IgM. 656
[566] Virus isolation can be used to definitively identify OvLV-infected animals.[566,569] Virus isolation, which is 657
time-consuming and expensive, is accomplished by coculture of infected fresh or frozen tissue with indicator cell lines. In culture, retroviruses form characteristic multinucleated syncytia.[570] Viral antigens can be detected in these syncytia by use of immunofluorescent staining.[570] PCR testing has been used as a research tool to demonstrate OvLV DNA in clinical specimens from naturally infected sheep.[574]

31.66.4 Pathophysiology

OvLVs are thought to gain access to the body via the oral or respiratory route. Infection is then established in the monocyte or macrophage cell line and spreads via these infected cells to the lungs, lymph nodes, choroid plexus, spleen, bone marrow, mammary glands, and kidneys.[570] The virus is able to persist in the face of humoral and cellular immunity through (1) latent infection of host cells by DNA provirus, (2) long-term nonproductive infection of blood monocytes (virus replicates only on differentiation of monocytes into macrophages), and (3) virus mutation with emergence of new antigenic variants that are not neutralized by preexisting antibody.[570]

31.66.5 Epidemiology

The seroprevalence of OPP in cull ewes in the United States ranges widely and increases with advancing age.[566] With the exception of West Texas, with an infection rate of 0.5%, serologic surveys in cull ewes in other states have revealed infection rates of 30% to 67%. The low seroprevalence in Texas has been attributed to the hot dry climate and extensive grazing practices.[570] Limited studies in large mixed-breed flocks have provided evidence that some sheep breeds may be more resistant to infection than other breeds.[566] Additional research is required before a particular breed or line of sheep can be viewed as resistant to OvLV infection. The lung and mammary gland are believed to be the main sources of excreted virus.[566] Studies conducted in Europe and Iceland have shown that transmission from the ewe to her lambs commonly occurs through the ingestion of infected colostrum and milk.[566] In other studies, close confinement of diseased or seropositive sheep with healthy or seronegative sheep resulted in disease or seroconversion in the previously healthy or seronegative animals; these infections were presumed to have occurred via the respiratory route.[566] OvLV transmission has been shown to occur

through fecal contamination of drinking water.[566] It is likely that other fomites (saliva, nasal discharge, urine) contaminating feed and/or water also contribute to the spread of disease.[507] Transmission through the uterine wall, or via germ cells, can occur but is rare.[566]

31.66.6 Necropsy Findings

Lesions may develop in any or all of the following tissues of OPPV-infected sheep: lungs and regional lymph nodes, brain, joints, mammary glands, and blood vessels.[567] Changes are most obvious in the lungs, which do not collapse on opening of the thorax.[569,570] Vertical rib impressions may be seen on the exterior lung surface. Affected lungs are heavy and have a mottled to uniform pink-brown to gray-blue discoloration. Secondary bacterial pneumonia may cause anterior-ventral pulmonary consolidation. Tracheobronchial and mediastinal lymph nodes are markedly enlarged, bulge on cut surfaces, and are homogeneous, gray-white throughout. Histologic examination reveals a diffuse lymphoproliferative pneumonia characterized by prominent lymphoid follicle formation adjacent to bronchioles and small vessels; discrete nodules of lymphocytes, unrelated to vessels or airways, are also found in the lung parenchyma.[567–570] Lymphocytes, plasma cells, and macrophages infiltrate into interalveolar septa, and hyperplasia of alveolar epithelium and terminal bronchial smooth muscle may be seen.

31.66.7 Treatment and Prognosis

OPP is not treatable. Antibiotics can be used to control secondary bacterial pneumonia, but most sheep die within a year of first exhibiting clinical signs.[567,568]

31.66.8 Prevention and Control

OPPV is difficult to eradicate from a flock once infection is established.[570] Control methods include (1) a “test-and-cull” practice and (2) isolation of infected adults and artificial rearing of their offspring.[567] With the first method, all sheep are tested annually for antibody, and seropositive animals and their progeny younger than 1 year of age are culled or isolated from the negative flock; culling is preferred because of the danger of cross-contamination. New additions should be seronegative and originate from seronegative flocks. Annual testing should be performed until two consecutive negative herd test results are obtained to be reasonably confident that the flock is virus free. With the second method, progeny are removed from their dams before they nurse and are fed cow's colostrum and raised in isolation. The clean herd should be kept isolated from infected sheep and goats and from humans and equipment in contact with infected sheep. Herd additions and annual testing should be handled as described for method one.

31.67 OVINE PULMONARY ADENOCARCINOMA

31.67.1 Definition and Etiology

OPA (sheep pulmonary adenomatosis or jaagsiekte) is a naturally occurring retrovirus-induced bronchioloalveolar carcinoma of sheep and, rarely, goats that has been associated etiologically with a type B/D retrovirus (JSRV).[575,576] OvLVs and herpesviruses have been isolated from OPA tumors; however, they are not consistently present[577] and do not induce OPA when inoculated experimentally.[578,579] One theory is that these

viruses act as cofactors in tumor induction. Defining the role of JSRV in OPA has been complicated by the presence of 15 to 20 endogenous jaagsiekte retroviruses (enJSRVs) that are stably integrated into the genomes of sheep and goats.[580,581] Recent research has indicated that exogenous JSRV is likely not of endogenous origin. There has been speculation that the endogenous viruses may modify the genome of exogenous JSRV, either by inducing the expression of an oncogene or by inactivating a tumor suppressor gene.[576] Sequence analyses of exogenous JSRV and enJSRV suggest that endogenous viruses do not directly contribute to the pathogenesis of OPA through large-scale recombination events, but small-scale recombination or complementation of gene function has not been definitively excluded.[580] There has been speculation that expression of enJSRV in the fetal or neonatal period may influence expression of OPA through induction of immunologic tolerance.[580]

31.67.2 Clinical Signs and Differential Diagnosis

OPA usually affects mature sheep between 2 and 4 years of age, although lambs as young as 3 months of age have been diagnosed with the disease.[576] Clinical manifestations include progressive weight loss, exercise intolerance, tachypnea, dyspnea, occasional cough, and crackles and wheezes on thoracic auscultation. In many cases, presence of abundant watery nasal discharge can be demonstrated by raising the rear limbs and lowering the head of the affected sheep ("wheelbarrow test").[576] Appetite and rectal temperature are usually normal unless secondary infection and intercurrent disease are present. Sheep with OPA typically succumb within a few weeks to months after first exhibiting clinical signs.

657 658

31.67.3 Diagnosis

The only reported laboratory abnormality in sheep with OPA is hypergammaglobulinemia. Some researchers have demonstrated the utility of serologic assays to identify OPA-infected sheep, but other investigators have been unable to demonstrate antibodies to JSRV in the sera of affected sheep.[576] PCR tests, capable of demonstrating viral nucleic acids of endogenous JSRV tissues in OPA-infected animals, have been developed.[575]

31.67.4 Epidemiology

OPA has been reported in many countries in Europe, Africa, and Asia but is a rare occurrence in sheep in Australia and New Zealand.[575,576] The prevalence of OPA varies among countries in which the infection occurs; it is endemic in Scotland, Peru, and South Africa, where annual losses range from 2% to 10%. In contrast, OPA is infrequently diagnosed in the United States and Canada, where totals of 11 and 43 cases, respectively, have been reported.[575,576]

OPA has been reproduced experimentally by intratracheal inoculation of lung homogenates or pulmonary lavage fluids obtained from infected animals.[582] Lambs between birth and 5 weeks of age have been shown to be more susceptible to experimental infection than 10-week-old lambs.[582] This age-related susceptibility to OPA suggests that natural virus transmission occurs in the neonatal period. Aerosol transmission and contamination of feed and water by respiratory secretions are likely methods of disease spread, particularly in confined sheep.

31.67.5 Necropsy Findings

Lungs of OPA sheep are heavy (two to three times normal weight) and exude clear fluid from the cut surface. The trachea and bronchi often contain clear, foamy fluid. Large, firm, gray masses are commonly encountered in the cranioventral regions of one or both lungs. Smaller (1- to 2-cm) nodules are occasionally visualized in the caudodorsal lung regions.[576] Metastasis to regional lymph nodes occurs in approximately 10% of cases, causing pulmonary lymph node enlargement.[583] Metastases to cardiac and skeletal muscles are infrequently reported.[583] Some cases of OPA are complicated by secondary acute or chronic bacterial pneumonia.

OPA is classified by the World Health Organization (WHO) as a bronchioloalveolar carcinoma arising from alveolar type II pneumocytes or nonciliated bronchiolar cells.[583] Neoplastic masses consist of columnar or cuboidal cells arranged in an acinar or papillary pattern. Some tumors are surrounded by areas of fibroplasia.

31.67.6 Treatment and Prognosis

There are no known treatments for this disease. Antibiotics may prolong the life of OPA-affected sheep through control of secondary bacterial pneumonia.[576]

31.67.7 Prevention and Control

Recently a PCR for JSRV, performed on peripheral leukocytes and tissues of naturally infected sheep, demonstrated that this test could detect virus in live sheep before the onset of clinical disease.[575] This may hold promise for instigation of test-and-cull programs in the future. OPA was eradicated from Iceland by slaughtering all sheep in endemic areas.

31.68 CAPRINE ARTHRITIS-ENCEPHALITIS

CAE is a persistent lentiviral infection of goats with two major clinical presentations: leukoencephalomyelitis in kids 2 to 6 months of age and chronic, hyperplastic polysynovitis in mature goats.[584,585] Mild interstitial pneumonia, which is silent clinically, is a common postmortem finding in goat kids with leukoencephalomyelitis.[585] In one study, 60% of goats serologically positive for CAEV had lesions of severe chronic interstitial pneumonia at slaughter.[585] Similarly, chronic interstitial pneumonia, accompanied by exercise intolerance and dyspnea, was described in dairy goats originating from herds that had clinical cases of arthritis and leukoencephalomyelitis.[586] The lung lesions in these goats resembled those of OPP[586,587] and were positive for CAEV. However, CAEV has been recovered from the lungs of goats with advanced arthritis but without pneumonia. In addition, goats inoculated intratracheally with purified CAEV did not develop pulmonary lesions.[586] This may indicate that there is no causal relationship between CAEV and interstitial pneumonia in goats, or that the lesions have a multifactorial cause. CAE is discussed in detail in Chapter 35.

31.69 CASEOUS LYMPHADENITIS

CLA, caused by *C. pseudotuberculosis* (previously known as *C. ovis*), is a worldwide disease of sheep and goats characterized by the development of pyogranulomatous abscesses in lymph nodes and internal organs.[588–591] Once

established in a herd or flock CLA is difficult to eradicate. The disease responds poorly to treatment, infected animals are difficult to detect via clinical signs or diagnostic testing, and the organism tends to persists in the environment.[588,589] CLA most commonly presents as an external form characterized by SC abscesses in superficial lymph nodes.[588] The internal, or visceral, form of CLA manifests as internal abscesses in the mediastinal and mesenteric lymph nodes and internal organs, such as the lungs, liver, spleen, kidneys, uterus, and so on.[588] Goats are more commonly afflicted with external abscesses, whereas the visceral form of CLA appears to be more common in sheep.[588] Visceral CLA may be asymptomatic but is usually associated with ill thrift and significant weight loss.[588,592,593] Clinical signs that may accompany abscesses in the lung parenchyma and mediastinal lymph nodes are exercise intolerance, tachypnea, dyspnea, and chronic cough. Because of the encapsulated nature of pulmonary abscesses and lack of exudate in airways, pulmonary crackles are rarely auscultated.[591] Nonspecific laboratory findings in sheep and goats with CLA include leukocytosis, hyperfibrinogenemia, hyperproteinemia, and hypergammaglobulinemia; however, laboratory findings are frequently normal in animals with chronic abscesses.[591] A definitive diagnosis of visceral CLA with pulmonary involvement can be achieved by demonstrating abscesses in the lungs and mediastinal lymph nodes with thoracic radiography, and by isolating *C. pseudotuberculosis* from a TTA.[588,591] Failure to isolate the organism from tracheal wash fluid, however, does not rule out CLA as the cause of pulmonary disease. Characteristic postmortem findings of the respiratory form of CLA are one to multiple thick-walled, laminated, encapsulated, caseopurulent abscesses in the bronchial lymph nodes, mediastinal lymph nodes, and/or lung parenchyma. The synergistic hemolysis inhibition (SHI) test, which screens for antibodies directed against the phospholipase D exotoxin of *C. pseudotuberculosis*, was developed to diagnose early infections (before the development of SC abscesses) and to assist in the diagnosis of internal abscesses.[594] Any titer higher than 1:4 is suggestive of exposure or early infection.[588] Titers of 1:512 and higher are highly correlated with internal abscesses.[588] In a field study the SHI test had a sensitivity of 96% in sheep and 98% in goats and detected subclinically affected animals.[595] A double-antibody sandwich ELISA directed at *C. pseudotuberculosis* is being employed in Europe to detect subclinically affected sheep and goats and has contributed to successful disease eradication from some flocks.[596] CLA is discussed in more detail in relation to the hemolymphatic system (see Chapter 37).

658

659

31.70 OTHER PNEUMONIAS

AMELIA R. WOOLUMS

STEVEN E. WIKSE

31.71 ASPIRATION PNEUMONIA

Aspiration pneumonia is caused by inhalation of large amounts of foreign material, often liquids. It is also called *gangrenous pneumonia, foreign-body pneumonia, medication pneumonia*, or *lipid pneumonia*. The most common cause is careless drenching or passage of stomach tubes during administration of milk or liquid medication. It also occurs occasionally in pail-fed calves, animals with pharyngeal paresis, animals with necrotic laryngitis, lambs with nutritional myodegeneration, anesthetized animals, sheep that are dipped, cattle that have parturient paresis, and cattle that ingest crude oils or fuel oils.[597,598] Meconium aspiration secondary to fetal distress has been recognized as a possible risk factor of neonatal calf mortality.[599] The condition is characterized by a mild diffuse alveolitis that results in hypoxia and acidosis, which leads to impaired absorption of colostral antibodies and inadequate passive transfer in affected calves.

If large quantities of fluid are aspirated, death may be almost instantaneous, but generally a gangrenous bronchopneumonia develops as a result of infection and the irritating properties of the inhaled material. Affected animals exhibit depression, polypnea, dyspnea, coughing, and fever and may have putrid breath. Crackles, wheezes, and occasionally pleural friction rubs can be heard on auscultation.

Diagnosis is based on the history, sudden onset, and severe signs. Differential diagnoses include acute bronchopneumonia and septicemia. Necropsy reveals consolidation of the anterior ventral areas of the lungs. Affected areas are severely hemorrhagic in acute cases and contain suppuration and liquefactive necrosis in subacute cases.

The prognosis is guarded in all cases of aspiration pneumonia, but some animals can be saved. Antibiotics combined with antiinflammatory agents should be promptly administered, and long-term antimicrobial therapy is required. Prevention of aspiration pneumonia centers on careful administration of medication and avoidance of other risk factors that may promote inhalation of foreign materials.

31.72 MYCOTIC PNEUMONIAS

Ruminants may occasionally have pulmonary infections with *C. immitis, Aspergillus* species, *H. capsulatum, C. albicans*, and fungi of the order Mucorales.[600] Coccidioidomycosis occurs in cattle and much less commonly in sheep and goats in the southwestern United States. It causes very few clinical signs in ruminants, but the occasional animal may exhibit a chronic cough and weight loss. Differential diagnoses include tuberculosis and CLA. Radiologic evaluation is helpful in establishing the presence of pulmonary masses. The diagnosis may be confirmed by culture, histologic identification of the characteristic spherules, and intradermal and complement-fixation tests. The organism is obtained from the soil and is not easily transmitted from animal to animal or to human, but nevertheless it represents a serious zoonotic disease concern. The major lesion is a granuloma with creamy pus in the bronchial and mediastinal lymph nodes. There is no treatment. Control of dust may lessen the incidence.[600]

Aspergillosis is a rare condition that usually occurs in housed calves, particularly in those that have had chronic antibiotic or steroid therapy or that are otherwise immunosuppressed or chronically ill. There are three forms. The acute form is characterized by a fibrinous pneumonia with fever, dyspnea, tachypnea, cough, nasal discharge, groaning, and a short course to death. The subacute and chronic forms are less severe and exhibit mainly anorexia, weight loss, and mild respiratory signs. Differential diagnoses include enzootic pneumonia, tuberculosis, and lungworms. Radiographs, transtracheal washings, histopathologic evaluation (with demonstration of branching septate hyphae), and culture of lesions help establish the diagnosis. The subacute and chronic lesions consist of multiple small, white, discrete granulomas with necrotic centers. The acute lesions are those of a severe fibrinous pleuropneumonia.[600] Treatment is frequently ineffective; antifungal agents such as nystatin, amphotericin B, and ketoconazole may be tried in individual cases. Doses and withdrawal times for these drugs are not established for ruminants, and because treatment of fungal pneumonia in other species requires months of therapy, treatment is not likely to be economically feasible in most cases.

Histoplasmosis is rare in ruminants. It is a polysystemic disease with chronic emaciation, dyspnea, diarrhea, and anasarca. An intradermal delayed hypersensitivity test, culture, or histopathologic identification of the yeastlike organism helps to confirm the diagnosis. Lesions include ascites, liver enlargement, gut edema, pulmonary emphysema, and pulmonary edema with abscesses. As described for aspergillosis, antifungal therapy may be attempted but is not likely to be economically feasible.

Pulmonary candidiasis has been reported as an outbreak in a feedlot. It was characterized by a chronic pneumonia with severe dyspnea but only moderate fever; a mucopurulent, brown-streaked nasal discharge; diarrhea; a crusted muzzle; and lacrimation without conjunctivitis. Differential diagnoses should include the various upper respiratory viruses, particularly IBR and BVDV, and bacterial bronchopneumonia. The diagnosis is made by the presence of the budding yeastlike organism in smears and cultures. Lesions include lung consolidation and abscesses.[600] Treatment has not been investigated.

Zygomycosis, phycomycosis, and mucormycosis are synonyms for a very rare opportunistic disease in ruminants. This is a systemic fungal infection that may affect the lung, stomach, liver, brain, and lymphatic system. Cattle with *Mucorales* species pneumonia exhibit tachypnea, dyspnea, nasal discharge, fever, and anorexia. The pulmonary lesions are a fibrinous pleuritis with firm, heavy, wet, mottled lungs. Histopathologic demonstration of broad aseptate hyphae in affected tissue and culture are the best means of diagnosis.[600] Treatment has not been investigated.

659

660

31.73 VENA CAVAL THROMBOSIS AND METASTATIC PNEUMONIA

31.73.1 Definition and Etiology

Metastatic or embolic pneumonia in cattle, also called *caudal vena caval thrombosis, pulmonary thromboembolism*, and *embolic pulmonary aneurysm*, is a distinct syndrome associated with multifocal abscessation of the lungs caused by septic thromboembolism of the pulmonary arterial system. The septic emboli arise from septic thrombi of the caudal vena cava (Fig. 31-68) or, less commonly, the cranial vena cava. Vena caval thrombi are in turn a sequela to various septic conditions such as jugular phlebitis, mastitis, metritis, foot rot, or, most often, liver abscesses secondary to rumenitis.[601] A variety of bacteria may be involved; those most frequently encountered include *F. necrophorum, Arcanobacterium (Actinomyces) pyogenes*, staphylococci, streptococci, and *E. coli*.

31.73.2 Clinical Signs

Because of its association with rumenitis, this condition is most commonly seen in feedlot cattle, but any age, breed, sex, and class of cattle may be affected. The problem is unusual in cattle less than 1 year of age. Cattle with metastatic pneumonia usually exhibit respiratory disturbance or weight loss or occasionally thoracic pain. The duration of signs is quite variable, ranging from acute respiratory distress to a chronic history of weight loss and coughing for weeks to months.[602,603] The classic presentation includes tachycardia, tachypnea (respiratory rate over 30 breaths/min), expiratory dyspnea and groaning, hyperpnea, coughing, heart murmurs and pale mucous membranes (caused by anemia), widespread wheezes, epistaxis, and hemoptysis.[601,602] Other signs, which are more variable, include fever, thoracic pain on deep palpation of the sternum and intercostal spaces, hepatomegaly (indicated by the ability to palpate the caudal edge of the liver in the right paralumbar fossa), SC emphysema, froth at the muzzle, and melena caused by coughing up and swallowing blood.[601,602] Nonspecific accompanying signs include depression, anorexia, ruminal stasis, scant feces, and decreased milk production. In chronic cases cor pulmonale may lead to signs of right ventricular failure such as jugular distention and brisket edema.[602] The combination of respiratory signs with anemia, widespread wheezes, and especially hemoptysis is generally regarded as pathognomonic for this syndrome.[602] Animals usually deteriorate rapidly once hemoptysis becomes evident, and the condition is essentially 100% fatal. Many patients die suddenly with an acute episode

of severe intrapulmonary hemorrhage or hemoptysis after a variable course of respiratory disease. Some of these cases in which the respiratory signs were overlooked may account for the reports of sudden death attributed to vena caval thrombosis.[602] Caudal vena caval thrombosis can also lead to hepatomegaly and extensive ascites, but most of these animals also have respiratory signs.[603] Sudden erosion of a large hepatic abscess into the caudal vena cava may also result in a massive embolic shower, with acute respiratory distress and death.[603]

Fig. 31-68 Postmortem photograph of thrombus in caudal vena cava, which leads to embolic pneumonia demonstrated in Fig. 31-69. Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.

In patients with the pathognomonic signs (the majority of cases), no differential diagnoses need be considered. However, many patients are examined before the onset of hemoptysis, and a few may die without exhibiting these signs.[603] Differential considerations in such cases, which usually manifest as acute dyspnea, should include anaphylaxis, the various ARDSs, hypersensitivity pneumonitis, lungworms, and acute bronchopneumonia. Patients with right ventricular failure should be differentiated from those with pericarditis, lymphosarcoma, cardiomyopathy, and endocarditis.

31.73.3 Pathogenesis

The classic pathogenesis of this disease begins with the development of rumenitis secondary to lactic acidosis caused by highly fermentable diets such as those used in feedlots, some dairies, and some growing rations. Bacteria such as *F. necrophorum* and *A. pyogenes* are then able to penetrate the damaged ruminal epithelium and are transported to the liver in the portal drainage system, where they are filtered out and result in abscesses. If an abscess is located next to the caudal vena cava (where the vessel is closely applied to the left border of the liver), a septic thrombus may form in the vena cava as a result of infiltration of its wall by the abscess (see Fig. 31-68). Septic emboli detach from the thrombus and reach the lungs through the pulmonary arterial system. Alternatives to this classic pathway are rare; they include the following: thrombosis of the cranial vena cava from primary lesions such as jugular phlebitis, thrombosis of the caudal vena cava from other subdiaphragmatic abscesses, right-sided endocarditis, and emboli arising from other septic foci such as mastitis, metritis, and foot rot. Large emboli may block lobar or larger arteries, causing an acute crisis and death. More typically, smaller emboli lodge in arterioles, where they cause arterial thromboembolism, arteritis, endarteritis, and pulmonary abscesses (Fig. 31-69). The widespread arterial embolism also results in pulmonary arterial hypertension. Arteritis and endarteritis weaken the vessel walls and, in combination with pulmonary hypertension, lead to the formation of aneurysms. In some cases a perivascular abscess not only erodes an arterial wall to produce an aneurysm but simultaneously erodes a bronchial wall; when the aneurysm ruptures, the abscess cavity channels the blood into the bronchus, resulting in massive hemoptysis. In other cases, rupture of aneurysms results in large interstitial hematomas. Both processes result in anemia; when coughed-up blood is swallowed, melena may result. Coughing and wheezes are probably caused by blood clots in airways, peribronchial aneurysms and abscesses, and suppurative pneumonia. Pain results from dissecting aneurysms and hematomas.[602]

31.73.4 Epidemiology

Metastatic pneumonia accounted for 1.3% of necropsy diagnoses in one large feedlot survey, with a rate varying between 1.6 and 7.3 cases per 100,000 head on feed. Cases occurred year round and during all stages of fattening, although 68% of cases occurred during the first 90 days on feed.[604] The case fatality rate is usually 100%.

Fig. 31-69 Postmortem photograph of lung from feedlot steer with embolic pneumonia caused by caudal vena caval thrombosis. Note multiple dark red emboli with raised abscesses scattered throughout lung. Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.

31.73.5 Necropsy Findings

Almost all patients with significant hemoptysis have a thrombus in the posterior vena cava between the liver and the right atrium. There is usually an adjacent hepatic abscess, varying degrees of venous congestion of the liver, and hepatomegaly. The lungs are large, uncollapsed, and firm. Aneurysms may occur in either lung or both. Hematomas associated with ruptured aneurysms are frequently 3 to 10 cm in diameter.[604] Large blood clots may be found in the airways, aspirated blood in the alveoli, and swallowed clots in the rumen. Areas of suppurative pneumonia and multiple abscesses are present (see Fig. 31-69).

31.73.6 Diagnosis

The CBC may reveal anemia and a neutrophilic leukocytosis with a regenerative left shift. Hyperglobulinemia is frequently present. Serum chemical analysis may reflect chronic passive congestion of the liver, with elevation of bilirubin and liver-derived enzymes. Radiographs often reveal only an irregular increase in lung density. Small discrete densities (areas of embolic infarction and collapse); large, discrete, spheric opacities (hematomas);

cavitating nodules, sometimes with gas-fluid interfaces (abscesses); bullae; and areas of consolidation may be observed in some cases.[602,603]

31.73.7 Treatment and Prevention

The prognosis is grave, so treatment is rarely indicated, and salvage is the most feasible recommendation. In valuable individuals, antibiotics and supportive therapy may be attempted. Penicillin is the drug of choice for the most common organisms involved; large doses (22,000 U/kg IM or SC twice daily as a minimum) for extended periods (weeks to months) are recommended. Long-acting oxytetracycline and florfenicol are other drugs that are effective against the bacteria likely to be involved. Supportive therapy for cases with acute severe dyspnea includes furosemide (0.5 to 1 mg/kg IV or IM once or twice daily) and flunixin meglumine (1.1 to 2.2 mg/kg once or divided twice daily). One or two doses of corticosteroids (dexamethasone at 0.05 to 0.2 mg/kg IV or IM q 24 h), or atropine (0.04 mg/kg SC daily), may be helpful in cases with severe respiratory distress.

On the basis of the assumption that rumenitis and liver abscesses are the first steps in the pathogenesis of most cases, measures to reduce the incidence of these problems are appropriate. Recommendations include slow adaptation of animals to high-energy rations and feeding of antibiotics to reduce the incidence of liver abscesses.

31.74 BOVINE TUBERCULOSIS

MICHAEL S. VANDERKLOK

31.74.1 Definition and Etiology

Mycobacterium bovis, know as bovine tuberculosis, is the most common cause of tuberculosis in cattle. The bacterium belongs to the *M. tuberculosis* (MTB) complex of organisms, which includes *M. tuberculosis, M. africanum*, and *Mycobacterium microti*. *Mycobacterium bovis* has the widest host range of the species included in this complex.[605] All species of mammals, including humans, are susceptible to *Mycobacterium bovis* infection, although the susceptibility of different species is variable. The importance of this organism as a zoonotic agent has led to the institution of long-standing programs for eradication of the disease, especially in developed countries. The occurrence of *Mycobacterium bovis* as an endemic disease in wildlife populations in mammalian species in numerous countries has created new challenges for control of this disease in domestic livestock.

The organism can affect animals of any age.[606] Commonly infected livestock species include cattle, goats, swine, and cervids. Horses have been regarded as relatively resistant, but reports from New Zealand indicate that large numbers of sheep can be affected.[607,608] Other *Mycobacterium* species occasionally cause clinical disease, especially *M. avium* in swine, but their main importance historically lies in the problems created for control and eradication programs through the reaction of exposed animals to the common tuberculosis tests. Disease caused by *M. avium* subsp. *paratuberculosis* (Johne's disease) has risen as a concern in dairy cattle in recent years.

31.74.2 Clinical Signs and Differential Diagnosis

Signs of *Mycobacterium bovis* infection can be very nonspecific, and in early stages of the disease are inapparent. Infected animals may not show clinical abnormalities, yet may pose health risks to other livestock and to humans. Patients may have chronic weight loss, variable appetite, and fluctuating fevers, which may be

accentuated after calving. Other signs depend on the organs involved. The route of invasion in ruminants is usually respiratory through inhalation; however, recent research and occurrences have demonstrated the capability of ingestion of contaminated feed and other forms of indirect contact to transmit the disease.[609–612] Signs related to the respiratory system are relatively common and usually mild, although severe chronic infections can lead to debilitation. Progressive emaciation can occur that is unassociated with other clinical signs, and such occurrences should lead to investigation of potential *Mycobacterium bovis* infection.[606]

Specific clinical signs of the disease are determined by the initial location of bacterial introduction to the body. Respiratory signs in ruminants include a soft, moist, chronic cough resulting from bronchopneumonia. Obvious dyspnea, tachypnea, hyperpnea, and adventitious lung sounds occur only in the terminal stages. Lung sounds include crackles, wheezes, and silent spots occupied by granulomas; pleural friction rubs may occur rarely. Enlarged mediastinal nodes may cause bloat. Intestinal ulceration and diarrhea may occur, and enlarged 661
mesenteric nodes may cause transport failure or obstructions. Involvement of retropharyngeal nodes may cause 662
dysphagia, stridor, and salivation. Lesions occur rarely in the peripheral nodes, the reproductive tract (causing infertility, abortion, metritis, and vaginitis), and the mammary gland. Other chronic pulmonary infections should be considered for differential diagnosis (e.g., chronic suppurative pneumonia, *Arcanobacterium (Actinomyces) pyogenes* abscesses, *C. pseudotuberculosis* CLA in sheep and goats, and mycotic pneumonias). Pharyngeal lesions should be differentiated from pharyngeal trauma, abscesses, lymphosarcoma or other neoplasia, rabies, botulism, actinobacillosis, necrotic laryngitis, and laryngeal abscesses, trauma, edema, paralysis, and tumors.

31.74.3 Diagnosis

Mycobacterial organisms in general precipitate a cell-mediated immune response but do not cause an immediate or sustained humoral reaction in mammalian species. The lack of specific antibody production in an exposed or infected animal has made development of serum-based laboratory tests for use in a live animal difficult. The intradermal tuberculin test has been the only clinicopathologic test routinely used. Recent advances in diagnostics have led to the introduction of tests that measure specific IFN-γ production in the blood of exposed or infected cattle.[613] In the United States, accredited veterinarians are authorized to administer 0.1 mL of mammalian tuberculin purified protein derivative intradermally in the caudal tail fold (CFT) as a primary diagnostic test. The test result is read in 72 ± 6 hours as negative or suspect. State or federal veterinarians may also use a 0.2-mL cervical test in known infected herds.

Only state or federal veterinarians may use the comparative cervical test (CCT), or state or federal veterinarians and approved accredited veterinarians may use the IFN-γ test (IG), to determine the disposition of cattle determined suspect by the CFT. In the CCT, biologically balanced mammalian and avian tuberculin are injected simultaneously in two sites on the same side of the neck, 12 cm apart and one above the other. The test site is assessed at 72 ± 6 hours and results determined by comparison of the relative increase in skin thickness between time intervals as measured by approved calipers. These relative increases are applied to a normogram to determine the final test result. Alternatively, the IG may be performed on animals suspect to the CFT by collection and submission of a whole blood sample to an approved laboratory for testing.[614] This test compares the relative production of specific IFN-γ of cells exposed to MTB antigen and *M. avium* antigen. The basis for following CFT suspect testing with the CCT or IG tests is that animals infected with mycobacteria other than the MTB complex react to avian antigenic stimulation to a greater degree than to bovine antigens.[613] Tests vary in nonbovid species and include application of the intradermal tuberculin test in the axillary area of new world camelids and in the cervical region of cervid species.[614]

Testing protocols in other countries can vary in relation to the specific composition of tuberculin, interpretation of the tests, and application of tests in different species or situations. The presence of control and eradication programs in most developed countries depend on the ability of these initial test procedures to differentiate herds or animals that may have been exposed to the organism. As there is no economically viable or routinely effective treatment for the disease in livestock, final determination of the presence or absence of *Mycobacterium bovis* is based on specific identification of the organism, such as via genetic identification or bacteriologic culturing.

Other tests no longer in use include the SC and IV thermal tests, in which a temperature spike to over 40° C (104° F) in 4 to 8 hours is the positive response; and the Stormont test, in which the intradermal test is performed twice in the same area 7 days apart. The response is determined 24 hours after the second test, and an increase in skin thickness of 5 mm or greater is the positive result. A tuberculin test may result in locally increased sensitivity for about 12 days; thereafter there is a temporary generalized hyposensitization. Because of this, follow-up intradermal tests must be performed before 10 days or after 60 days, and the IG test performed within 30 days, after initial CFT injection in the United States.[614] A relative hyposensitization also may occur just before and for 4 to 6 weeks after calving.

Animals with chronic disease or advanced pulmonary lesions may be anergic and may not react to immune-based testing.[615] False-positive reactions may occur as a result of human or avian tuberculosis, Johne's disease, saprophytic *Mycobacterium* species, or other agents such as *Nocardia* species.[613] Radiographs may be helpful in establishing the presence of pulmonary masses in individual cases. Postmortem examination of animals delivered to slaughter facilities inspected by the Food Safety Inspection Service and necropsy are used by control officials to determine the presence or absence of lesions. Histopathologic examination, PCR testing, and bacterial culture are all used to determine the final diagnosis in animals with lesions and suspect or reactor animals.

The accuracy of antemortem diagnostics for *Mycobacterium bovis* is limited by the organism's failure to produce a reliable cellular or humoral response, and the prevalence at which animals are exposed to cross-reacting organisms. Sensitivity of the CFT in field trials has been reported to be 63% to 97%, and increased test sensitivity can be seen in cases of individual animals with more extensive lesions and in herds that contain a higher prevalence of *Mycobacterium bovis* infection.[613,615,616] Therefore the test is more valuable in making decisions regarding the presence of *Mycobacterium bovis* in herds rather than individual animals.[617] It has been reported that *Mycobacterium bovis* strain type may influence the effectiveness of the CFT.[605] The specificity of intradermal tuberculin testing has been reported to be 75.5% to 99.0%,[613] although accurate estimates are difficult because of differences in research and field trial testing protocols. In areas with a low prevalence of disease, overall testing specificity is enhanced by using a combination of the CFT and CCT or IG tests in sequence.

Determination of *Mycobacterium bovis* infection through examination of animals presented at slaughter facilities is routinely used in developed countries. Slaughter examination systems have a lowered sensitivity compared with intradermal testing but are seen as a cost-effective surveillance method.[618] Sensitivity of postmortem examination is affected by the procedure used and the tissues examined. The most common areas of lesion development in naturally infected cattle are in the lymph nodes that drain the respiratory tract. From 70% to 90% of *Mycobacterium bovis* lesions are found in the lymph nodes of the head or in the thoracic cavity. In low-prevalence areas, animals may have no, or only one, macroscopically visible lesion.[617–619] Because *Mycobacterium bovis* is difficult to culture, aseptic collection technique and appropriate storage of tissues during transport are critical for appropriate diagnosis.

31.74.4 Pathophysiology

The organism usually enters ruminants through the respiratory route, occasionally by ingestion. The infectious dose has a significant effect on the severity and progression of the disease. Animals exposed to high doses of the organism develop more severe lesions and produce an earlier and more consistent period of bacterial shedding than those exposed to low doses. It has been reported that a dose as small as one CFU can cause disease.[619,620]

662
663

Inhalation of the organism, the most common method of infection, usually results in a small necrotic granulomatous lesion occurring in the lungs. Granuloma formation is less common when the digestive tract is involved. Infection of the upper respiratory tract or pharyngeal area may also be caused by ingestion of infected feeds.[610] From the initial site of entry the organism invades the local lymph nodes (retropharyngeal, tracheobronchial, mediastinal, mesenteric), where it causes necrosis surrounded by a granuloma containing mononuclear cells. Localized lesions stimulate development of a fibrous capsule that varies in severity depending on the rate of development. This combination of lesions at the site of entry and the local lymph nodes forms the primary complex. From there a postprimary dissemination occurs to various organs and can result in diffuse miliary tuberculosis, discrete nodular lesions in various organs, or chronic organ tuberculosis. The disease in cattle is progressive and eventually causes weakness, debility, and death.[605,606,610,619] Hypotheses based on knowledge of human tuberculosis have suggested that the majority of cattle exposed to *Mycobacterium bovis* may have the ability to clear the disease or enter a period of latency.[615] If proven true, this could have significant impact on eradication programs.

31.74.5 Epidemiology

Contact with infected animals is the most common source of exposure, and the organism is present in exhaled droplets, sputum, feces, milk, urine, vaginal discharge, semen, and draining nodes. Tuberculous lesions occur in the head or respiratory lymph nodes in 70% to 90% of reactors with confirmed infections. However, lung lesions are found in 1% to 2%, to less than 10%, of these infected animals on postmortem examination.[617,618] Animals with no visible signs of organ involvement have historically been regarded as nonexcreters and been determined to be unimportant in transmission of the disease. If careful laboratory examinations are made, over 70% of cattle with lesions in respiratory lymph nodes have small lung lesions, and in 19% of confirmed cases *Mycobacterium bovis* is present in the tracheal mucus. All cattle with tuberculous lesions are therefore considered potential shedders.[621] Research has supported that *Mycobacterium bovis* adheres to a commonly held belief about many diseases: cattle with more advanced lesions have a higher shedding rate than animals with less extensive disease.[622] Feces can remain infective for 6 to 8 weeks, and stagnant water for 18 days. Milk historically was a common route of infection in young animals. Recent research has demonstrated that *Mycobacterium bovis* can persist on feedstuffs such as corn, carrots, apples, hay, and sugar beets for up to 16 weeks at 0 ° C (Whipple, unpublished data).

Housing and crowding increases the contact of naive animals with secretions of infected animals and can enhance spread of this disease. The disease can also be transmitted by indirect contact through contaminated feed and water, feeding and watering equipment, cleaning equipment, or movements of personnel—anything that can mechanically transfer the organism between locations. Movement of untested infected animals through purchases, sharing of breeding animals, and fenceline contact with other herds have historically been the most common ways of transferring the disease.

Mycobacterium bovis has been found to occur as an endemic disease of wildlife populations in multiple countries. Such occurrences, and associated transmission from wildlife into domestic livestock herds, poses a new challenge to the control and eradication of the disease. Wildlife involvement in the transmission of disease to cattle has occurred with free-ranging white-tailed deer *(Odocoileus virginianus)* in the United States, badger *(Meles meles)* in Great Britain, and brushtail possum *(Trichosurus vulpecula*) in New Zealand, among others. Studies have demonstrated that these species can be reservoirs for transmission to livestock through indirect contact and contamination of feed, water, and environmental substrates.[610,611,622] The foraging habits of mammalian herbivores may also contribute to an increased risk of exposure to the organism in areas with wildlife reservoirs.[623,624] Movement of infected wildlife species through rehabilitation or reintroduction programs can be an avenue for spreading the disease between areas.

Bovine tuberculosis is an important zoonotic disease because of its potential for spread in nonpasteurized milk from infected animals. The disease may also be spread between animals and humans that are in close association. The incidence of tuberculosis has been greatly reduced by control programs in many developed countries but still persists and presents a potential disease hazard to humans in many areas of the world.[605] Within developed countries the residual cases are the most difficult and expensive to detect and remove, and consequently outbreaks still occur. In the United States, fairly large-scale outbreaks have been reported in dairies that were previously free of the disease, and the proportion of feeder animals that accounts for slaughter cases has increased in recent years. Importation of feeder cattle from Mexico has been shown to be a source of disease introduction for the United States.[625] Movement of infected cattle is also a contributor to the spread of *Mycobacterium bovis* in Great Britain.

31.74.6 Necropsy Lesions

The pathognomonic lesion of *Mycobacterium bovis* infection is the granuloma, which is thought to be a result of chronic antigenic stimulation and an attempt to localize the invading organism.[626] Tuberculous lesions primarily occur in the respiratory tract and associated head and thoracic lymphatic tissue but can exist in other areas depending on the initial location of introduction of the organism. It is common that infected cattle may display no grossly visible lesions or may have a visible lesion in only one lymph node.[616,617,621] Macroscopic lesions appear as firm encapsulated nodules, with thick, yellow to orange, creamy to caseous pus, and may be calcified. They may occur in any lymph node, but especially the bronchial, mediastinal, and mesenteric nodes, and in a variety of organs, particularly the lungs and liver. The organs may be riddled with small miliary tubercles, and in the lungs these may coalesce into a suppurative bronchopneumonia. Swine may have involvement of the joints of the forelimb or hindlimb.[627] Chronic lesions are characterized by a discreet, thickened fibrous capsule containing thick caseous material.[606]

Histopathologically lesions in lymph nodes or organs are granulomatous with a central area of mineralization and necrosis. Macrophages have a distinctly elongated appearance and can coalesce into multi-nucleated giant cells (Langerhans cells). These fused cells form the center of the developing tubercles. The presence of acid-fast bacteria within these lesions strongly suggests the presence of *Mycobacterium bovis*, although there may be only small numbers of widely dispersed organisms. Lesion development can be divided into four different stages: stage 1 (no necrosis), stage 2 (minimal central necrosis), stage 3 (central caseous necrosis with minimal necrosis), and stage 4 (extensive multicentric caseous necrosis with mineralization).[626] Differentiation between the thickness of the fibrous capsule and the histopathologic stage of development may assist in determining the chronicity of the infection.

663
664

31.74.7 Treatment, Prognosis, Prevention, and Control

In developed countries the disease is not treated in livestock, and affected animals are slaughtered. Species infected with *Mycobacterium bovis* that are considered valuable as zoologic exhibits or that are rare or endangered have undergone attempted treatment for the disease. These treatments have included human tuberculosis drugs such as isoniazid, streptomycin, paraaminosalicylic acid, and others.[606] Outside of these rare cases, treatment for bovine tuberculosis in animals is not considered effective on the disease or practical with regard to cost.

The development of an effective vaccine for bovine tuberculosis has been a desired tool to use in preventing and eradicating *Mycobacterium bovis*. Vaccines may increase resistance to infection or reduce the disease severity and potential risk of transmission from an infected animal. Much research is now going into development of an effective vaccine, but field study methods need to be developed that mimic natural infection.[628,629] The use of a vaccine at the end stages of an eradication program may increase the difficulty in locating the last vestiges of infection, because of the tendency of vaccines to mask disease, which is generally not desired. Much of the vaccine research is aimed toward usage in areas with widespread disease or in wildlife species in areas where the disease is endemic in these populations. Recent results in the United States involving challenge studies in white-tailed deer have demonstrated decreased lesion severity in vaccinated animals.[630]

Eradication schemes in numerous countries rely on a program of surveillance in livestock and wildlife, testing of animals before movement, and systems to track animals between farms in order to identify animals exposed to the disease and potential sources of infection. More recently, surveillance and control programs for wildlife species deserve consideration as these may also be a source of infection. In the United States, individual farms infected with *Mycobacterium bovis* are handled through a series of testing protocols intended to eliminate infection through removal of all infected animals, or by whole herd depopulation.[614] Because of limitations in the sensitivity of antemortem diagnostic tests for tuberculosis, depopulation of infected herds and other exposed animals is thought to be the most effective way to ensure eradication of the disease.[616]

When herds are depopulated and the owner intends to repopulate in the future, it is important to remove or thoroughly clean and disinfect facilities and equipment potentially exposed to the organism. The ability of *Mycobacterium bovis* to survive for extended periods in the environment, and the ineffectiveness of disinfection of organic materials, necessitates that pastures and fields to be used in repopulation schemes be left vacant for a period of time before use. This period of “down time” will be affected by climatic conditions, as the organism is less resistant to sunlight and drying, but can survive for longer periods during certain seasons. Instances of infection that are thought to originate from wildlife sources may precipitate changes in facilities, management, feeding practices, or wildlife control to prevent reinfection. Current experience with endemic *Mycobacterium bovis* infections in wildlife in numerous countries have demonstrated that eradication of the disease in these species is difficult, and a long-term proposition. More work is needed in the areas of diagnostic testing, environmental sampling, vaccine development, and management practices that may decrease the risk of disease spillover, in order to achieve successful control and eradication of the disease in the future.

31.75 DISEASES OF THE THORACIC WALL AND CAVITY

AMELIA R. WOOLUMS

JOHN A. SMITH

31.76 PLEURITIS AND PLEURAL EFFUSIONS

31.76.1 Definition and Etiology

Acute, primary pleuritis is rare in ruminants. It is almost always a secondary condition. The most common primary cause is most likely bronchopneumonia caused by *M. haemolytica* or *H. somni*. Other possible causes of pleuritis and pleural effusions include traumatic reticulopericarditis, extension from other causes of peritonitis, tuberculosis, liver abscesses, tumors (especially lymphosarcoma), external trauma, fractured ribs, gunshot, perforating injuries, sporadic bovine encephalomyelitis (SBE), contagious bovine and caprine pleuropneumonia, various septicemic conditions, acorn toxicity and other causes of uremia, uroperitoneum, right ventricular failure, hypoproteinemia, ruptured thoracic duct, and hemothorax from trauma or hemangiosarcoma.

31.76.2 Clinical Signs

The signs depend on, and may be overshadowed by, the primary disease process. Pleuritis is a painful, septic process, whereas the signs associated with nonseptic effusions depend largely on the cause. Signs referable to pleuritis itself include anorexia, depression, fever, weight loss, decreased milk production, progressive dyspnea, and a characteristic stance and respiratory pattern, with the head and neck extended, elbows abducted, restricted excursion of the thorax, abdominal breathing, tachypnea, and a grunting or groaning with respiration. The animal may be reluctant to move. If a cough is present, it is often soft and suppressed because of pain. Jugular distention and pulsation may result from interference with venous return.[631] Auscultation may reveal creaking or rubbing noises in dry pleuritis or a cranial-ventral masking of sounds caused by effusion. Percussion may reveal dullness ventral to the fluid line and may elicit pain. Differential diagnoses for dyspnea with abnormally quiet lung fields may include the atypical pneumonias, pneumothorax, and space-occupying lesions such as large abscesses, tumors, and diaphragmatic hernia. Once pleuritis or pleural effusion has been identified, the main differential diagnostic consideration is the determination of the underlying cause, as listed previously.

31.76.3 Diagnosis

A CBC helps to separate infectious from noninfectious causes and distinguish relatively acute conditions (with significant left shifts) from those of a more chronic nature (with mature neutrophilia, hyperglobulinemia, and nonregenerative anemia of chronic disease). Serum chemical determinations and urinalysis identify hypoproteinemia and azotemia. A thoracocentesis should be performed and submitted to cytologic and cultural examination for bacteria, mycoplasma, and chlamydia. Nonseptic transudates indicate conditions such as neoplasia, heart failure, hypoproteinemia, and uremia. Effusions of sporadic bovine encephalomyelitis are relatively acellular with high protein and fibrinogen levels, whereas septic exudates high in both cells and protein occur with pneumonia, hardware, peritonitis, abscesses, penetrating trauma, and septicemias. A transtracheal wash is usually indicated because of the common association with pneumonia. Pericardiocentesis, abdominocentesis, and radiographs may indicate the primary source of an infection. Tuberculosis tests, leukemia virus titers, chlamydial titers for SBE, electrocardiography, echocardiographic examinations, ultrasonographic examination of the liver, and exploratory laparotomy may also help to detect other primary processes.

664
665

31.76.4 Treatment

The primary problem should be treated. Effusions should be drained, either periodically or continuously through a Heimlich valve or a suction device fashioned from a syringe with the plunger transfixed with a pin. Effective drainage can be difficult in ruminants because of their propensity for fibrin formation and loculation of the fluid. Intermittent drainage is as effective as continuous drainage and simpler to maintain. Attempts at lavage have rarely been successful because of adhesions. Appropriate antibiotics are indicated in the presence of sepsis. NSAIDs (aspirin, 100 mg/kg PO twice daily; flunixin meglumine, 1.1 to 2.2 mg/kg IV or divided twice daily) are useful to relieve pain, ease respiration, and improve appetite. Rest and good nursing care are essential. The prognosis obviously depends on the extent and duration of the disease. Although many animals that have severe cases survive, such animals often remain chronically underweight.

31.77 PNEUMOTHORAX

Pneumothorax is not common in ruminants. Most cases result from the rupture of an emphysematous bulla associated with pneumonia, straining, or coughing or from puncture of the lung by a fractured rib. The bullae that occur in BRSV-induced pneumonia are a common source. Trauma to the pharynx or larynx can also lead to pneumothorax,[632] presumably caused by air traveling from the cranial cervical regions through soft tissues and into the thoracic cavity. Penetration from the exterior is possible but less common. A case has been described in a postparturient cow with no other underlying cause found.[633] A retrospective study of 30 cattle with pneumothorax presented to a referral hospital found that 18 of the cases (60%) were associated with bronchopneumonia, seven cases were associated with interstitial pneumonia, three cases were associated with laryngeal or pharyngeal trauma, and two cases were associated with neonatal respiratory distress.[632] Of interest was the finding that 13 of the 18 cases with bronchopneumonia were chronic, based on history and diagnostic findings; an association between pneumothorax and chronic bronchopneumonia had not been previously reported. The rate of survival for cattle with pneumonia and pneumothorax was lower than for cattle presented with pneumonia without pneumothorax, with an overall survival rate of 60% for cattle presented with pneumothorax.

Clinical signs of pneumothorax include inspiratory dyspnea, sometimes severe, with open-mouth breathing sometimes present.[633] One side of the thorax may be relatively collapsed and immobile, with a compensatory increase in the size and excursion of the other side; however, this latter finding is often subtle and difficult to appreciate. Ruminants have a complete mediastinum; thus when pneumothorax occurs it is usually unilateral, and the animal is able to ventilate adequately using the opposite lung. Unless an infectious disease is responsible, affected animals are often alert and anxious. They may attempt to stand with the forefeet elevated. There is a pronounced abdominal component to the respirations. Cyanosis may occur, and airflow may be markedly reduced in severe cases. On auscultation there is an obvious disparity between the two sides; bronchovesicular sounds will be diminished dorsally on the affected side or may be entirely absent. Those lung sounds that are audible have a harsh, high-pitched, large airway character similar to those of a consolidated lung, especially over the carina; these sounds seem to be distant, as if the animal were breathing in a barrel. The point of maximum intensity of the heart may be displaced, and tachycardia is often present. Percussion may reveal an abnormal resonance when compared with that of the normal side, and simultaneous auscultation and percussion may produce a “ping” over the thorax. SC emphysema is a fairly common feature, and pleuritis is often a sequela. Differential diagnoses of the inciting cause should include the various causes of ARDS, bronchopneumonia, viral pneumonias (especially BRSV), pleural effusions, diaphragmatic hernia, other space-occupying lesions (large abscesses, tumors), and clostridial infections.[633]

Pneumothorax can be diagnosed with radiographs, transthoracic ultrasound, or thoracocentesis[632]; radiographs and ultrasound will also be useful to characterize the extent of any underlying lung disease. Other diagnostic tests to characterize underlying lung disease as described for infectious bronchopneumonia or interstitial pneumonia are appropriate.

If the affected animal shows signs of significant distress, the air in the pleural space should be evacuated. Evacuation can be accomplished by aseptically placing a teat cannula into the thoracic cavity at the dorsal aspect of the thorax at the tenth intercostal space and withdrawing air by use of an extension set and three-way stopcock. In some cases this method can be successfully used to intermittently remove air; in other cases, continuous removal with a pleural evacuation device (Pleur-evac A-8000, Deknatel Inc., Fall River Mass.) has been more effective.[634] If continuous evacuation is attempted the animal must be adequately restrained; this is likely to be possible only with hospitalized animals. Other treatment includes therapy appropriate for underlying acute or chronic pneumonia as described previously for infectious bronchopneumonia or interstitial pneumonia. External wounds allowing air to enter the thorax should also be closed if present.

31.78 DIAPHRAGMATIC HERNIA

31.78.1 Definition and Etiology

Diaphragmatic hernias are uncommon in ruminants but have been reported in calves, cattle, sheep,[635] and domestic buffalo.[636,637] The condition appears to be much more prevalent in the buffalo but otherwise is analogous to that in cattle.[638] Hernias may be congenital, but most appear to be acquired, including those occurring in neonates. A congenital weakness in the diaphragm may predispose to some cases. Causes include difficult parturition, external trauma, and, by far the most common cause, traumatic reticuloperitonitis (TRP).

31.78.2 Clinical Signs and Differential Diagnosis

Affected animals can be asymptomatic for a prolonged period.[638] Most affected cattle are in late gestation or have calved recently. The history may include decreased milk production, weight loss, capricious appetite, difficulty in swallowing or regurgitation, previous signs of abdominal pain (possibly associated with acute TRP), vomiting, and abnormal posturing of the head and neck on swallowing or regurgitation. Respiratory signs are actually fairly uncommon, with the exception of large congenital hernias, in which there is obvious severe dyspnea and abdominal respiration from birth. Occasional cough and dyspnea have been reported, and auscultation may reveal asymmetric sounds, with lack of lung or heart sounds in the affected area, or splashing sounds similar to those heard with pericarditis. GI signs are actually more common and include bloat, signs consistent with TRP, difficulty or pain on passage of a stomach tube, diarrhea, constipation, and ruminal hypomotility. Some cows may retch or vomit on regurgitation. Pain is evidenced by odontoprisis or grunting on regurgitation. The primary differential diagnoses are TRP, pericarditis, esophageal stricture, esophageal foreign body (choke), neoplasia, and abscessation.[638]

665
666

31.78.3 Diagnosis

Radiographs are the best means of confirming the diagnosis. The normal outline of the diaphragm and heart may be obscured,[636,637] and the honeycombs or foreign objects in the reticulum may be seen in the thorax[637] because

this organ is most commonly involved. Oral barium may also aid in the radiographic interpretation, particularly in early small hernias that will be missed on plain films. Pleuritis and other masses such as tumors and abscesses can also mimic hernias on plain films.[637] Because TRP is frequently involved, the CBC, pleural effusions, and abdominocentesis may reflect the septic process. In cases not associated with TRP, the pleural effusion may be hemorrhagic in acute cases and normal in chronic cases.[638]

31.78.4 Necropsy Lesions

The hernial ring is usually located at the junction of the musculotendinous portion of the diaphragm, about 12 cm ventral to the vena cava and slightly lateral to the midline. The ring is usually round to oval, with a diameter of 7 to 20 cm. The reticulum is usually herniated, most frequently to the right side of the chest. The liver, spleen, rumen, omasum, abomasum, intestine, and omentum may also be involved. Extensive adhesions usually develop between the herniated organs and the thoracic organs, and evidence of hardware can often be found.[639]

31.78.5 Treatment and Prognosis

Treatment is surgical. A two-stage approach is usually used. First, a standing left flank laparotomy and rumenotomy are performed; the defect is identified, foreign bodies are removed, and the ruminoreticulum is emptied. Because of the complete mediastinum, ventilatory assistance is rarely needed during this stage. Next, the animal is placed under general anesthesia with positive pressure ventilation. Various approaches have been used for this portion, including ventral midline, paramedian, semilunar postxiphoid, paracostal, and transthoracic with rib resection. The hernia is reduced, and the rent repaired with sutures or mesh grafts. Mesh grafts are contraindicated if infection is present.[638]

31.79 PLEURAL MESOTHELIOMA

Mesotheliomas have been reported in cattle and goats,[640] including a congenital form in calves.[641] Most are peritoneal, but pleural mesotheliomas also occur.[642,643] Mesotheliomas result in the accumulation of large amounts of fluid in the involved body cavity; signs of pleural mesothelioma are therefore related to pleural effusion. They include dyspnea, tachypnea, decreased lung and heart sounds (sometimes unilateral, with a concomitant increase in sounds on the normal side), dullness on percussion, exercise intolerance, cyanosis, tachycardia, anorexia, weight loss, decreased production, cough, and weak pulses. If peritoneal lesions are also present, as is common but not universal, ascites is also present. Radiographs confirm the pleural effusion, and thoracocentesis yields a serous, sometimes blood-tinged or gelatinous fluid. Cytologic examination may reveal reactive mesothelial cells. At necropsy the pleura is thickened and contains multiple nodules of gray to yellowish white tissue measuring several millimeters to several centimeters in diameter. Metastasis is uncommon. The tumor can be difficult to diagnose histologically and may resemble inflammation, pleural tuberculosis (“pearl disease”), or metastasis of another tumor.[641] There is no treatment.

31.80 MISCELLANEOUS CONDITIONS

JOHN C. BAKER

JOHN A. SMITH

31.81 LUNG TUMORS

Lung tumors are uncommon in large animals, with slaughterhouse surveys reporting an incidence of 19 per million cattle.[644] Those reported include pulmonary alveolar carcinomas, pulmonary adenomas, pulmonary adenocarcinomas, bronchogenic carcinoma, and pulmonary blastoma.[645–647] Malignant forms metastasize to regional lymph nodes and occasionally to other organs. Lymphosarcoma is the most frequent neoplasm to become metastatic to the lung, and uterine and ovarian adenocarcinoma may undergo metastasis to the lung.[647] Because many lung neoplasms in cattle are incidental findings at slaughter or necropsy, clinical signs are therefore not well documented. The lesions are typically discrete, round, yellow to gray masses distributed throughout the lung tissue. Tumors are most likely to be detected antemortem by radiographic examination. Differential diagnoses in such cases include pulmonary abscesses, mycotic pneumonias, and tuberculosis.

31.82 BRONCHOBILIARY FISTULA

A communication between the bile duct and a cavitating lesion in the lung has been described in a 3-year-old Charolais cow.[648] The cow had weight loss of 8 months' duration, before which she had been normal. Clinical signs were tachypnea, an expiratory press, bilateral crackles and friction rubs in the ventral lung fields, and a greenish yellow nasal discharge. The adventitious sounds were slightly more prominent on the right, and a silent area was detected in the caudodorsal right lung field. Radiographs revealed a cavitation with a fluid line in this area, and thoracocentesis yielded a sterile green fluid. At surgery, pleural-diaphragmatic adhesions and a mass in the right diaphragmatic lobe were found. A drain was installed, and fluid similar to bile, with a bilirubin of 3.1 mg/dL and alkaline phosphatase concentration of 2694 IU/L, was drained. At necropsy the lesion was a smoothlined cyst communicating by way of tracts through the adhesions with the biliary system and the bronchioles. Greenish fluid was found in the airways of both lungs.

32 Chapter 32 Diseases of the Alimentary Tract

Consulting Editors

Samuel L. Jones

Bradford P. Smith

32.1 DISEASES OF THE EQUINE ALIMENTARY TRACT

Samuel L. Jones, Consulting Editor

32.2 DIAGNOSTIC PROCEDURES IN THE EXAMINATION OF THE EQUINE ALIMENTARY SYSTEM

Samuel l. Jones

Anthony P. Pease

A thorough physical examination is compulsory, and tests that provide a minimum database (complete blood count [CBC], serum chemistries, and urinalysis) are often indicated in horses with suspected alimentary tract disease. Once a list of differential diagnoses is compiled, a number of ancillary diagnostic tests are available to narrow the possibilities. Each diagnostic test or procedure is limited in the type and extent of information that can be obtained, and therefore the clinician should select the complement of procedures that is most likely to provide the information required to make a proper diagnosis and determine the appropriate therapy.

32.3 RECTAL EXAMINATION

A systematic approach to examining the abdominal and retroperitoneal viscera should be established and applied during each examination to ensure that all pertinent regions and structures are examined. When feasible and if required, the patient should be sedated to allow a more thorough examination. In some cases, epidural anesthesia is required to obtain adequate access to structures during rectal examination. The principal goal of a rectal examination is to identify changes in size, texture, shape, or location of visceral organs, peritoneum, mesentery, vasculature, or objects that are normally not present.

In the pelvic region of the normal horse, the urethra and accessory sex glands (male) or the vaginal vault and cervix (female) can be palpated. The urethra is usually not discernible in the female, but abnormalities such as uroliths may be felt. In the caudal abdominal cavity the bladder, the uterus in females, and the pelvic flexure and small colon typically should be felt. The pelvic flexure and left ventral and left dorsal colons are normally located ventrally, on midline or toward the left side of the abdomen. The small colon, with formed fecal balls palpable, courses throughout the caudal abdomen, mostly on the left side. In females the left ovary can be felt in the left dorsal, caudal region of the abdomen. Both ovaries should be palpated in conjunction with palpation of the uterus. The peritoneal surface should be felt along the surface of the abdominal wall and the surfaces of the viscera. It should feel smooth, with no crepitus or irregularities. Advancing along the left side of the abdomen, the spleen can be felt as a smooth structure, with the caudal border having a well-delineated, tapered border. The size and location of the spleen are variable, because it can extend from the left body wall to the right ventral region of the abdomen.

Advancing cranially and dorsally, the left kidney can be palpated. The kidney should feel smooth with the renal pelvic fissure discernible, although in the overweight horse extensive perirenal fat may obscure this detail.

From the left kidney, moving toward midline and extending from the abdominal aorta, the cranial mesenteric and ileocecocolic arteries may be felt. Palpation of fremitus in these arteries may be associated with arteritis and thrombus formation secondary to *Strongylus vulgaris* larval migration, although this association has been very inconsistent. Fremitus is frequently absent when severe arteritis exists, or the arteries may be entirely normal and fremitus felt. Fremitus can often be elicited by compressing the wall of the normal artery, thus accelerating flow through the compressed lumen. The mesenteric root of the colon can be felt ventral to the cranial mesenteric artery. This should palpate as a mildly taut band of tissue extending from the dorsal midline ventrally. Excessive tension, displacement, thickening, or masses within the mesentery should be considered abnormalities. It may be possible to palpate an enterolith, fecalith, or gravel impaction in the transverse colon, although this may be beyond the reach of the examiner because the transverse colon is located cranial and medial to the left kidney.

Sweeping to the right side of the abdomen, the base and cupola of the cecum can be felt. The body of the cecum can be followed partially by sweeping along the medial aspect of the cecum, cranially toward midline. The cecum has a prominent ventral band and sacculations. Gas, together with ingesta that is soft and mainly of a fluid consistency, can be felt within the cecum. Firm or excessive ingesta suggests an abnormality.

Findings that are different from normal often must be differentiated as being variations of normal or truly abnormal. Some common abnormal findings include abnormalities of the peritoneal surface. Crepitus, or a “plastic wrap” texture, is indicative of gas secondary to trauma or infection. An irregular or rough surface may be indicative of fibrin on a visceral surface or neoplasia, or with a perforated intestine there may be ingesta adhered to a visceral surface. There are many abnormal presentations of the large colon, most of which are associated with signs of colic. Thickening of the wall of the colon may be appreciated on rectal palpation and is indicative of edema or cellular infiltration of the colon. Palpation of abnormal masses in the wall of the colon or associated with the colonic mesentery is indicative of infection, infarction, granulomatous colitis, or neoplasia.

667

668

Normally the small intestine is not discerned by palpation. Occasionally, though, peristaltic contractions may be felt in the small intestine as it courses across midline toward the base of the cecum. In some cases this will cause the small bowel to palpate as a firm, tubular structure. Relaxation of the peristaltic contraction should be discerned in such cases. Distention of small intestine is abnormal. In some cases the bowel may feel thickened, which can occur with ileal muscular hypertrophy, edema, or inflammatory disorders of the small bowel.

Other abnormal findings that may accompany disorders of the abdominal alimentary system include masses, adhesions, enlarged and thickened mesenteric arteries, and caudal displacement of the spleen (secondary to gastric distention or neoplasia).

32.4 PARACENTESIS

Abdominal paracentesis is performed routinely in patients with suspected disorders of the abdominal viscera. Cytologic examination of peritoneal fluid; white blood cell (WBC) and red blood cell (RBC) counts; protein, fibrinogen, lactate, phosphate, and glucose concentrations; lactate dehydrogenase (LDH), creatine kinase (CK), and alkaline phosphatase (ALP) activity; and pH can be quantitated. The results of peritoneal fluid analysis may help establish a specific diagnosis, but, more important, may reflect inflammatory, vascular, or ischemic injury to the intestine requiring surgical intervention.

32.5 ENDOSCOPY

There are two basic types of endoscopic equipment available: equipment based entirely on a fiberoptic system and equipment based on a video chip system. A typical endoscope found in many private practices is a fiberoptic endoscope that has an insertion tube that is 100 to 110 cm in length and 10 to 14.5 mm in outer diameter. The larger-diameter tube can be inserted only through the nasal passages of older yearlings and adults and is not suitable for alimentary endoscopy, whereas a diameter of 10 mm allows passage through the turbinates of young foals. An insertion tube of 100 cm is sufficient for esophagoscopy in foals up to approximately 3 months of age. For older animals, an insertion tube length of 150 to 180 cm is required for esophagoscopy.

An insertion tube length of 110 cm is sufficient to reach the stomach of foals up to 30 to 40 days of age. A length of 150 to 180 cm is required for weanlings, and 200 cm is usually required for yearlings and adults. An insertion tube length of 200 cm is sufficient to reach the stomach of all adults of warm-blooded breeds, although 280 to 300 cm is required to examine the pylorus in adult horses. A 280- to 300-cm-long insertion tube permits duodenoscopy in adult horses.

Before a gastroscopic examination, suckling foals up to 20 days of age are not routinely kept from nursing for more than 1 hour. Older foals and mature horses should not have solid feed for 6 to 10 hours so that ingesta from the stomach may be adequately emptied. Longer duration of feed deprivation (18 hours) is desirable to view the antrum and pylorus of horses. Many foals less than 30 days old do not require sedation for gastroscopy, although sedation with 0.5 mg of xylazine per kilogram may facilitate the procedure. Sedation is required if the foal is to be placed in a recumbent position so that the entire glandular portion of the stomach can be examined. Sedation of older foals and horses is required. Xylazine (0.5 mg/kg given intravenously [IV]) usually provides adequate sedation. For greater sedation, detomidine (0.005 to 0.05 mg/kg IV) or a combination of xylazine and butorphanol (0.01 mg/kg) are effective.

After insertion of the endoscope, the stomach is distended with air until the nonglandular and glandular regions of the gastric surface can be observed. Distention with air is tolerated by foals and horses and has been associated only rarely with adverse effects. Occasionally, sick neonates with poor intestinal motility developed small intestinal distention and experienced discomfort after gastroscopy.

More complete descriptions of techniques of gastroduodenal endoscopy can be found elsewhere.[1,2]

Endoscopy of the rectum and distal small colon can be performed with most flexible endoscopes in use in equine practice and should be preceded, as much as possible, by evacuation and saline lavage of the rectum and distal small colon. The mucosal surface should appear pink to pale red and should have a smooth, “velvety” appearance. Mucosal edema or thickening, hyperemia, irregularities, defects, tears, and intraluminal masses are abnormal findings. Because of the concern for trauma to the rectum and small colon, the horse should be adequately sedated and restrained before preparation and examination of the distal alimentary tract.

32.6 LAPAROSCOPY

Laparoscopy can offer valuable diagnostic information regarding the abdominal cavity and is only minimally invasive.[3,4] It should always be preceded by a thorough physical examination, including abdominal palpation per rectum, paying particular attention to the sites for trocar insertion to ascertain that there are no adherent masses or viscera in the area. If abdominocentesis is to be part of the diagnostic workup, it should be performed before laparoscopy because of the effect of laparoscopy on abdominal fluid values. In experimental animals undergoing

diagnostic laparoscopy with carbon dioxide insufflation, both the abdominal WBC count and the abdominal total protein increased.[5]

The indications for laparoscopy include palpable abdominal masses, enlarged viscera, adhesions, acute or chronic colic, weight loss, or the desire to obtain visceral biopsy specimens. Contraindications include adherent viscera or masses at the site of laparoscopic trocar insertion, diaphragmatic hernias, or extreme bloating. Horses with acute colic can be safely examined laparoscopically if one is careful when inserting the trocars and telescopes.

The basic instruments for laparoscopic examinations include a laparoscopic telescope, laparoscopic cannula and trocar assembly, fiberoptic light source and cable, insufflator, and biopsy and manipulation instruments. The 30-degree laparoscope allows better visualization of the less accessible areas compared with the 0-degree telescopes. Video cameras make visualization easier with less eyestrain but require more powerful light sources (250 watts). The cost of laparoscopic instrumentation has decreased recently as a result of the explosion of popularity of laparoscopy in humans, increasing the supply and availability of used instruments.

Horses should be fasted for 18 to 24 hours before most laparoscopic procedures; water is allowed on an ad libitum basis. Fasting increases intraabdominal visualization and decreases the possibility of penetrating a gas-distended viscus. The animal is restrained in standing stocks if the procedure is to be done while it is standing. Preoperative antibiotics, antiinflammatory drugs, tetanus prophylaxis, and a sedative analgesic combination are administered. It is important to administer the analgesics before abdominal insufflation. The flank areas are prepared for aseptic surgery. Local anesthetic agents are infiltrated subcutaneously (SC) and intramuscularly (IM) in the middle of the paralumbar fossa slightly above the crus of the internal abdominal oblique muscle for the insertion of the laparoscopic telescope. If additional instruments are to be used, their insertion sites are similarly anesthetized.

668

669

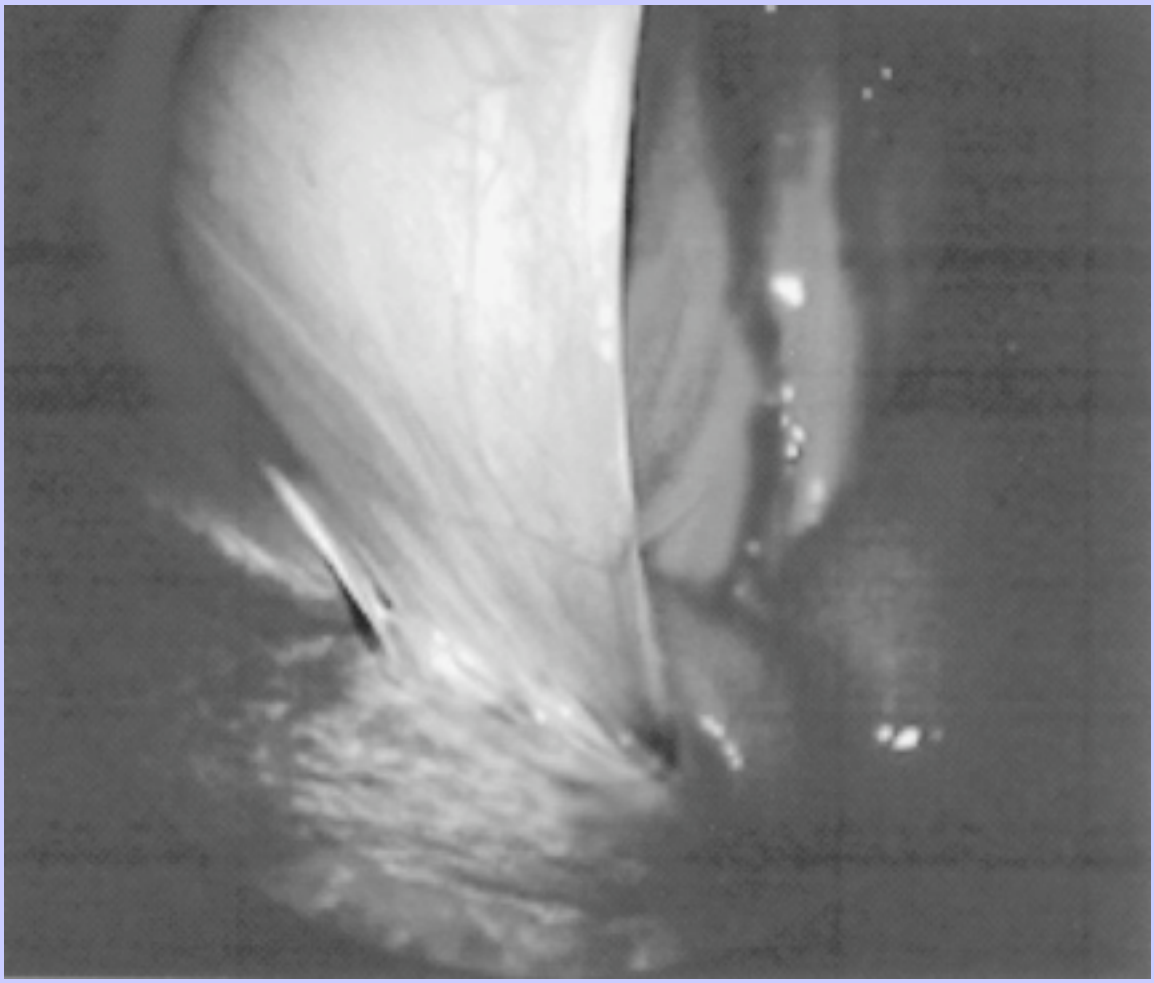
It is preferable to begin the laparoscopic procedure on the left side of the abdomen to minimize the chance of penetrating the cecal base. The horse is then draped and a stab incision is made. The laparoscopic cannula and trocar assembly are inserted through the musculature and into the abdominal cavity. It is useful to orient the trocar toward the opposite coxofemoral joint when inserting it. The trocar is exchanged for the telescope, and confirmation of entry into the abdominal cavity is made before insufflation is commenced. If the abdominal cavity has not been penetrated, a quick thrust with the telescope will usually penetrate the peritoneum. Insufflation of the abdomen with CO_2 to 8 to 10 mm Hg will usually be sufficient for most examinations.

Systematic examination of the abdominal cavity is then carried out. On the left side of the abdomen the spleen, left kidney, nephrosplenic ligament (Fig. 32-1), stomach, left side of liver, diaphragm, and ventral colon may be visualized cranially. Looking caudally, the examiner will see the root of the mesentery, the isolated small intestinal and small and large colon sections, the urogenital tract, the bladder, and the terminal rectum. The procedure is repeated on the right side of the abdomen. Looking cranially, the examiner will see the liver, epiploic foramen, right kidney, descending duodenum, cecal base, and large colon. Caudally, the urogenital tract, root of mesentery, and isolated pieces of intestine are visible. Liver biopsies and right kidney biopsies are taken from the right side. Left kidney and spleen biopsies are taken from the left side of the abdomen. Mesenteric lymph node biopsies are usually obtained via the left flank. Other masses are biopsied from the more accessible side. At the end of the procedure the abdomen is deflated, and the skin is closed with skin sutures only. Closure of the skin incision should wait until examination of both sides is completed in order to minimize subcutaneous emphysema.

In some horses with ventral or cranial abdominal masses as determined with ultrasound, it is useful to anesthetize the animal in dorsal recumbency for better characterization of the mass. Biopsies may be readily obtained. In horses with acute colic but without obvious signs indicating the necessity for surgery, laparoscopy can help in making the decision to continue medical therapy or proceed to surgery. Strangulated sections of small intestine can be seen, proximal enteritis can be diagnosed, and edema and vascular compromise to the large colon can be seen.

No abnormalities may be detected in some animals with very localized lesions, or lesions may be inaccessible, depending on location.

Fig. 32-1 Laparoscopic view of nephrosplenic ligament in a horse.



Laparoscopic complications are similar to those of any other abdominal exploratory procedure. Inadvertent penetration of a viscus may occur. The left kidney may be perforated if the laparoscope is inserted too far dorsally. The spleen may be penetrated if the laparoscope is inserted too far ventrally or is not aimed toward the opposite coxofemoral joint. The cecum may be perforated when entering from the right side. Fasting the horses and carefully inserting the laparoscopic trocars will minimize the occurrence of these problems. Subcutaneous emphysema occurs commonly but has not caused any clinical problems. The peripheral WBC count increased but stayed within normal limits in experimental animals undergoing laparoscopy.[5]

32.7 IMAGING OF THE ALIMENTARY TRACT

Anthony P. Pease

32.7.1 Radiography

In the horse the alimentary tract is a dynamic and complex environment to evaluate with any modality. Because of the size of the animal, as well as the distinct difference between air and soft tissue, radiographs are a useful diagnostic tool to evaluate the teeth, pharynx, esophagus, stomach, and intestinal tract. Portable x-ray units with maximal kVp settings up to 100 and the upper limits of the mAs settings at 30 make it possible for ambulatory practitioners to obtain diagnostic images of the head and cranial esophagus. However, to obtain images of the thoracic esophagus and abdomen, a referral clinic with a more powerful x-ray generator is usually required.

For the average foal, abdominal radiographs have been described using exposures ranging from 80 to 88 kVp and 20 to 26 mAs for the standard abdomen.[6] In adult horses, exposures range from 60 to 140 kVp and 20 to 70 mAs.[7,8] In order to completely evaluate the abdomen, it has been recommended that the abdomen be divided into four quadrants (cranioventral, midabdominal, caudodorsal, and caudoventral).[7] Large cassettes (35 cm × 43 cm) and fast screens are also needed to ensure a diagnostic image is obtained. Because of the large amount of scatter radiation produced from the high exposure and thickness of tissue penetrated, an 8:1 to 10:1 grid should be used.[6–10] Alternatively, an air gap technique can be used to prevent image degradation.

Availability of computed radiography (CR) and digital radiography (DR) has greatly increased the diagnostic capabilities of conventional radiographic examinations. Both of the systems available to the equine practitioner are considered indirect imaging modalities in which the x-ray photon interacts with an intensifying screen to convert the x-ray photons to light. This light then interacts with an imaging plate: film, as with a conventional radiographic system; within a photostimulable phosphor, as with CR; or within a flat-panel detector, as with DR. Regardless of the method, these images are considered “indirect” because the x-ray photon is first changed to light and then detected by the imaging medium.[11] The main benefits of CR and DR are the increased latitude of the film. It is possible to change the contrast and grayscale levels after the exposure if an adequate number of photons are available to the detector. The DR systems also offer a rapid evaluation of the image because the cassette is directly connected to the computer. This makes the portable systems able to show radiographic images within 10 seconds after the exposure is made. In contrast, the CR system requires the cassette to be placed into a reader in order to display the image. Finally, because both CR and DR are generally Digital Imaging and Communications in Medicine (DICOM) compliant, this allows any specialists with standard medical imaging software to view the images via a compact disk (CD) or via the Internet.

669

670

Survey radiography is generally helpful to evaluate the cervical esophagus for evidence of rupture as well as to evaluate the abdomen. Esophageal ruptures secondary to an obstruction or vigorous placement of a nasogastric tube result in a small volume of gas that tracks just dorsal to the trachea (Fig. 32-2). This can be confused with a tracheal laceration; however, with tracheal lacerations generally the gas accumulation will surround the trachea and the volume of gas within the subcutaneous tissues and the cranial mediastinum will be severe. In addition, esophageal obstructions, also called *choke*, can sometimes be identified on survey radiographs depending on the material that is causing the obstruction and the amount of air or contrast medium that is able to surround the structure (Fig. 32-3). Although the nature of the obstruction cannot be determined, the extent of the abnormality can sometimes be identified.

Abdominal radiography is useful to evaluate the small and large intestines for sand accumulation, enterolithiasis, impactions, or small intestinal disorders in foals. When sand is ingested, it generally will accumulate within the large colon along the ventral abdomen[8] (Fig. 32-4). Radiography has been found to be a useful method to monitor the resolution of sand impactions after medical management; however, sequential examinations are

needed to verify that the volume of sand has reduced.[8] If the volume of sand is large enough, it is difficult to determine if an enterolith is present because of summation of the two lesions. Enteroliths are a solid concretion of mineral that usually forms around a nidus, such as a metallic foreign body (Fig. 32-5). The mineral composition is varied, as illustrated by the different opacities present within the enterolith. Radiographs have a 96.4% positive predictive value to detect enteroliths in high-prevalence areas. These enteroliths were generally found to be within the midabdominal radiograph, and 67% of small colon enteroliths caused large colon distention, which was also identified on radiographs.[7] Impactions are more difficult to diagnose because usually there is just increased feed accumulation within the abdomen. Although no enterolith or obstruction is identified, granular material can be seen, usually within the ventral colon near the sternal flexure. This is because pelvic flexure impactions will cause the feed material to accumulate orad, causing distention of the left ventral colon (Fig. 32-6). Intestinal disorders such as functional ileus secondary to enteritis (Fig. 32-7) or obstruction secondary to intussusception or meconium impaction (Fig. 32-8) in foals can also be identified on abdominal radiographs. These images show large dilation of the small intestine, and differentiation between functional and mechanical ileus in foals is generally based on the size of the intestine and the volume of gas that is present.[9] Evaluation of the abdomen using ultrasound may aid in qualifying the small or large intestinal motility as well as identifying the source of an obstruction if the determination on radiographs cannot be made.

670
671

Fig. 32-2 Standing lateral radiograph of a 13-year-old Morgan gelding with an esophageal tear. Note the tubular region of small gas opacities caused by air trapped around the outer border of the esophagus *(arrows)*. An esophageal perforation secondary to an ingested foreign body was confirmed with endoscopy.

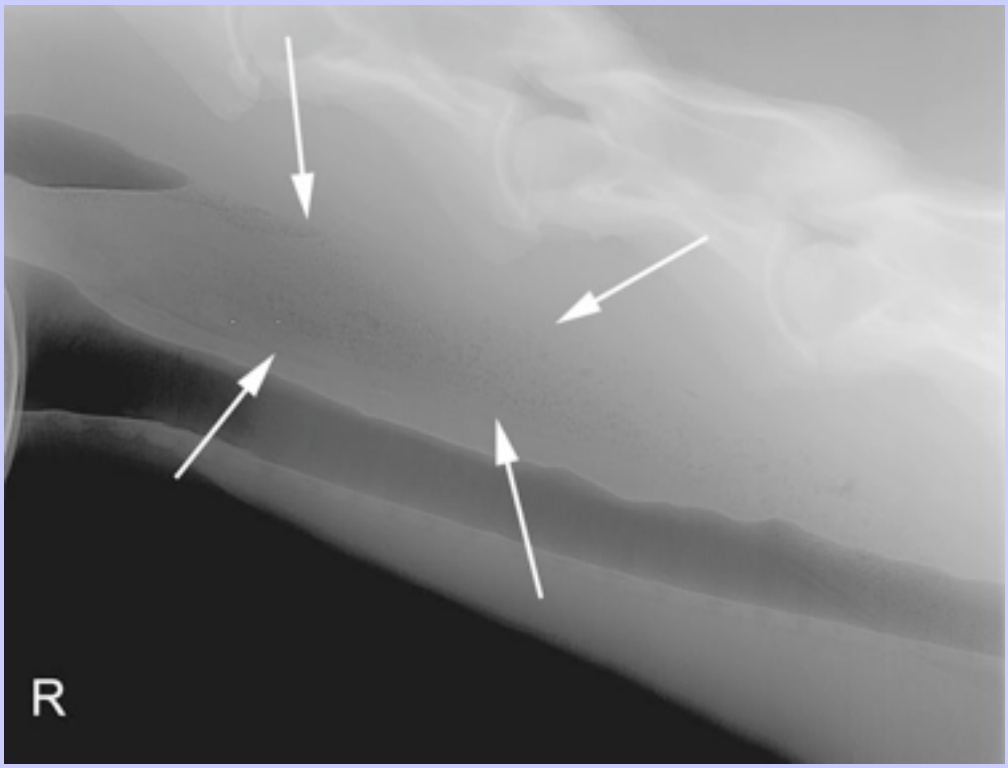


Fig. 32-3 Standing lateral radiograph of a 12-year-old quarter horse mare. Note the ovoid mass surrounded by gas just dorsal to the trachea *(arrows)*. This lesion was a mixture of hay and grass.

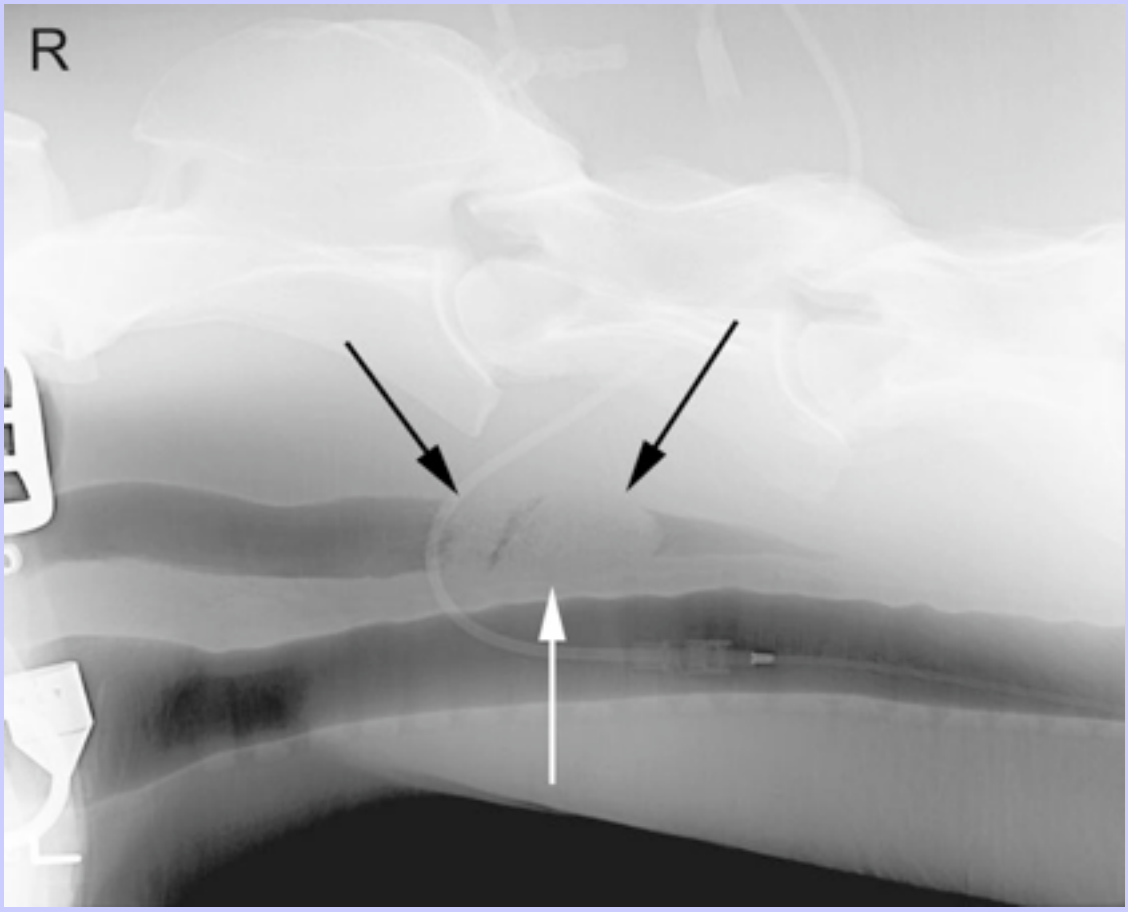

Fig. 32-4 Standing lateral radiograph of a 4-year-old Arab mare with a history of colic. Note the large amount of opaque material within the ventral colon, likely secondary to sand accumulation.

Fig. 32-5 Radiograph of enterolith obtained after surgical removal from the small colon. Note the variation in opacities caused by the various types of mineral that are contained within the enterolith.

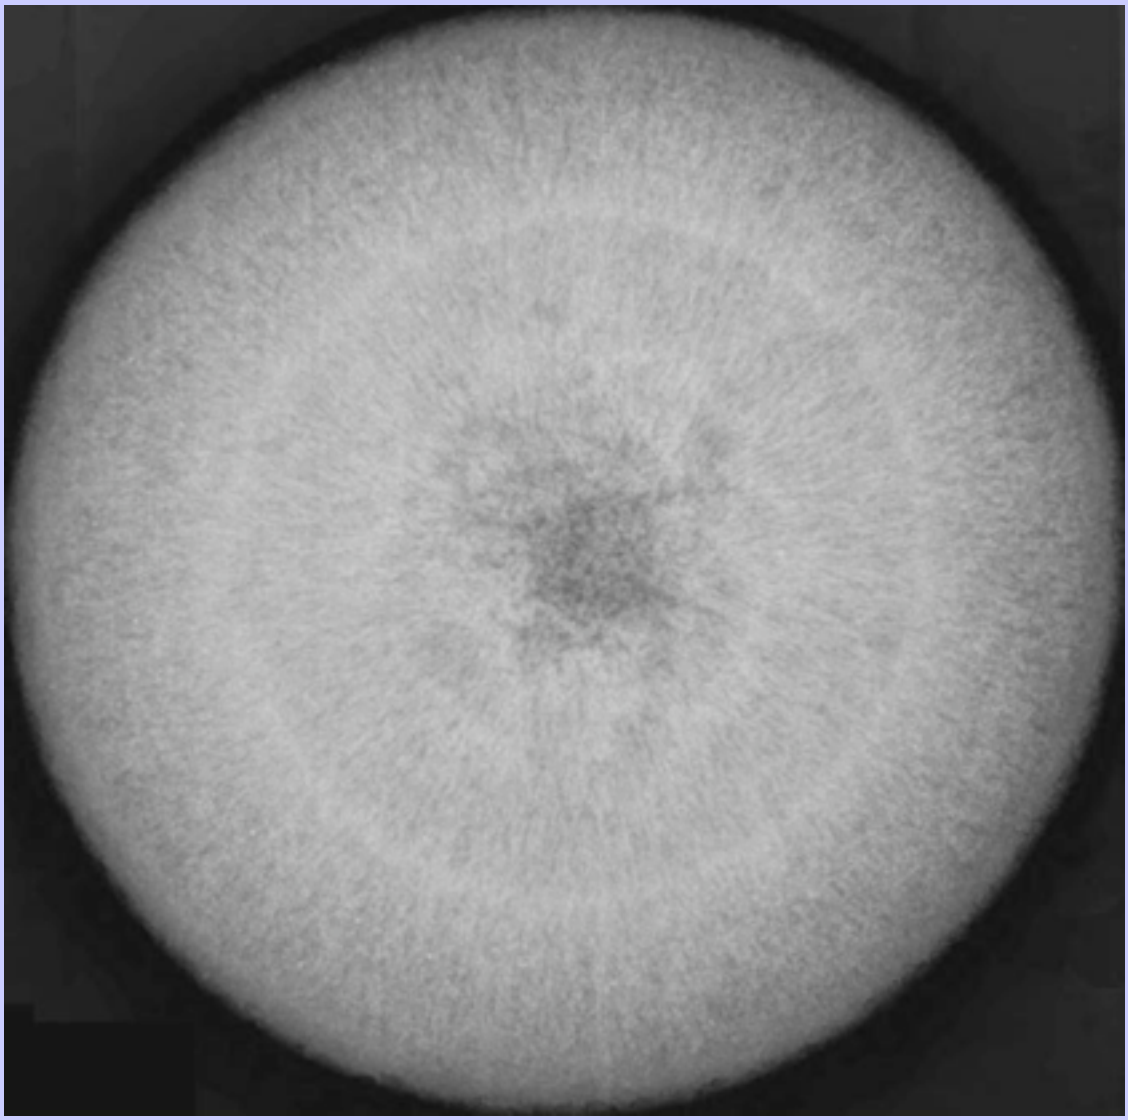

Fig. 32-6 Standing lateral radiograph of a 3-year-old Paint horse gelding with a pelvic flexure impaction. The radiograph shows the sternal flexure with a large amount of granular material and a small amount of sand accumulation in the ventral colon.

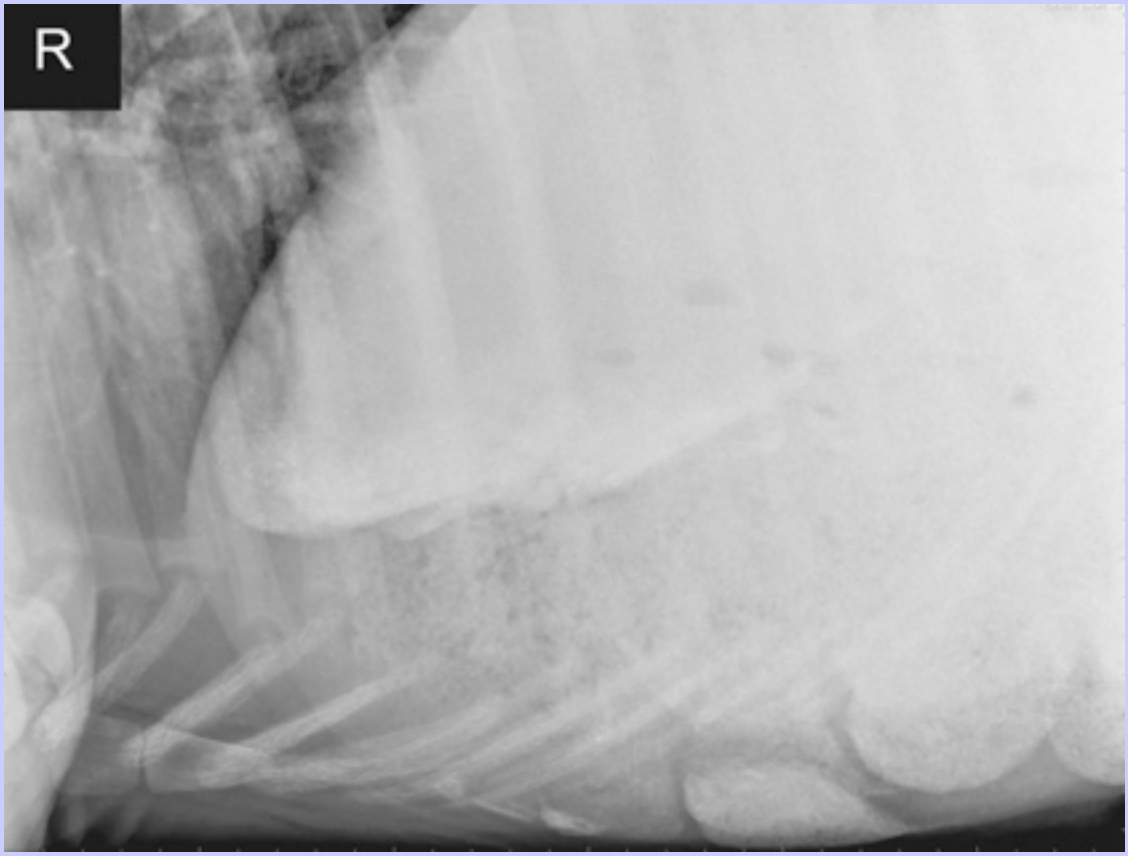

Radiography also allows for the use of contrast medium administration to further outline the alimentary tract as well as evaluate pharyngeal function and esophageal motility.[12–14] In my opinion, first administering approximately 60 mL of barium sulfate paste or liquid orally via a 60-mL dosing syringe and obtaining radiographs of the laryngeal region and esophagus provide useful information about swallowing as well as large obstructions. If the barium liquid is identified dorsal to the soft palate, within the larynx or trachea, abnormal pharyngeal function is likely present.[12] The barium paste will coat the pharynx and esophagus and is useful to identify any ulcerations or irregularities in the mucosal surface. After those procedures have been performed or if there is no evidence of an oropharyngeal dysphagia, then an esophagram is performed. This procedure is done using approximately 200 to 500 mL of barium sulfate liquid diluted 1:1 or 2:1 with water to bring the total volume to 500 to 1000 mL. This liquid is administered through a nasogastric tube or cuffed endotracheal tube placed within the cranial esophagus to the level of C2 to C3. If a cuff is available, the cuff can be inflated with approximately 10 mL of room air. A radiograph is then made to verify that the tube is not within the trachea, and when it has been confirmed that the tube is within the esophagus, the dose of barium is administered using a stomach pump. Toward the end of the dose, while still pumping the liquid, radiographs of the cranial, mid, and

671
672

caudal esophagus are obtained (Fig. 32-9). The use of the pump provides distention of the esophagus to help identify strictures or irregularities in the esophageal wall.

Fig. 32-7 Standing lateral radiograph of a 1-day-old, premature quarter horse filly. Note the large amount of gas-distended intestine. Because of the large amount of small intestinal distention, functional ileus is the primary differential diagnosis.

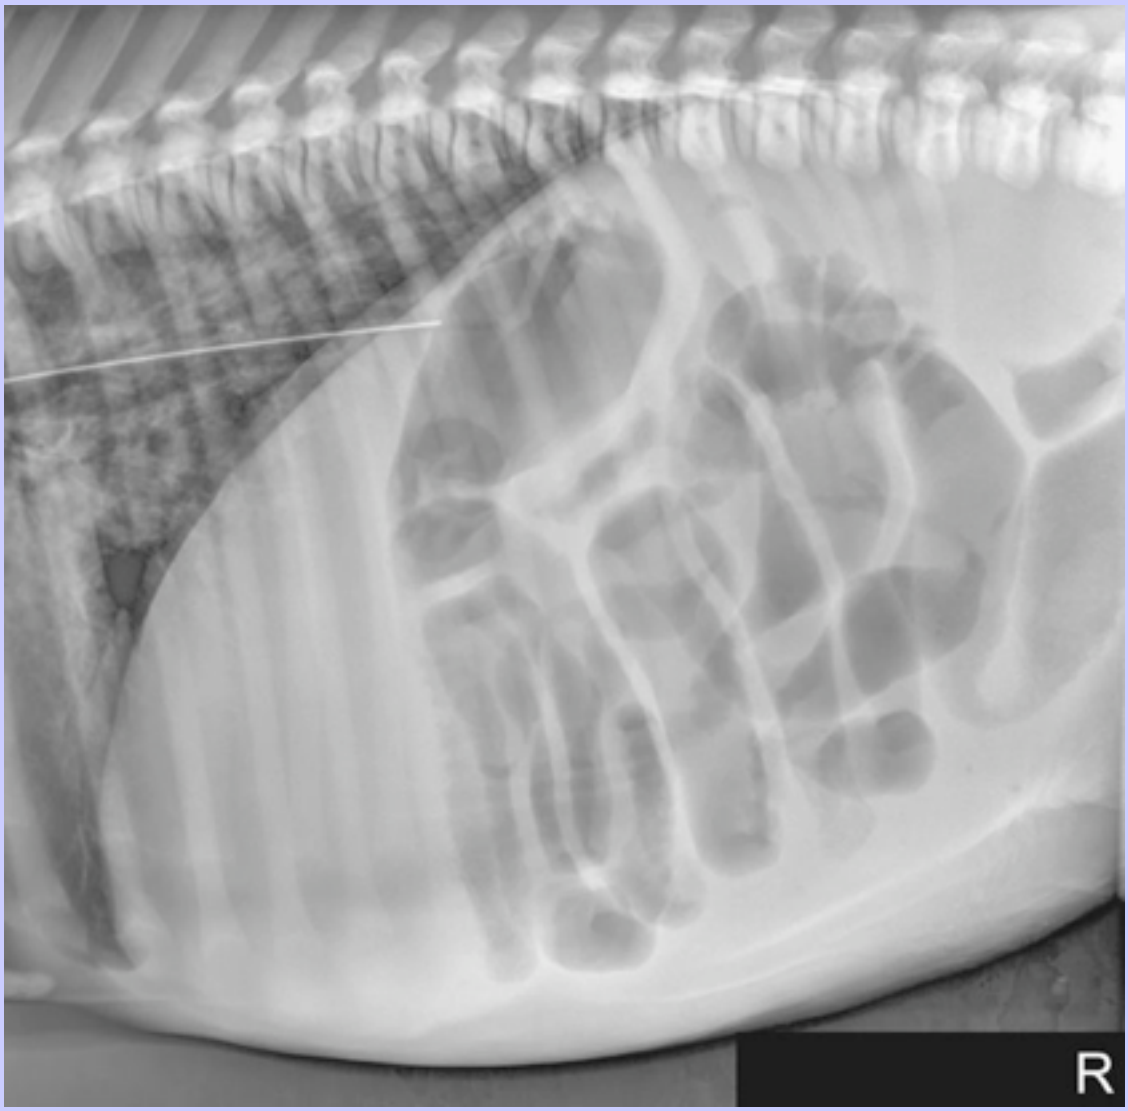

Fig. 32-8 Standing lateral radiograph of a 2-day-old thoroughbred colt with a meconium impaction. Note the large amount of gas distention of the colon.

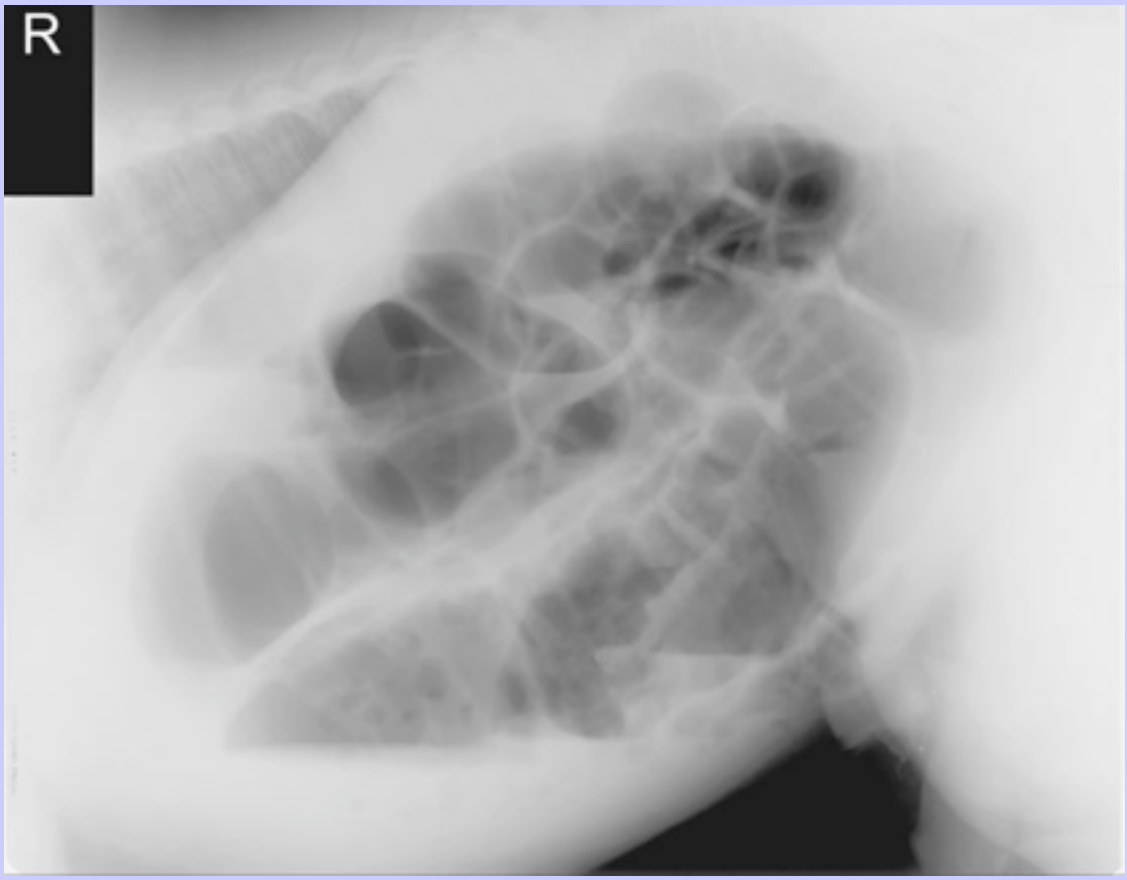

Fig. 32-9 Standing lateral radiograph showing a normal esophagram using barium liquid. The *arrow* marks the region where the nasogastric tube ends. This is approximately at the level of C3.

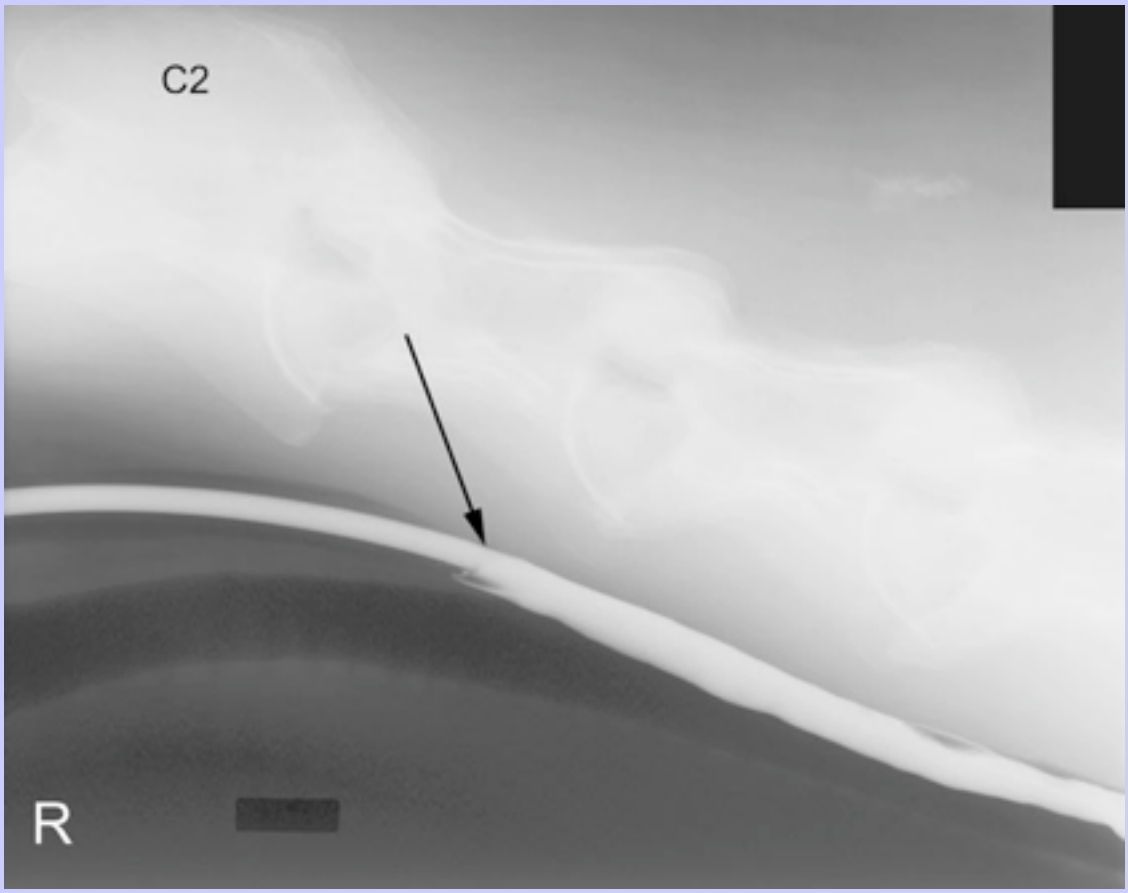

Fig. 32-10 These are transverse **(A)** and three-dimensional reconstructed computed tomography images **(B)** of the head of a 4-year-old pony mare with chronic draining tracts from the mandible. The *arrows* illustrate the tract through the mandible that communicates with the apical portion of the left mandibular first molar (tooth #309).

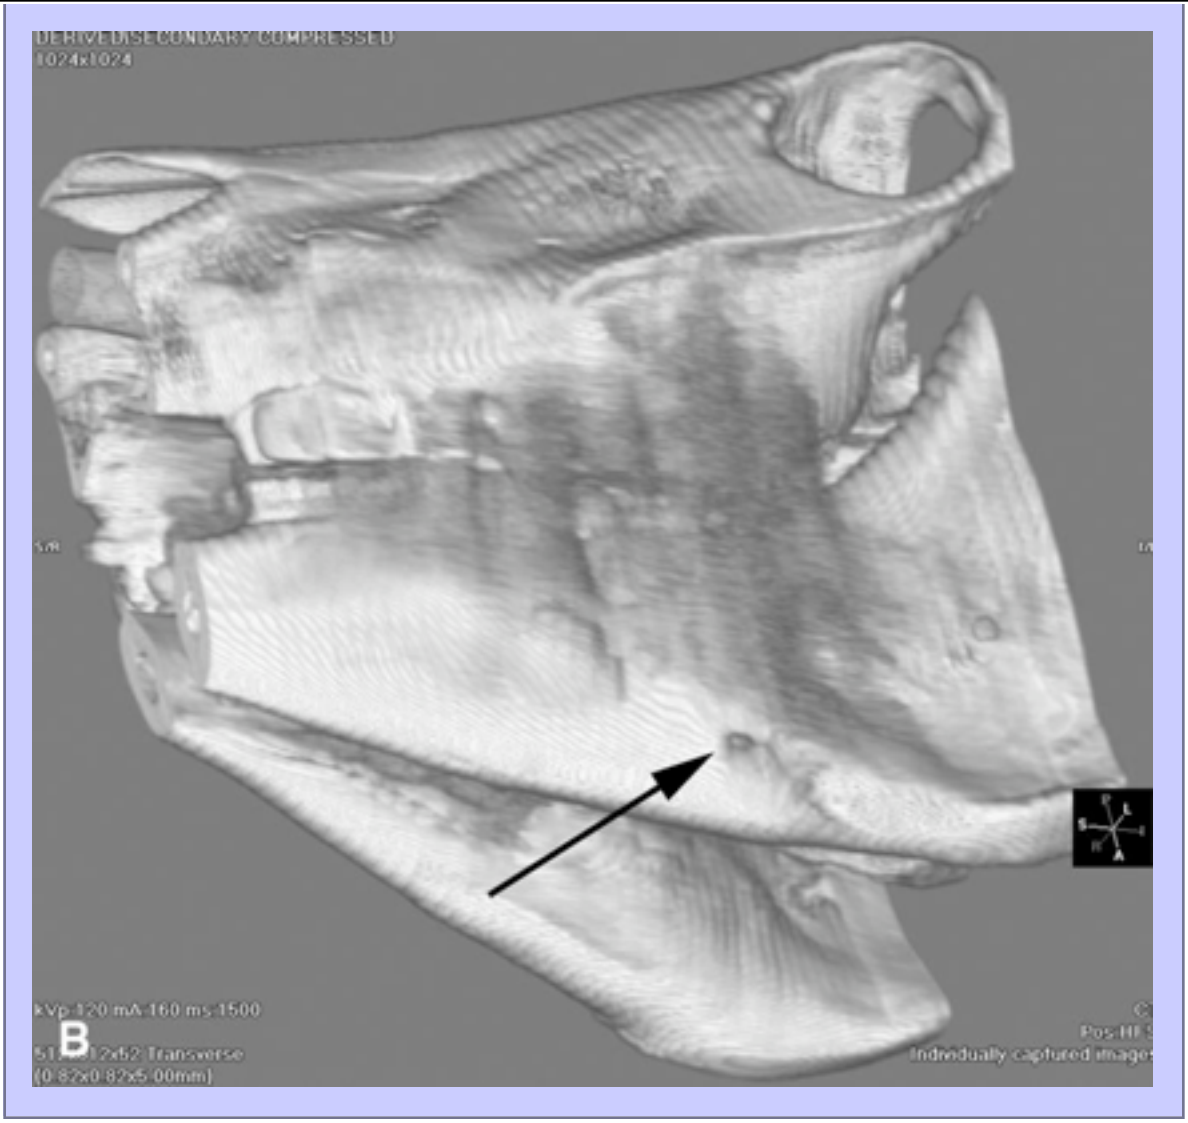

Positive (barium sulfate) and negative (room air) contrast medium radiography have also been used to evaluate the stomach and intestinal tract through oral administration of contrast medium,[6,15,16] and the rectum and colon have been evaluated via retrograde administration of contrast medium.[16] These methods allow for the evaluation of the stomach, intestinal tract, and rectum for regions of obstruction as well as ulcerations, tumors, motility disorders, and/or malformations. Although these methods have been described, ultrasound has virtually eliminated the need to expose personnel and patients to the repetitive, high doses of radiation needed to obtain sequential radiographs of the abdomen.

Computed tomography (CT) and magnetic resonance imaging (MRI) are of little use for evaluation of the alimentary tract (except for the head). This is mainly because of the size of the patient compared with the size of the gantry and bore in CT and MR units, respectively. Dental disorders such as abscesses and fractures can be clearly seen on CT images, especially after three-dimensional reconstructions (Fig. 32-10), and CT is also useful to detect pharyngeal and esophageal masses that may not be fully identified with conventional radiographs. CT and MRI can be used in foals that are able to be placed within the gantry or bore of the magnet; however,

because of the motion of the gastrointestinal tract and the long acquisition times used with respiratory gating sequences, MRI has not been used widely to evaluate the thorax or abdomen. A single case report has been published that described the use of contrast esophagraphy and CT to aid in the surgical planning of a persistent right fourth and left sixth aortic arch that caused a vascular ring anomaly in a foal.[17] However, the applications for these technologies have yet to be realized.

672

673

32.7.2 Ultrasound

Ultrasound machines have become lightweight, extremely portable, and affordable to the general practitioner. Although the machine is affordable, image quality is highly dependent on the ultrasound probes available for the examination and experience of the sonographer. These ultrasound probes come in various shapes and sizes including linear array probes, curvilinear probes, and sector-phase array probes. The physics behind the probe technology is beyond the scope of this text, but the main generalizations are that phase array probes are mainly used for cardiac examination, curvilinear probes give a large field of view, and linear array probes give exceptional superficial detail. For abdominal evaluation, a curvilinear probe is the most practical choice. The second choice offered with probe technology is the frequency. Frequency of ultrasound probes determines both the resolution and the penetration that can be achieved. The higher the frequency of the probe selected, the better the image quality (resolution). However, the increased resolution comes at the cost of penetration. A 10-MHz probe can generally image only approximately 6 cm into the abdomen, whereas a 1-MHz probe can image approximately 30 to 36 cm. For this reason, one should select the highest frequency probe possible to image to the desired depth. For example, if the ventral colon were examined, because it is relatively close to the skin surface (approximately 5 cm), then an 8- to 10-MHz probe would give the best detail for the desired depth. If the nephrosplenic space were to be imaged, this structure is approximately 12 to 15 cm deep from the skin surface, and a 5-MHz probe would be needed. This will cause a reduction in image quality, but the sacrifice is needed to gain the desired depth. The ultrasound examination requires the use of large volumes of isopropyl alcohol to wet the hair and to serve as a coupling medium to provide airtight contact between the skin and the probe. Acoustic coupling gel and clipping can be performed to enhance image quality, but in my experience, using isopropyl alcohol provides a good image, and clipping can be done in limited areas as needed to enhance the image quality.

In the last 5 years ultrasound has come to the forefront of evaluation of the equine alimentary tract, primarily centering on the abdomen. Ultrasound has been used in foals to determine the growth rate and normal appearance of thoracic and abdominal organs[18] and in adult horses to evaluate the gastrointestinal tract for causes of pain including torsion, small intestinal obstruction, colon impaction, large colon displacement, intussusception, strangulating lesions, and enteritis and colitis.[10,19–23] This modality is even more useful because it provides real-time information to help assess contractility of the intestine. Although this has been explored using both standard two-dimension imaging, also called *B-mode* or *brightness-mode* imaging, and spectral Doppler imaging,[24] the presence of gas within the bowel and the fact that the bowel is usually perpendicular to the image plane makes quantitative evaluation of intestinal contractility difficult at best. When compared with radiography to identify intestinal sand accumulations, ultrasound was found to be 87.5% sensitive and specific using radiography as the gold standard.[10] The main limitations are the artifacts secondary to gas within the colon and the fact that gas and mineral are both echogenic on ultrasound, whereas they have opposite opacities on radiographs.

Ultrasound evaluation of horses with abdominal pain (colic) provides a rapid method to identify abnormalities within the gastrointestinal tract. Distention of the small intestine to a diameter greater than 5 cm has been strongly associated with strangulating or obstructing lesions[19] (Fig. 32-11). In foals with intussusception, the small intestine appears enlarged and there is generally distended small intestine orad to the lesion; however, at

the site of the intussusception there is a normal-appearing small intestinal wall (intussuscipiens) surrounded by a larger structure that appears to surround the inner small intestinal wall (called the *intussusceptum)*[19] (Fig. 32-12). Large colon torsion occurs when the large colon rotates 360 degrees or more around the root of the mesentery to cause occlusion of venous drainage while maintaining arterial flow. This causes the wall to become thick and edematous. If ultrasound is performed in the cranioventral abdomen, just caudal to the xiphoid process, then a colon wall size greater than 9 mm is 100% specific for a large colon torsion[21] (Fig. 32-13). A large colon displacement would have minimal to no vascular compromise, so it would be an ultrasound diagnosis based on exclusion. Chronic displacements did have a mild amount of edema in the colon wall, causing the size to be approximately 7 mm thick but never greater than 9 mm in the one study described.[21] The colon and small intestinal wall will also become thick with inflammation. Small intestinal wall thickness greater than 4 mm is indicative of inflammation.[19] The right dorsal colon can be imaged in the right tenth to twelfth intercostal space around the region of the costochondral junction, and a focal wall thickness of 9 to 12 mm has been identified with right dorsal colitis.[23]

673

674

Fig. 32-11 Transabdominal ultrasonographic image of a 6-year-old thoroughbred gelding with acute onset of colic. The small intestine is 7 cm in diameter and was noted to have minimal to no contractility. This is consistent for mechanical ileus. A strangulating lipoma was identified at surgery. Courtesy of Cornell University.

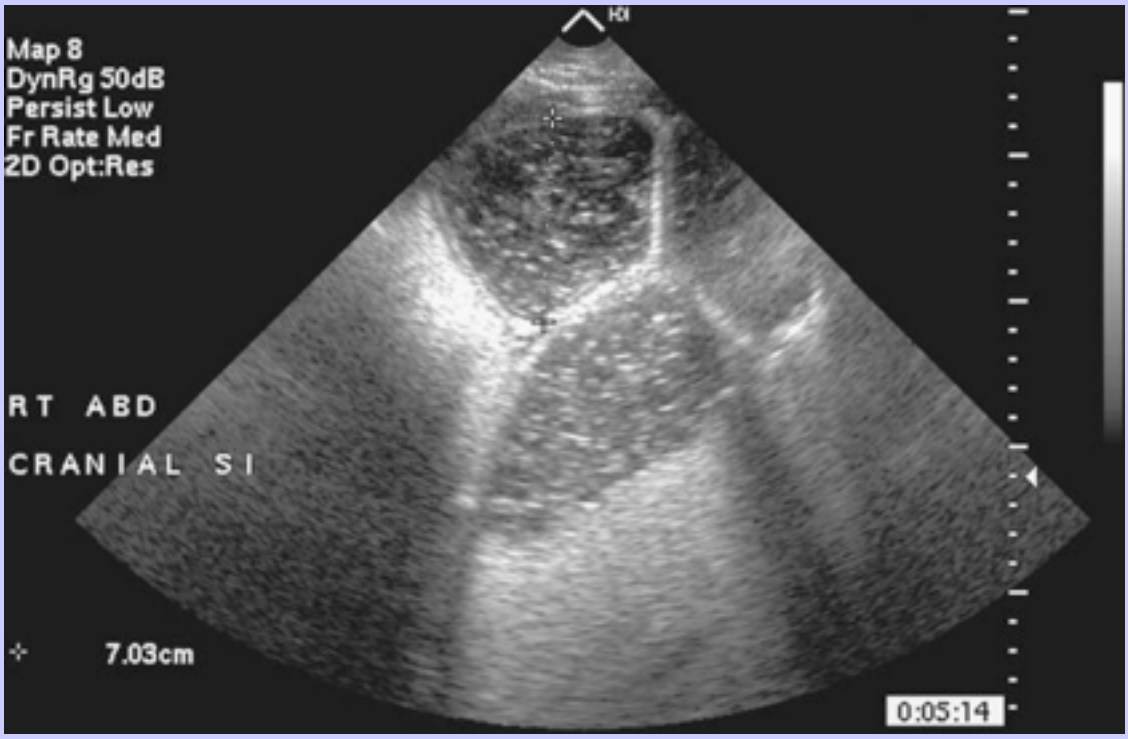

Fig. 32-12 Transabdominal ultrasound image of an adult standardbred mare. The image shows an inner intestinal structure surrounded by a second intestinal structure consistent with an intussusception. At surgery this was confirmed as an ileocecal intussusception. Courtesy of Cornell University.

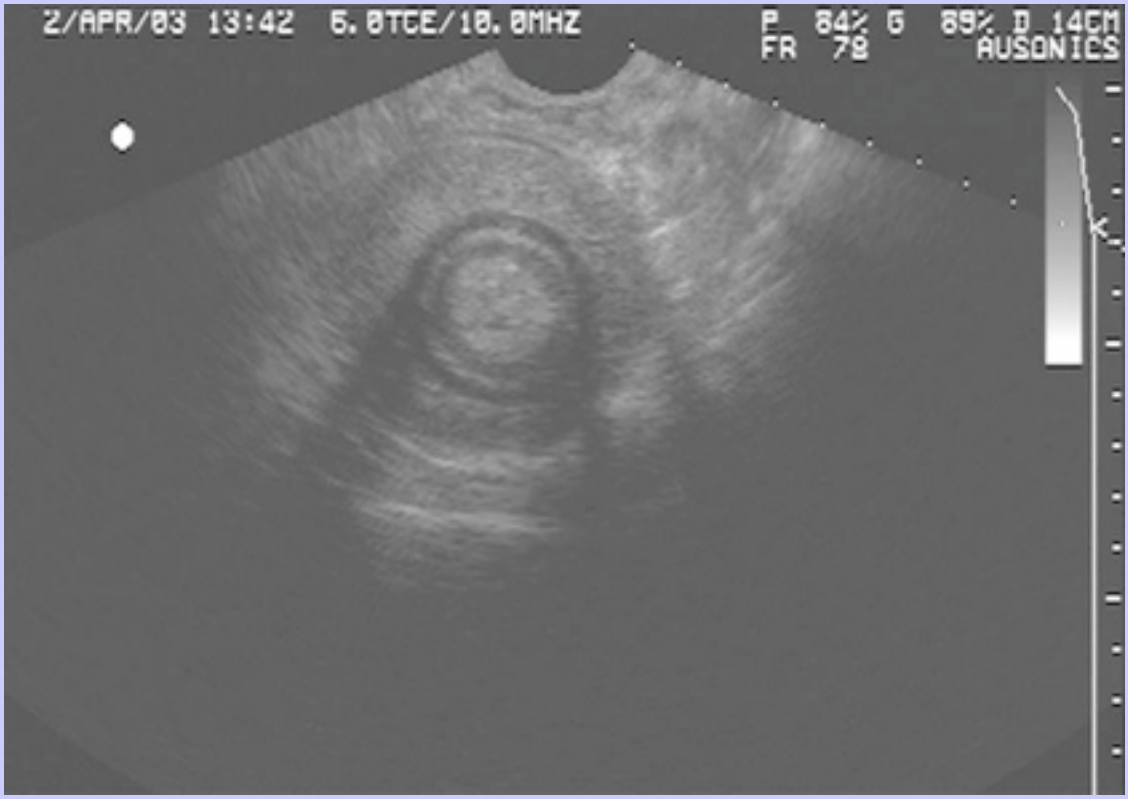

Fig. 32-13 Transabdominal ultrasound images of the large colon. **A**, In colon torsion the large colon wall is severely thick (2 cm) secondary to edema. For comparison, a normal colon wall thickness (**B**) should be 0.2 to 0.4 cm in thickness.

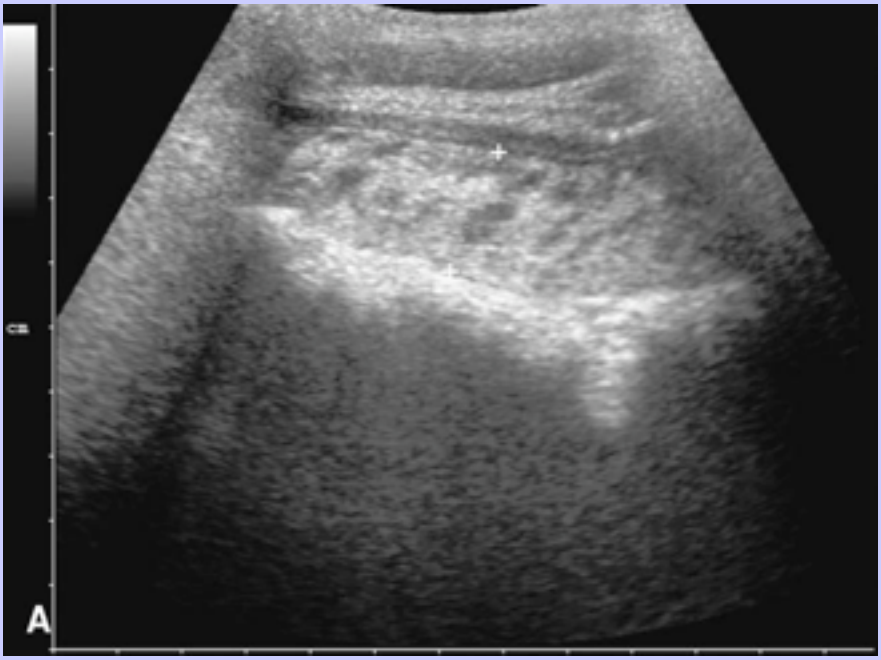

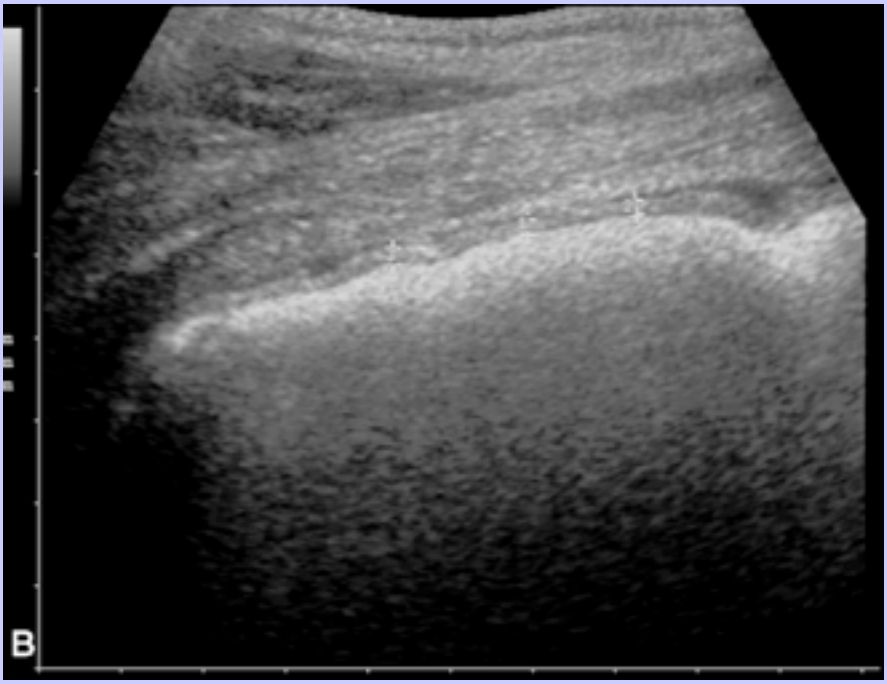

32.7.3 Scintigraphy

Nuclear medicine is a widely used modality to image the gastrointestinal tract in humans and animals. Although physical obstruction can be assessed with endoscopy, ultrasound is unable to identify the pylorus in the normal horse because of the peripheral nature of the colon and colonic gas. Nuclear medicine provides a functional evaluation of the pylorus to determine if delayed gastric emptying compared with normal horses is present. This modality works better than gastric emptying with barium sulfate because of the minimal invasive nature and ease of acquisition of images. However, the need for a gamma camera to generate the images and the licensing requirements to handle radioactive material make this modality less universally available. The primary use for evaluating the gastrointestinal tract with scintigraphy is to evaluate gastric emptying time.[25–28] Two protocols have been outlined in the references provided. The first uses the readily available technetium-99m pertechnetate (^{99m}Tc) bound to disofenin or sulfur colloid.[26,29,30] This combination of radioisotope and radiopharmaceutical is fed in a pelleted ration alone or mixed with radiolabeled eggs. The normal range for the $t_{½}$ gastric emptying has been reported to be 1.49±0.17 hours[30] and 1.56±1.08 hours.[29] The other method is the carbon-13 (^{13}C) bound to octanoic acid breath test (^{13}C-OABT). This method was validated compared with the ^{99m}Tc sulfur colloid and found to have similar results compared with the solid phase gastric emptying $t_{½}$.[24] The main difference is that the ^{13}C-OABT is measured in the exhaled breath of the horse and with spectroscopy rather than using a gamma camera. The rationale for ^{13}C-OABT is that because a gamma camera is not needed, this test may be more portable and useful for field investigations.[29]

Another nuclear medicine procedure in the realm of alimentary tract evaluation involves the use of ^{99m}Tc hexamethylpropyleneamine oxime (^{99m}Tc-HMPAO). This procedure allows for radiolabeling WBCs in order to determine areas of inflammation.[31,32] The use of ^{99m}Tc is a matter of convenience because it is also used in equine bone imaging. Thus, detection equipment, such as a low-energy, all purpose collimator, is readily available in many practices. HMPAO is used because it binds to granulocytes and therefore should travel to areas of increased inflammation.[32] HMPAO also associates with the reticuloendothelial system, enabling localization within the lungs, liver, spleen, kidneys, and urinary bladder. The main drawback is that with the activity bound to WBCs there is a general lack of anatomic information, which can cause lesion localization to be difficult.[32] Although this technique is expensive and labor-intensive, the results from the limited studies available appear encouraging.

32.8 BIOPSY

The decision about whether to obtain a biopsy is often based on the ease of obtaining a sample and the relative value of the evaluation that can be made. Very small samples, such as those obtained with an endoscope biopsy instrument, are relatively easy to obtain, but they provide limited information. Full-thickness bowel specimens, obtained by means of ventral midline or flank laparotomy, are more difficult to obtain, but they provide much more information.

Taking a biopsy sample by endoscopy allows the practitioner to choose the biopsy site on the basis of the appearance of the mucosal surface, which most frequently reflects an inflammatory disorder. Conversely, when a biopsy sample is obtained through laparotomy, the serosal surface of the bowel may not reflect a disorder within the bowel wall. In such instances it may be useful to obtain several biopsy specimens. Rectal mucosal biopsies are easily performed. Many instruments can be used to obtain the biopsy specimen, and a uterine biopsy forceps works

well. A fold of mucosa can readily be pinched between two fingers, and a sample of this tissue is obtained. The size of the sample is adequate for histologic or bacteriologic examination.

32.9 FECAL EXAMINATION

Cytologic, biochemical, bacteriologic, immunologic, and electron microscopic evaluations can be performed on fecal samples. In addition, observation of the consistency and color, the presence of foreign material such as sand or gravel, and the presence of parasites should be included in the examination of the alimentary system. In addition to fecal consistency, fecal particle size can be used to evaluate the efficiency of mastication or the colonic transit time. Increased particle size, with loose or watery stool, is suggestive of decreased colonic transit time.

674

675

Cytologic examinations are primarily used to evaluate the parasite burden of the animal. Ova of large and small strongyles, tapeworms, round worms, and *Strongyloides westeri* are most common. Coccidia are occasionally observed but are clinically unimportant. Examination of fecal WBCs has been advocated in the evaluation of horses and foals with enterocolitis. Because these cells are very labile, their presence in large numbers indicates that an inflammatory process is present and that the inflammation is in the distal colon or is associated with decreased transit time.

Determination of fecal occult blood has been recommended to diagnose gastric ulcers, duodenal ulcers, and other potentially hemorrhagic disorders of the alimentary tract. However, the usefulness of this test has been shown to be quite limited, because negative results can be obtained when blood is present in the proximal portion of the gastrointestinal tract.[33] The sensitivity of most commercially available tests is poor, giving negative results in the face of severe gastric bleeding.

Fecal culture is an essential component in the evaluation of many patients. In bacteriologic culture techniques for fecal samples, selective media that are designed to isolate *Salmonella* are routinely used. These media include selenite broth, tetrathionate broth, brilliant green agar, XLD agar, and *Salmonella-Shigella* agar. Less selective media, McConkey's and eosin methylene blue agars are desirable to culture other potential gram-negative bacterial pathogens such as *Escherichia coli*, but the mere presence of *E. coli* in the feces does not determine its pathogenicity. Enterotoxigenic *E. coli* have been isolated from foals with diarrhea, but special tests, such as polymerase chain reaction (PCR) assays, must be performed to determine whether an isolate produces enterotoxin.

Tests for detection of enterotoxins of *Clostridium difficile*[*] and *Clostridium perfringens*[†] in fecal specimens are available at diagnostic laboratories or can be performed using enzyme-linked immunosorbent assay (ELISA) kits.

The presence of rotavirus in a fecal sample can be determined by use of an ELISA or an agglutination test. Both assays test for the presence of viral antigen in the feces. The ELISA is reported to be more sensitive than the agglutination test but is less specific. Therefore the agglutination test is likely to give more false-negative results, and the ELISA test is likely to give more false-positive results. The ELISA test is more time-consuming and inconvenient to perform than the agglutination test. When rotavirus is a concern, particularly as a farm problem, a reasonable approach is to screen fecal samples with the agglutination test and repeat testing of samples that yield negative findings with the ELISA.

* *C. difficile* Tox A/B Test, TechLab, Blacksburg, VA.

† *C. perfringens* enterotoxin test, TechLab, Blacksburg, VA.

32.10 ABSORPTION AND DIGESTION TESTS

Tests that evaluate the ability of the equine intestinal tract to digest and absorb nutrients have a more limited clinical application than in human or small animal medicine, but they can be useful in the evaluation of horses with chronic weight loss, suspected small intestinal inflammation or neoplasia, gastric and small intestinal partial obstruction, and postoperative small intestinal malabsorptive disorders. For absorption tests to be diagnostic, the intestinal disorder must either be diffuse or affect the delivery to and transit through the small intestine.

Maldigestion tests are performed to evaluate exocrine pancreatic function and small intestinal mucosal brush border disaccharidase activity. Pancreatic exocrine deficiencies have not been described in the horse, probably because equine pancreatic secretions consist primarily of water and bicarbonate and have less enzymatic activity than in monogastric omnivorous species. Mucosal brush border disaccharidase-related maldigestion is relevant in viral and bacterial enteritides of foals, particularly rotavirus and coronavirus enteritides. As a result of these viral infections, there is loss of the superficial villous epithelial cells of the small intestine, in which the disaccharidases lactase, cellobiase, maltase, sucrase, and trehalase are located.[34] Lactase levels are greatest in young suckling foals, and loss of this enzyme activity, secondary to loss of the mucosal villous cells, leads to lactose maldigestion. Lactose tolerance can be tested by administering a 20% solution of D-lactose at a dose of 0.5 to 1 g/kg. This dose should result in an approximate doubling of the serum glucose level within 60 minutes of administration.[35]

Clinically applicable absorption tests include the D-glucose and D-xylose absorption tests. The glucose absorption test has the advantage of being relatively easy and inexpensive to perform. However, cellular uptake and metabolism of glucose, as well as intestinal absorption, influence the results and thus are undesirable variables. The xylose absorption test is therefore advantageous because it more directly measures intestinal absorptive capacity. The results of both tests, though, are affected by gastric emptying rate and small intestinal transit time. In the United States, D-xylose is available only through chemical suppliers and only for research purposes; its availability for clinical diagnostic use is restricted.

The D-glucose and D-xylose tests are performed similarly. After an 18- to 24-hour fast, a 10% solution of D-glucose or D-xylose, 0.5 to 1 g/kg, is administered through a nasogastric tube. For the measurement of glucose, blood is collected in sodium fluoride tubes; and for the measurement of D-xylose, blood is collected in heparinized tubes. Samples are taken at 0, 30, 60, 90, 120, 150, 180, 210, and 240 minutes after administration. Peak levels, which normally range from 20 to 25 mg/dL, occur 60 to 120 minutes after administration, and levels thereafter should decrease. The normal curve resembles an inverted V. Variability in absorption curves occur as a function of age and type of feed the horse is given.[36] Delay or flattening of the absorption curve may reflect delayed gastric emptying, increased intestinal transit time, or impaired intestinal absorption.[37] Accurate interpretation of the results of these tests depends on the results of other diagnostic evaluations. In addition, different types of diet have been shown to affect the height, although not the shape, of the absorption curves significantly. In general, diets that have a higher digestible energy content result in a lower peak in the curve.

32.11 BREATH TESTS

In humans, dogs, and cats, breath tests are used to assess a variety of intestinal disorders. The urea breath test is used as part of an assessment of *Helicobacter* status of the patient,[38] but this is not an issue for horses. The hydrogen breath test is used in assessments of intestinal bacterial overgrowth and in determination of carbohydrate digestion and absorption in the intestine. In patients with an abnormal intestinal bacterial population or carbohydrate malabsorption, there will be excessive bacterial fermentation of carbohydrate, with one byproduct

being hydrogen. Because hydrogen is freely diffusible from the bowel into the blood, and from the blood into the alveoli, measurement of exhaled hydrogen gas can be used to assess the status of intestinal bacterial fermentation of carbohydrates. In horses, the hydrogen breath test is most applicable to conditions in which there is carbohydrate malabsorption and thus increased delivery of soluble carbohydrate to the large intestine for bacterial fermentation to occur. There are two reports of this technique in horses, one in which different carbohydrate substrates were evaluated in ponies[39] and another in which the hydrogen breath test was used in conjunction with D-xylose absorption in nine horses with a variety of clinical disorders.[40] In the study with ponies ($N = 7$), fasting resulted in negligible levels of breath hydrogen excretion. Sustained increases in breath hydrogen concentration greater than 10 ppm were observed for all ponies after the ingestion of oats or the administration of wheat flour, for three ponies after the administration of glucose and xylose, and for two ponies after the administration of lactulose and lactose. The pattern of breath hydrogen excretion was subject to variation among animals after the ingestion of identical test meals. In the clinical study the diseased horses showed higher fasting breath hydrogen (H_2) levels (range 7.5 to 61.5 ppm) than normal horses (range 0 to 5 ppm). After xylose administration, none of the healthy animals showed an increase in breath H_2 production, and five of diseased animals showed increases in breath hydrogen. In this group of patients, abnormalities in hydrogen breath measurement were more apparent than abnormalities in D-xylose absorption.

676

32.12 DENTISTRY AND ORAL DISEASE

Jack Easley

The horse has evolved over millions of years to become a continuously grazing animal and in doing so has developed its own dental form and function. The horse's oral and dental structures provide it with the ability to detect, prehend, masticate, and begin the digestion of forage. As we have domesticated and confined the horse, we have altered its diet to consist of less continual grazing and more interval feeding of dry hay, grain, processed forages, and other concentrates. Selective breeding and domestication have increased the incidence of equine dental and oral disease in today's equine population.

32.13 DENTAL AND ORAL ANATOMY

The structures the horse uses in eating include tactile and prehensile lips; hypsodont incisors, premolars, and molars; facial bones; muscles of mastication; tongue and hard and soft palates; buccal mucosa; cheeks; olfactory organs; taste buds; salivary glands and ducts; and blood vessels and nerves that support these structures. The equine mouth is a long cylindric cavity that is the beginning of the alimentary canal and is commonly referred to as the *oral cavity*. The muscular lips make up the entrance to the mouth, which is bounded laterally by the cheeks, dorsally by the hard palate and ventrally by the body of the mandible and the mylohyoid muscles. The caudal aspect of the mouth is composed of the soft palate, root of the tongue, and epiglottis and is continuous with the oropharynx.[41,42]

The blood supply to the mouth is derived from the maxillary, mandibular, labial, and sphenopalatine arteries. The venous drainage is chiefly through the linguofacial veins. Sensation to the mouth and cheeks is derived from the trigeminal nerve (cranial nerve V), and motor function from the facial nerve (cranial nerve VII). The hard palate has a central raphe that divides the surface into right and left halves. The flat portion of the palatal mucosa just caudal to the upper incisors may appear swollen in the young horse when permanent incisors are erupting. This normal mucosal enlargement seen in 2- to 5-year-old horses has been referred to as *lampas*. Farther caudally, the hard palate becomes more concave and contains paired transverse ridges, which are instrumental in moving a food bolus caudally, in a spiral fashion, as the horse masticates forage. The muscular tongue sits in the bottom of the

mouth, supported in a sling formed by the mylohyoideus muscles, between the paired hemimandibular rami. The root of the tongue is attached to the lateral aspect of the soft palate, the pharynx, and hyoid bone. The lingual muscles receive their motor innervation from the hypoglossal nerve (cranial nerve XII) and sensory innervation from the lingual branch of the mandibular nerve and glossopharyngeal nerve (cranial nerve IX).

The mandible is the largest bone of the face and is formed by paired hemimandibles that fuse rostrally at the mandibular symphysis when the horse is approximately 2 to 3 months old. Each hemimandible is composed of a horizontal and a vertical ramus. The dental alveoli are contained within the horizontal ramus. The vertical ramus terminates with the coronoid process rostrally and the mandibular condyle caudally. The temporalis muscle inserts on the coronoid process.

Between the incisors and the rostral aspect of the mandibular cheek teeth, on the horizontal rami of the mandible, are the “bars” of the mouth. This large interdental space or natural diastema is the resting area for the bit. Canine teeth, if present, are located in these spaces. The ventral border of the mandible of the young horse is wide and round, but as the horse ages and the mandibular cheek teeth continue to erupt, the ventral border of the mandible becomes more sharply angled. Eruption swellings or “bumps” often develop along the ventral border of the mandible of young horses as the permanent mandibular cheek teeth erupt.

The paired incisive (premaxillary) bones form the rostral part of the upper jaw and contain the alveoli of the upper incisors. Caudally the incisive bone becomes thinner and forms the rostral part of the hard palate. The suture line between the incisive bones and the maxillary bones is an anatomically weak area and a common site of fracture. The upper canines, if present, are situated just caudal to this suture line.

The paired, large maxillary bones extend from the incisive bone rostrally to the nasal bones dorsally and lacrimal bones caudally. The facial crest is a prominent ridge of bone on the lateral aspect of the maxillae. This crest continues caudally as the zygomatic process and joins the malar and temporal bones to form the zygomatic arch. The ventromedial aspects of the maxillary bones join to form a horizontal shelf that provides rigid support to the majority of the hard palate. The alveoli of the upper canines, premolars, and molars are embedded in the maxillae. The position of the alveoli of the upper cheek teeth is somewhat variable, but usually the alveoli of the first two cheek teeth lay rostral to the sinuses. The apices of the third and fourth cheek teeth lie within the rostral maxillary sinus in the young to middle-aged horse, and the apices of the caudal two cheek teeth lie within the caudal maxillary sinus. Each alveolus is separated by transverse interalveolar bony septa.

The horse has five paired paranasal sinuses: the conchofrontal, sphenopalatine, caudal maxillary, rostral maxillary, and ethmoidal sinuses. The rostral and caudal maxillary sinuses are contained within the maxillae and are usually separated by a thin bony septum, although this septum often breaks down in the presence of sinus disease. The infraorbital canals (one on each side of the head) traverse longitudinally through the maxillary sinuses.

Bacterial sinusitis can occur secondary to disease of the third, fourth, fifth, and sixth upper cheek teeth and classically results in a unilateral, malodorous, nasal discharge. Almost the entire lumen of the maxillary sinuses of a young horse is occupied by dental alveoli, but as the facial bones grow and reserve crowns of the upper cheek teeth erupt, the cheek teeth move rostrally and ventrally, causing the sinus compartments to enlarge. The paranasal sinuses drain into the caudal aspect of the nasal cavity via a slitlike opening, the nasomaxillary aperture. The medial compartment of the rostral maxillary sinus, or ventral conchal sinus, has poor drainage and is a common site for inspissated exudate to accumulate. Its secretions must drain into the lateral compartment of the rostral maxillary sinus before draining into the caudal aspect of the middle meatus through the nasomaxillary aperture.

676

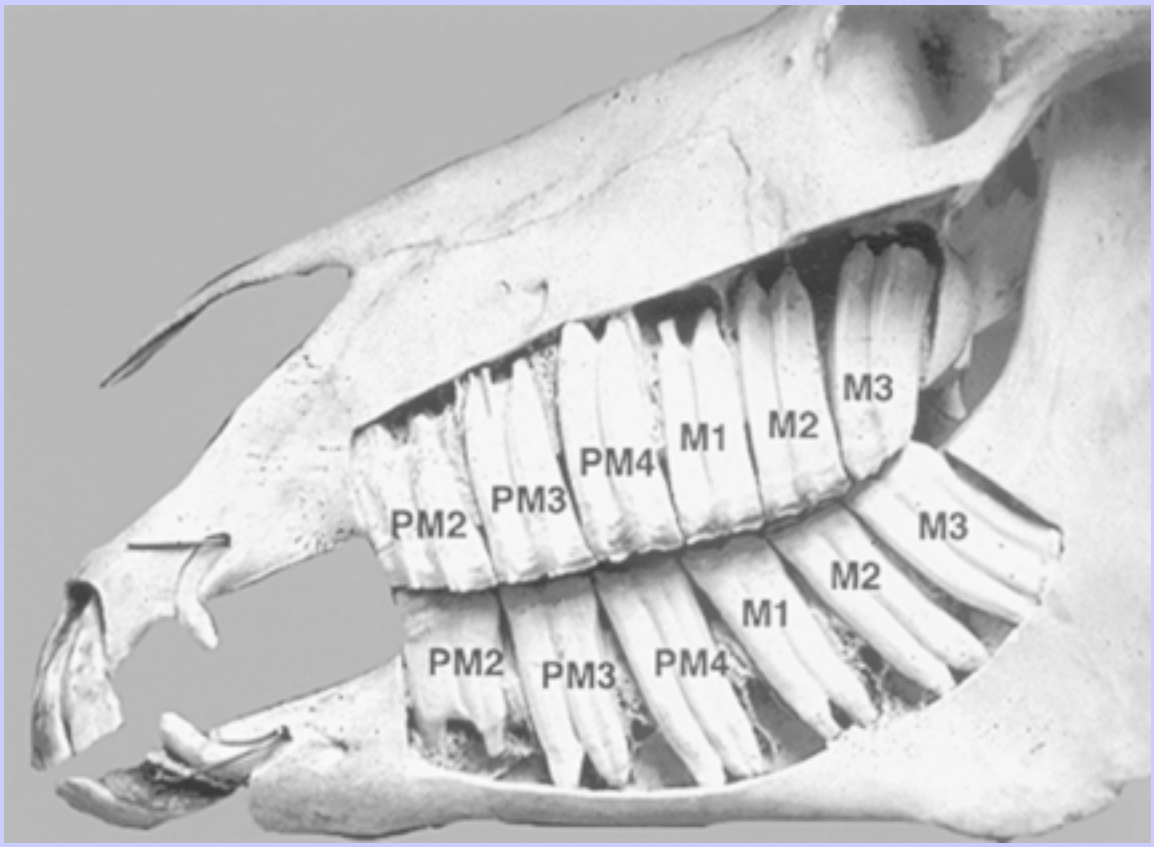
677

The temporomandibular joint is a synovial joint formed by the articulation of the squamous temporal bone with the condylar process of the mandible. The joint lies approximately 15 cm above the level of the occlusal surface of the

cheek teeth. The cavity of the joint is large and divided by a cartilaginous, intraarticular disk. The joint is bound by a tight capsule and lateral and caudal ligaments. The equine temporomandibular joint has a wide range of lateromedial movements, which allows for the medially directed power stroke of mastication, but limited vertical and rostrocaudal movements.

To affect the wide lateromedial range of motion in the temporomandibular joint during the power stroke of mastication, the masseter and pterygoid muscles have evolved into most highly developed muscles of mastication in the horse. The powerful masseter muscle originates along the full length of the facial crest and zygomatic arch and has wide insertions along the caudolateral aspect of the mandible. The superficial muscle fibers of the masseter run almost vertically, whereas the deep fibers course in a ventrocaudal direction. The masseter pulls the jaw to the ipsilateral side and contributes to closure of the jaw. The origins and insertions of the medial and lateral pterygoid muscles are similar to those of the masseter, but these muscles lie on the medial aspect of the mandible. The digastricus muscle originates on the occipital bone and attaches to the caudal aspect of the mandible. This muscle assists in opening the mouth, but because gravity also assists in opening the mouth, this muscle is small. The temporalis muscle functions to close the jaw, but because the temporomandibular joint of the horse is capable of only slight vertical movement, this muscle is also small and poorly developed. The muscles of mastication are all innervated by the trigeminal nerve (cranial nerve V).

Fig. 32-14 Lateral view of cadaver equine skull. *M*, Molar; *PM*, premolar.



32.14 TEETH

The foal has erupted 24 deciduous teeth by the time it is approximately 6 months old. Expansion of the cranial and facial bones during the first 2 to 3 years of life allows room for the expansion of the dentition from 24 deciduous teeth to the 36 to 44 permanent teeth present in the adult horse. The mouth of the mature horse contains six incisors in both the upper and lower jaws and six permanent upper cheek teeth and six permanent lower cheek teeth on each side of the mouth (Fig. 32-14). The rostral three cheek teeth are premolars, and the caudal three cheek teeth are molars. Incisors and premolars have deciduous and permanent sets. Molars erupt later than the deciduous premolars and do not have deciduous counterparts. The occlusal surface of the cheek teeth of the upper jaw is broad and square, and that of the lower cheek teeth is narrower and rectangular.

The cheek teeth in each quadrant of the horse's mouth are commonly referred to by number (1 to 6), from rostral to caudal. The vestigial and inconsistently present first premolar, often referred to as a *wolf tooth*, is not included in the 1 to 6 nomenclature. To help avoid confusion, the American Veterinary Dental College Nomenclature and Classification Committee has endorsed the use of the Modified Triadan Tooth Numbering System for the horse.[43] This three-digit tooth numbering system is based on a full phenotypic dentition composed of 44 teeth. The first digit designates the location of the quadrant, or arcade, and whether the dentition is deciduous or permanent. The permanent teeth in a quadrant are designated using numbers 1 to 4, and the deciduous teeth in a quadrant are designated using numbers 5 to 8. The numbering sequence for the permanent teeth starts with #1 for the upper right teeth, #2 for the upper left teeth, #3 for the lower left teeth, and #4 for the lower right teeth. In each dental quadrant, the incisors are numbered 01 to 03, and the first or central incisor is always 01. The canines, whether present or not, make up the 04 position in this formula. The premolars are numbered 05 to 08, and the molars are numbered 09 to 11.

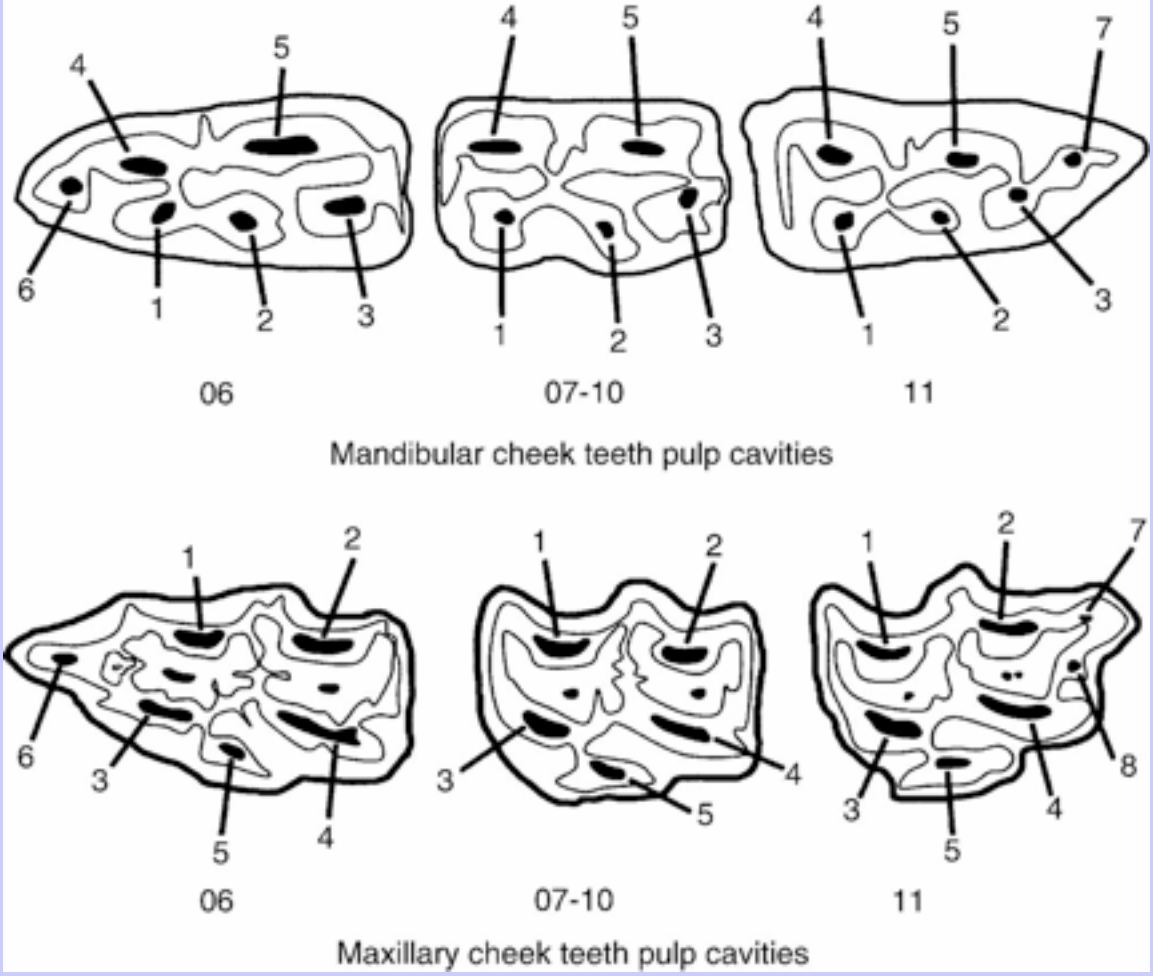
677

678

The equine incisors and molarized cheek teeth are hypsodont and have long anatomic crowns. The tooth crown is the enamel-containing portion of the tooth. When these hypsodont teeth erupt, their occlusal surface is covered with thin layers of cementum and enamel, which wear away from masticatory forces and abrasive forage, to expose the true or functional occlusal surface of the tooth. This process is termed *coming into wear*. The functional occlusal surface of hypsodont teeth is composed of thin, brittle sheets of hard enamel sandwiched between softer layers of cementum and dentin. This three-textured occlusal surface is self-sharpening and resistant to wear and fracture. The occlusal surfaces of the molar arcades wear in an undulating fashion with 13 loph basins (food channels) between transverse ridges.

The incisors and upper cheek teeth have enamel invaginations in the crown, termed *infundibula*. These enamel invaginations are partially filled with cementum, which receives its blood supply from the soft tissue covering the tooth before eruption. The shallow infundibulum present on each incisor has a wide opening at the occlusal surface, referred to as a “cup.” As the incisor wears, the small apical portion of the infundibulum eventually becomes exposed at the occlusal surface and is termed “the spot.” Each upper cheek tooth has a rostral and a caudal infundibulum. These enamel invaginations, or cones, give the central area of these teeth a hard wear surface. The center of the cement lake that fills the infundibulum contains a hole, which is the remnant (i.e., a “ghost”) of the central blood vessel that once supplied nutrition to the now dead infundibular cementum.

Fig. 32-15 Diagram of the premolar and molar pulp cavities.



Much of the crown of the hypsodont teeth of the horse is held in reserve subgingivally, in the alveolar bone. The apex of the tooth slowly completes its development by forming roots for several years after the tooth erupts. The interior of the tooth is composed primarily of dentine, with primary dentine lining the common pulp chamber of the newly erupted hypsodont tooth. The pulp chambers of hypsodont teeth are active throughout the horse's life and continuously produce secondary dentine within the pulp cavity. Continuous production of secondary dentine prevents the vital pulp from being exposed at the occlusal surface as the tooth wears. The depth of secondary dentine at the occlusal surface of the pulp horns varies in horses but is at least 5 to 7 mm thick and generally increases in thickness as the tooth ages. Secondary dentine absorbs pigment from feed and is seen as a brown area on the occlusal surface of the tooth.

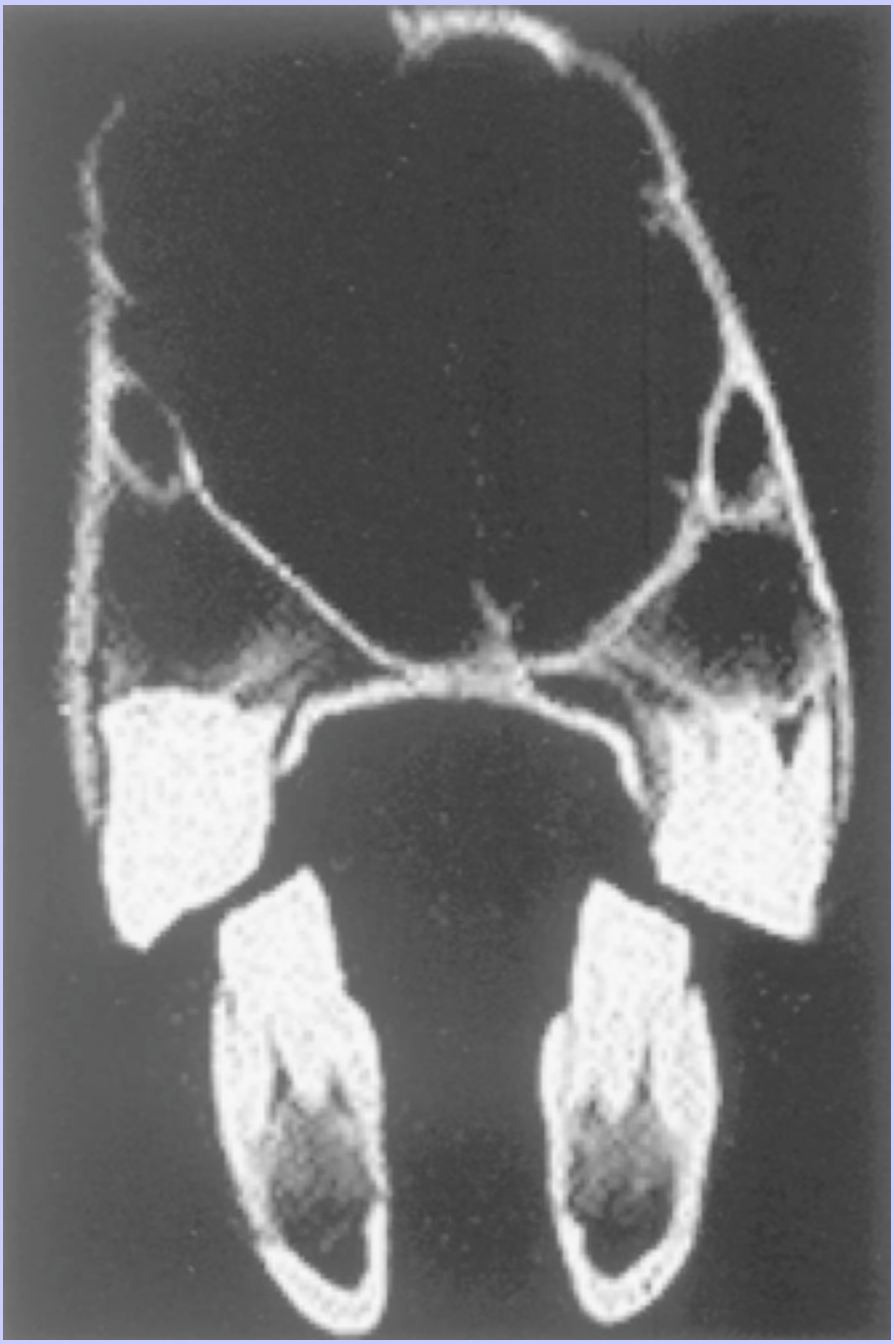
The pulp cavity of the young, permanent cheek tooth is large, but as the tooth ages the pulp divides into smaller pulp chambers, or horns, by deposition of secondary dentine. From 2 to 4 years after eruption, mandibular cheek teeth have a distinct, apically located, common pulp chamber that communicates with the pulp horns. Five pulp horns are present in the 07s to 10s, six pulp horns are present in the 06s, and six or seven pulp horns are typically present in the 11s (Fig. 32-15). By 6 to 8 years after a mandibular cheek tooth erupts, production of secondary

dentine divides the endodontic system of the tooth into two distinct compartments or roots. Each compartment consists of a root canal, a pulp chamber, and two or three pulp horns. Each maxillary cheek tooth has three roots. 678
Because of the continuous production of cementum around the apical or root portion of the tooth and continuous 679
wear of the crown, old equine teeth are primarily composed of cementum. When most of the enamel of the crown has worn away, the softer dentine and cementum are quickly worn flat, leading to the condition known as “smooth mouth.”[44]

Innervation of the dental structures is supplied by the trigeminal nerve, which exits the skull just below the ear. This nerve traverses rostrally and then divides into ophthalmic, maxillary, and mandibular branches. The maxillary nerve enters the caudal aspect of the maxilla ventral to the orbit via the maxillary foramen and runs through the maxilla in the infraorbital canal, giving off branches that supply the maxillary cheek teeth. The nerve then exits the maxilla at the infraorbital foramen, located just rostral and dorsal to the facial crest. As the mandibular nerve runs medially along the horizontal ramus of the mandible, it branches into smaller nerves, including the mandibular alveolar nerve, which enters the mandibular canal at the mandibular foramen on the caudomedial aspect of the mandible and innervates the mandibular cheek teeth. The inferior alveolar nerve exits the mandibular canal at the mental foramen at the rostrolateral aspect of the mandible just rostral to the mandibular cheek teeth to become the mental nerve, which supplies the ipsilateral soft tissues over the incisive portion of the mandible.

The horse is anisognathic, which means that the bottom jaw is narrower (by about 25%) than the upper jaw. The molar tables are sloped at a 10- to 15-degree angle from dorsal lingual to buccal ventral (Fig. 32-16). Lateral excursion of the jaw during mastication favors occlusal wear of the buccal aspect of the lower molar arcades and the lingual aspect of the upper molar arcades. As the horse chews, the jaw moves in a rotary motion from side to side with limited rostral to caudal excursion. The molars are constructed so that the enamel, cementum, and dentine interdigitate to provide a sharp, serrating surface that allows for uneven, continuous wear when the horse is eating.

Fig. 32-16 Computed tomographic scan of the equine skull at the level of the first molars. Dorsal is at the top. Note that because the upper molars are offset laterally from the lower molars, the molar tables are sloped at a 10- to 15-degree angle from dorsal lingual to buccal ventral.



The extent of lateral excursion of the mandible during normal mastication is affected by the length of stem or roughage in the horse's ration. Horses on pasture or hay have a wide area of mandibular excursion, whereas horses eating pellets or concentrates have a more limited range of lateral jaw excursion. Horses fed predominantly pellets or only a small quantity of long-stemmed roughage tend to have incomplete wear of the molar surface, predisposing the arcades to development of sharp enamel edges, a vaulted ceiling of occlusion, or the serious problem of shear mouth. Malocclusion of the incisors or the molar arcades perpetuates abnormal wear patterns that can eventually lead to severe dental disorders.

Rostral or caudal molar malocclusions or problems with eruption (e.g., displaced, deformed, missing, or supernumerary teeth and delayed eruption) lead to uneven dental wear. Horses with asymmetry between the upper and lower molar arcades, such as from mandibular fracture, facial injury, congential deformities such as brachygnathism (parrot mouth) and prognathism (sow mouth), or an abnormally narrow mandible in relation to the maxillae, often develop abnormal dental wear, resulting in sharp enamel points, dental overgrowths, shear mouth, step mouth, or wave mouth.

Equine males normally have two upper and two lower canines (or bridle teeth). The upper canines erupt just caudal to the suture between the incisive and maxillary bones. The lower canines are located further rostrally, producing a long lower diastema or interdental space. Canines of mares are rudimentary or absent.

The rudimentary first premolars, or wolf teeth, are constant in fetal life in both the upper and lower jaws. Many never develop to the point of eruption but instead degenerate and become incorporated in the maxilla or mandible. The upper first premolars erupt in 20% to 80% of horses, whereas the lowers erupt in only 1% to 5% of horses.

The dynamic changes that take place in the horse's head continue at a slower pace throughout life after the horse matures. The hypsodont premolars, molars, and incisors with their large reserve crowns and slowly forming short roots continually erupt and wear. With continuous eruption and wear of the hypsodont teeth, all horses eventually wear their cheek teeth to the roots.

32.15 DENTAL EXAMINATION

A horse's dentition should be examined biannually as a routine part of a health maintenance program. Eating efficiency and oral hygiene are the most important considerations from a medical standpoint when providing dental care, but often owners are more enthusiastic about dental care because of its positive effects on the horse's athletic performance. Written documentation of findings during dental examination is necessary to formulate a problem-oriented treatment plan and to follow progress after the horse receives routine maintenance and/or treatment for dental abnormalities. A consistent routine on the part of the examiner increases the efficacy and quality of the examination (Box 32-1).

Signs of dental disease may be obtained from the history or observed in a horse suffering from dental problems. A history of abnormal head carriage or head tossing while being ridden or during eating, prolonged time of eating, halitosis, dysphagia, drooling, dribbling feed (i.e., quidding) or eating hay before grain should lead one to consider that a dental problem exists.[45] Indicators of a dental problem in performance horses include tail wringing, head shaking, lugging in or out on the track, and fighting the bit (i.e., refusing to collect the head). In addition, intermittent dorsal displacement of the soft palate in performance horses may be a sign of a dental abnormality.

679

680

32.15.1 Box 32-1 Recommended Timetable for Routine Dental Examinations and Common Corrective Procedures

32.15.1.1 BIRTH

1 Examine for congenital defects of lips or palate.

2 Assess tongue motion and strength.

3 Identify dental malocclusions.

4 Evaluate all body systems.

32.15.1.1.1 Recommended Procedures

1 Provide genetic and orthodontic consultation and perform corrective surgery if necessary.

2 Look for other problem signs such as underdeveloped carpal or tarsal bones, ruptured extensor tendons, hernias, etc.

32.15.1.2 6 TO 8 MONTHS OF AGE

1 Check incisor and premolar occlusions.

2 All incisors should be erupted.

3 Check for sharp enamel points or hooks.

4 Check tongue and buccal mucosa for ulcers.

32.15.1.2.1 Recommended Procedures

1 Provide orthodontic consultation, and float teeth if necessary.

32.15.1.3 16 TO 24 MONTHS OF AGE

1 Check for expanded lower wolf teeth eruption.

2 Check points and hooks on premolars.

3 Look for bit lesions.

32.15.1.3.1 Recommended Procedures

1 Float teeth and round off rostral corner of premolar 2.

2 Extract wolf teeth.

32.15.1.4 2 TO 3 YEARS OF AGE

1 Look for upper and lower wolf teeth.

2 Check corners of mouth and interdental space for bite injuries.

3 Evaluate incisors and molars for eruption and premolars for points and loose or retained deciduous teeth.

32.15.1.4.1 Recommended Procedures

1 Float outside of upper and inside of lower cheek teeth.

2 Remove caps if present and ready.

3 Extract wolf teeth.

32.15.1.5 3 TO 4 YEARS OF AGE

1 Check corners of mouth and interdental space for bit injuries.

2 Evaluate incisors for retained deciduous teeth or supernumerary teeth.

3 Evaluate molars for eruption and premolars for points and retained or loose deciduous teeth.

4 Evaluate size and shape of lower jaw and percuss sinuses.

5 Check for blind wolf teeth.

32.15.1.5.1 Recommended Procedures

1 Remove caps if present and loose.

2 Float teeth.

3 Remove wolf teeth.

32.15.1.6 4 TO 5 YEARS OF AGE

1 Check all incisors for eruption and wear occlusion.

2 Check canine teeth for sharp edges or eruption delays.

3 Evaluate entire molar arcade for proper eruption and alignment (third cheek tooth).

4 Visually check upper rostral and lower caudal cheek teeth for hooks from malocclusion.

5 Digital check for points on sharp edges of cheek teeth.

6 Percuss sinuses.

32.15.1.6.1 Recommended Procedures

1 Remove deciduous teeth if loose and ready.

2 Reduce hooks if present.

3 Float teeth.

4 Remove mucosa over canines if gingival cysts are present.

32.15.1.7 5 YEARS AND OLDER

1 Examine mouth visually and digitally, especially noting hooks and uneven wear.

2 Evaluate canines for sharp edges and tartar.

3 Percuss sinuses.

4 Use olfactory senses to detect evidence of oral decay or gingivitis.

5 Observe incisors for even wear.

6 Evaluate lateral jaw excursion.

32.15.1.7.1 Recommended Procedures

1 Float teeth.

2 Remove hooks.

3 Level or shorten incisors if indicated.

Good dental health is extremely important to the equine digestive system. Chronic colic or choke can result from improper mastication of feed, and reluctance to drink cold water may be caused by dental pain. Proper mechanical digestion of feed allows better carbohydrate absorption in the small intestine and improved fiber fermentation in the cecum and large colon. Improper mastication of roughage and concentrate produces large feed particles with decreased surface area per mass. The large particles are poorly digested in the small and large intestine because decreased surface area of the feed does not allow proper enzymatic degradation and bacterial fermentation. Finding whole grain or stem particles more than 5 mm long during examination of the manure indicates that the horse suffers from improper mastication.

The physical examination begins with observation of the horse's body condition, attitude, and temperament. The horse's overall condition should be evaluated in light of its use and dietary intake. Assigning a body score is an accurate way to subjectively record body condition (Table 32-1).[46] Objective assessment of body condition using a scale, a weight tape, or photographs is also beneficial and provides reliable data to evaluate the effects of treatment. The age of the horse should be considered during evaluation, because different conditions need to be addressed as the horse ages. The use of the horse should be considered during evaluation, because horses that wear a bit might require dental care not required by horses that do not wear a bit. Stable surroundings should be carefully observed for evidence of vices, such as cribbing or poor eating habits, such as dribbling hay or grain.

Table 32-1 Henneke Body Condition Scoring System

Condition	Neck	Withers	Shoulder	Ribs	Loin	Tailhead
1 Poor	Bone structure easily noticeable	Bone structure easily noticeable	Bone structure easily noticeable	Ribs protruding prominently	Spinous processes projecting prominently	Tailhead, pinbones, and hook bones projecting prominently
2 Very thin	Bone structure faintly discernible	Bone structure faintly discernible	Bone structure faintly discernible	Ribs prominent	Slight fat covering over base of spinous processes Transverse processes of lumbar vertebrae feel rounded Spinous processes are prominent	Tailhead prominent
3 Thin	Neck accentuated	Withers accentuated	Shoulder accentuated	Slight fat cover over ribs Ribs easily discernible	Fat buildup halfway on spinous processes, but easily discernible Traverse processes cannot be felt	Tailhead prominent but individual vertebrae cannot be visually identified Hook bones appear rounded, but are still easily discernible Pin bones not distinguishable
4 Moderately thin	Neck not obviously thin	Withers not obviously thin	Shoulder not obviously thin	Faint outline of ribs discernible	Negative-crease (peaked appearance) along back	Prominence depends on conformation Fat can be felt; hook bones not discernible
5 Moderate (ideal weight)	Neck blends smoothly into body	Withers rounded over spinous processes	Shoulder blends smoothly into body	Ribs cannot be visually distinguished, but can be easily felt	Back is level	Fat around tailhead beginning to feel soft

6 Moderately fleshy	Fat beginning to be deposited	Fat beginning to be deposited	Fat beginning to be deposited	Fat over ribs feels spongy	May have a slight positive crease (a groove) down back	Fat around tailhead feels soft
7 Fleshy	Fat deposited along neck	Fat deposited along withers	Fat deposited behind shoulder	Individual ribs can be felt with pressure, but noticeable fat filling between ribs	May have a positive crease down the back	Fat around tailhead is soft
8 Fat	Noticeable thickening of neck	Area along withers filled with fat	Area behind shoulder filled in flush with body	Difficult to feel ribs	Positive crease down the back	Fat around tailhead very soft
9 Extremely fat	Bulging fat	Bulging fat	Bulging fat	Patchy fat appearing over ribs	Obvious crease down the back	Bulging fat around tailhead

681

682

Body and head conformation should be considered in evaluating the masticatory system. The head should be observed from both sides and the front to detect asymmetries, protuberances, or swellings. Horses with small heads have more of an angle in the curve of the mandibular ramus (i.e., the curvature of Spee) and are predisposed to dental crowding and ramps on the lower dental arcades.

The horse should be approached at its left shoulder. The tongue should be checked for proper movement, abnormal swelling, and signs of trauma, and the horse's ability to swallow should be evaluated. Excessive lacrimation, abnormal nasal discharge, or halitosis should be noted. The horse should receive a neurologic evaluation if any cranial nerve deficits are detected. Finally, the mandibular rami, masseter muscles, temporomandibular joints, and submandibular lymph nodes should be palpated to detect enlargements or asymmetry.

The frontal and maxillary sinuses should be percussed with the horse's mouth open. The width between the mandibular rami should be noted, because this width correlates with the room in the mouth for the bit. The sides of the head lateral to the upper dental arcades should be compressed, starting at the orbit and moving forward to the first cheek tooth at the level of the nasomaxillary notch, to detect protuberances, depressions, asymmetry, or evidence of pain. The commissures of the lip should be observed and palpated for signs of trauma inflicted by sharp teeth or improperly fitting bits. The incisor arcades should be visually evaluated from the front and both sides. The occlusal surfaces should make good contact and be level. The horse's age should be assessed by the dentition and compared with its actual age.[47] In movement of the lower jaw from side to side, the normal slide and separation of the incisor arcades as the jaw moves through normal lateral excursion should be observed.

For the oral cavity to be examined in detail, the horse should be fitted with a loose-fitting halter. If the horse is fractious or resists examination, it should be sedated before proceeding with the oral examination. Sedation should be given only after the horse's signalment (i.e., breed, age, body condition), temperament, and health (i.e., mucous membrane appearance, capillary refill time (CRT), heart rate, and rectal temperature) have been assessed.

The mouth should be rinsed thoroughly with clean water. Trapped feed in the mouth should be removed manually or with a dental pick and irrigation. Horses with sharp buccal points on the upper dental arcade often resist

application of a full-mouth speculum; therefore floating the upper arcades before applying the speculum may decrease resentment to the speculum. With a full-mouth speculum in place and the head properly restrained, a detailed visual and tactile oral examination should be carried out. A bright light source is necessary to illuminate the entire oral cavity for complete visual inspection. The examiner should manually inspect all hard and soft tissue in the oral cavity. The use of a dental mirror and pick is often necessary to see and probe the occlusal surfaces and pockets between the cheek teeth. Endoscopic examination of the oral cavity using a videoendoscope or an endoscope with a camera aids in identification of obscure lesions. Because rabies is a potential cause of dysphagia in the horse, the examined should have an adequate titer for rabies antibodies.

32.16 DENTAL RADIOLOGY

Diagnostic radiology is a valuable aid in the diagnosis of equine dental disease. The excellent contrast among air, bone, soft tissue and teeth provides good radiographic detail. Good-quality films can be obtained using a portable x-ray machine and rare-earth intensifying screens without a grid. Digital radiology provides high-quality radiographic images and allows for these high-quality images to be shared electronically for consultation with colleagues.

Indications for radiographic examination of the head include a suspicion of dental infection, maleruption, or a diastema and oral pain of unknown origin. The skull should be examined radiographically before and after dental extraction. Any facial swelling, deformity, neoplasm, trauma, or fracture may warrant radiographic evaluation to aid in diagnosis and treatment.

Radiographs can be taken with the horse standing and sedated. The head and radiographic cassette can each be placed on a stand to decrease distortion caused by motion. A lateral projection centered over the rostral edge of the facial crest should be taken to demonstrate fluid lines within the sinuses. The lateral view superimposes the dental arcades and should not be relied on to diagnose diseases involving the dental reserve crown and roots. Lesion-oriented oblique projections demonstrate the apical portion of the upper or lower cheek teeth and are helpful in diagnosing periapical dental disease. Open-mouth, oblique radiographic projections are beneficial in evaluating the exposed crown of the cheek teeth. Special, 4- × 8-inch, flexible dental cassettes can be used to obtain intraoral radiographic projections of the maxillary dental arcades. Dorsoventral radiographic projections centered over the tooth in question or area of concern can demonstrate periodontal disease on the buccal aspect of the upper cheek teeth or a large area of infundibular decay. Intraoral, occlusal radiographic projections are useful in demonstrating fractures of the incisors or other lesions rostral to the bars of the mouth. Other imaging techniques, such as ultrasonography, nuclear scintigraphy, CT, and MRI are helpful in the diagnosis of many oral and dental-related diseases.[48]

32.17 TREATMENT

A plan for treatment based on the results of history, clinical findings, and oral examination should be outlined to the owner and/or trainer before proceeding with a dental procedure. The owner and/or trainer should be informed of any abnormalities and given a plan for treatment, as well as an estimate of the cost, before any corrective procedure is performed.

Therapy must be planned to ensure that all equipment necessary to complete the task is at hand. The horse should be properly restrained, and adequate help should be present to assist in completing the procedure. A dental record aids in documenting findings during examination and the procedures performed (Fig. 32-17).

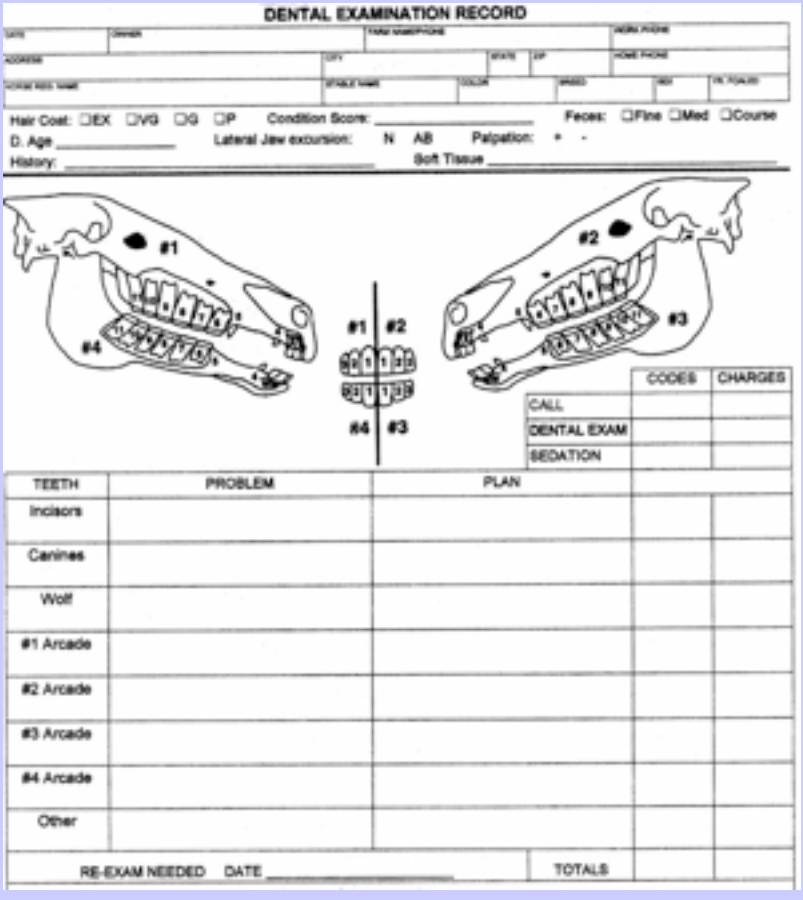
32.17.1 Routine Dental Maintenace

32.17.1.1 FLOATING

Dental floating is an age-old and routine method to correct abnormalities associated with dental eruption and occlusal wear. Floating also allows sculpting of the teeth to accommodate the bit. The main purpose of molar floating, or leveling, is to remove points or sharp edges from the buccal aspect of the upper molar arcades and lingual aspect of the lower molar arcades. Floating may also entail removing minor hooks or ramps from the rostral or caudal aspect of one or more arcades or leveling of minor elevations on the occlusal surface of the arcades. Routine floating and other corrective measures in the mouth may require both the added physical restraint provided by a dental halter and mild, chemical sedation.

Proper equipment is required to float all aspects of the exposed crowns of the cheek teeth, regardless of horse's size. Small instruments are often needed to access the oral cavity of miniature horses or ponies, and extra long and heavy instruments are often required to work effectively in the mouth of the large warmblood or draft horses. Sharp float blades made of carbide chips or sharp tungsten carbide planing blades make the work of floating more efficient and less strenuous than in the past, when steel blades were used. 682 683

Fig. 32-17 Form used to record dental examination findings.



The outward curve of the upper arcade makes the central buccal area (i.e., the area involving premolar 3 [PM3] through molar 2 [M2]) the easiest to reach with the float. To reach all areas of PM2 and M3, the head of the float should be offset or angled. In most cases the lower arcade can be floated to remove the lingual enamel points using a flat, long-handled float. To remove rostral and caudal hooks, special equipment such as carbide planing blades, power burrs, sliding chisels, or single action molar cutters may be required. (Note: Using sliding chisels and molar cutters to remove a hook can result in serious damage to the tooth). The use of dental equipment requires special training and skill to prevent iatrogenic injury to the horse's mouth.

The use of a mouth speculum or a dental wedge aids not only the oral examination, but also floating. (Note: The use of a dental wedge can result in serious damage to the teeth.) A mouth speculum ensures that the horse's mouth remains open, increasing safety for both the horse and the examiner. For horses with slightly ramped back teeth caused by a greater than normal curvature of Spee, a mouth speculum and a slightly curved or swivel-headed float may be needed to float the occlusal surface of the last molar.

To increase a horse's comfort while it wears a bit, the rostral aspect of the first upper and lower cheek teeth are sometimes rounded and the buccal cusps of the upper PM2s and PM3s are reduced. A horse that has received these procedures is said to have received a “bit seat.” In theory, a bit seat is created to prevent the soft tissue of the mouth from pressing against sharp points on the PM2s. To prevent exposing the pulp cavity when forming bit seats or correcting overgrowths, care should be taken not to “overfloat” the occlusal surface of a tooth. An offset float or an S-shaped rasp is usually necessary to create a bit seat.

32.17.1.2

WOLF TEETH

Most horses that are worked with a bit in the mouth benefit from having wolf teeth extracted. Some wolf teeth exfoliate naturally when the horse is approximately 3 years old, at the same time the cap of the first cheek tooth (i.e., 06 or PM2) is shed and the permanent tooth erupts. Although not all wolf teeth cause discomfort, a loose or sharp wolf tooth can be a distraction or even cause pain of such severity that it leads to bad bitting habits. Determining if the wolf teeth are responsible for a bitting problem is often difficult. Sometimes a wolf tooth does not erupt in a normal downward path, but instead migrates rostrally beneath the gum, causing a subgingival enlargement that irritates the horse. Such unerupted first premolars have been referred to as “blind” or “occult” wolf teeth and should be removed. Most wolf teeth are easily elevated with the horse sedated. Infiltrating a few milliliters of local anesthetic solution around the wolf teeth may aid in their removal.

32.17.1.3

CANINE TEETH

Canine teeth are present in most male horses over 4 years old. The unopposed positions of the canine teeth in the diastema make them unlikely to cause or develop problems. Some mares have small or rudimentary canines that can become loose or accumulate tartar, necessitating their removal. Canines of a stallion or gelding, especially canines that are long or sharp, can interfere with bitting and can be a nuisance or danger to the groomer or handler. Canines are more likely to accumulate tartar than are other teeth. Crowns of the canines can be ground 2 to 3 mm and polished to remedy any of these problems. Erupting canines in the 4- to 6-year-old horse may cause subgingival pain, especially when overlying tissue is contacted by the bit, which in turn may cause head shaking or other bad habits. The thin layer of tender mucosa over the canine should be removed. The root of a canine of the male is long and curved, making this tooth extremely difficult to extract. If a canine tooth must be removed because of injury or infection, it is usually removed by creating a bone flap over the root.

683 684

32.17.1.4 DENTAL CAPS

As the developing permanent premolar pushes to the surface, it presses on the roots of the worn down deciduous tooth, gradually cutting off that tooth's nutrition. The deciduous tooth dies as its blood supply diminishes, causing it to become loose and displaced. The osseous alveolar walls adjust to these changes by producing and reabsorbing bone, to provide a new socket for the embedded portion of the newly formed permanent tooth. The remaining portion of the deciduous premolar has up to four “legs” (i.e., root slivers) that straddle the crown of the permanent tooth. If these slivers are fractured, they may remain embedded in the gingival tissue after the cap is shed, causing gingivitis or periodontal disease.

The eruption pattern of the permanent molarized dentition follows a sequence that predisposes to entrapment of the deciduous PM3 and PM4. Delayed shedding of deciduous premolars can predispose to gingivitis, periodontal irritation, or apical infection. Retained, split, or displaced deciduous premolars can be distracting to a young horse in training and have been implicated as a cause of intermittent dorsal displacement of the soft palate.

Retained caps can cause lingual displacement or delayed eruption of the permanent premolars. Horses with retained caps may develop bony enlargements called “eruption cysts,” on the ventral aspect of the horizontal ramus of the mandible or on the dorsal aspect of the maxillae, rostral to the facial crest. Often such swellings are benign, but if eruption is severely inhibited, blood-borne bacteria can colonize in the inflamed dental pulp, leading to anachoretic pulpitis and periapical dental infection, which lead to more severe facial or mandibular swelling. A draining tract often accompanies swellings caused by periapical infection, especially those on the mandible. Caps should be evaluated by palpation as well as visually. A crease or neck can be seen or felt just above the gumline at the juncture separating the deciduous and permanent tooth. Radiographic examination of the premolars may be necessary to identify retained caps.

If a cap has been shed, the caps that remain on the same tooth in the other three arcades should be considered retained and should be removed. By placing a molar forceps on the tooth and rotating the forceps lingually, the cap is easily removed. The cap should be extracted in a manner that ensures that the roots, especially the buccal roots, are removed, because slivers of roots of a retained cap are irritating and can predispose the horse to development of periodontal disease.

32.17.1.5 INCISORS

After the cheek teeth have been evaluated and treated, the horse's mouth should be completely reexamined, both visually and by palpation, to ensure that all sharp or uneven edges have been smoothed and that no teeth have been broken or loosened during floating. The speculum is then removed, the mouth closed, and excursion of the jaw reevaluated to confirm that the mandible is capable of full excursion.

With the jaw in the resting state, normally only the incisors are in occlusion. The incisors should meet evenly and slide to the side unobstructed until the cheek teeth begin to contact. As the mandible moves laterally, the upper and lower arcades contact, and the incisors are lifted apart as the mandibular cheek teeth slide up the sloped occlusal surface of the upper cheek teeth. Uneven or excessively long incisors may need to be aligned or reduced. Minor incisor leveling can be performed with a flat carbide float or a motorized burr. Care should be taken not to reduce the crown to the extent that that the pulp is damaged. When floating has been completed, the horse should have a full, comfortable range of motion of the jaw. As the horse chews, the upper and lower dental arcades should be in proper contact with each other.

32.18 EQUINE DENTAL DEVELOPMENTAL ABNORMALITIES

Equine dental developmental abnormalities can involve tooth number, morphology, or position in the dental arcades. Abnormalities of dental development and eruption occur quite commonly in the horse and result in a wide range of clinical conditions. Some developmental abnormalities of the teeth of a young horse may not cause the horse to exhibit clinical signs of dental disease until the horse reaches middle age. A congenital or developmental problem present at the time of tooth eruption often leads to acquired dental problems as the teeth continue to erupt and wear. Consequently, several different dental abnormalities, the origins of which are interrelated, are often present by the time the horse is presented because of signs of dental disease. A detailed oral examination should include checking for the proper number and position of teeth. Because only the exposed crown of a tooth can be visualized in the oral cavity, many developmental defects may not be recognized simply by oral examination. If a developmental abnormality is suspected, the dentition should be examined radiographically to further delineate abnormalities.

32.18.1 Supernumerary Teeth

Supernumerary teeth are teeth in excess of the normal, expected number in any of the dental arches. This disorder has been referred to as *polydontia* or *hyperdentition*. Supernumerary teeth can be loosely categorized morphologically into two categories: (1) supplemental teeth that resemble teeth of the normal series in crown and root morphology but not always in size, and (2) rudimentary or dysmorphic teeth that are abnormally shaped and smaller than normal teeth.

These extra teeth are usually encountered at the caudal aspects of the arcades, but supernumerary teeth can also occur lingually, buccally, or rostrally to the arcades. Clinical signs caused by supernumerary cheek teeth are most commonly associated with dental overgrowths and diastemata, which often cause periodontal disease. Examination of a radiograph that encompasses the entire affected dental arcade is often necessary to recognize a supernumerary tooth.

Supernumerary incisors are reported more commonly in horses than are supernumerary cheek teeth. The main differential diagnosis for supernumerary incisors or cheek teeth is retained deciduous teeth, and in some cases, determining whether an extra tooth is a retained deciduous tooth or a supernumerary tooth is difficult. Radiographic examination of the affected jaw may be indicated to determine the identity of an extra incisor. A retained deciduous incisor has a more mature root and a shorter reserve crown than those of the adjacent permanent incisors.

Management of horses with supernumerary teeth is generally limited to regular assessment of the dentition, coupled with aggressive floating to minimize the opportunity for soft-tissue damage caused by unopposed dental elongations or sharp enamel points. If complications occur, such as severe periodontal disease or paranasal sinusitis, the supernumerary tooth or displaced adjacent tooth should be extracted, and appropriate therapy undertaken to manage associated disease.

684

685

32.18.2 Oligodontia

Oligodontia is the condition in which the number of teeth is less than normal. Oligodontia can be caused by congenital absence of a tooth germ or by traumatic loss of a tooth. Absence of a tooth in the dental arcade, regardless of the cause, leads to dental drift, or tipping of adjacent teeth. Lack of wear of the antagonist to the missing tooth can lead to dental elongations and abnormal mastication. Radiographic examination of the

dentition is often necessary to confirm a diagnosis of oligodontia. Oligodontia may be associated with other epidermal defects, such as faulty development of hair and hooves.

32.18.3 Dental Dysplasia or Hypoplasia

Dental dysplasia (i.e., abnormal growth and/or development of a tooth or teeth) may result in an irregularly shaped tooth that does not fit properly into a dental arch. The poor fit may lead to entrapment of food and periodontal disease. Enamel hypoplasia can be caused by certain drugs or chemicals administered to the dam during gestation, or it may be idiopathic. Dental dysplasia can involve the abnormal formation of all tissues of the tooth or only a single tissue. When enamel is dysplastic, however, the other calcified tissues of the teeth, cementum and dentine, also become dysplastic because enamel acts as the scaffolding and template for their deposition. Abnormal morphology of enamel has been associated with branched pulp horns and abnormally shaped teeth. Cemental hypoplasia usually involves the infundibular portion of the tooth but can be seen as a defect of the peripheral cement of the coronal or reserve crown or the roots.

32.18.4 Abnormal Dental Eruption

Abnormal dental eruption, or maleruption, is often seen after trauma to developing teeth or surrounding bones but has also been reported to be congenital or idiopathic. Cheek teeth can become vertically impacted when dental buds develop in crowded areas in the dental arcades. Teeth may become rotated or displaced because of developmental malpositioning of tooth buds or overcrowding before, during, or after eruption.

Dixon and colleagues reported that 70% of displacements of cheek teeth were developmental and caused by overcrowding of the cheek tooth arcade at the time of eruption. These researchers frequently found that if a cheek tooth was displaced in one arcade, the same tooth in the contralateral arcade was also displaced. They concluded that the remaining 30% of displacements were caused by abnormal positioning of the dental bud.[44] They found that a tooth might fail to erupt if it is displaced horizontally to the adjacent teeth. Developmental diastemata, or abnormal spaces or gaps between cheek teeth, are often the result of insufficient angulation of rostrally and caudally located teeth toward the center of the arcade to achieve good compression of adjacent teeth. Dental buds with normal angulation that develop too far apart can also result in diastemata.

Malocclusion of incisors can be congenital, developmental, or acquired. Mandibular brachygnathism (i.e., parrot mouth or overjet) is a congenital incisor malocclusion, the origin of which is usually genetic. Many horses have some degree of overjet of the premaxillary incisors, but the overjet rarely causes a problem with prehension unless the premaxillary and mandibular incisors totally lack occlusion. If brachygnathism is discovered when the foal is young, orthodontic treatment may correct or at least improve the condition.

A main consideration with an incisor overjet in the adult horse is the malocclusions of the cheek teeth that accompany this condition. The maxillary cheek teeth arcades of horses with an overjet are usually positioned rostral to the mandibular cheek teeth arcades, causing a rostral overgrowth of the upper PM2s (i.e., 106 and 206) and a caudal overgrowth of the lower M3s (i.e., 311 and 411). These overgrowths must be reduced to allow proper lateral excursion of the jaw and mastication.

Prognathism (i.e., sow mouth or undershot jaw) occurs with less frequency in the horse and is seen most commonly in miniature or dwarf breeds. Early detection and correction of the malocclusion in the foal may prevent the condition from worsening. The cheek teeth of a horse with prognathism should be evaluated for malocclusion caused by overgrowth of the upper M3s (i.e., 111 and 211) and the lower PM2s (i.e., 306 and 406).

Bony malformation or curvature of the skull can result in malocclusion of both the incisors and the cheek teeth. The most common malocclusion caused by bony malformation of the skull is an offset or diagonal incisor bite. Some bony malformations, such as campylorrhinus lateralis (i.e., wry nose), are obvious, but subtle changes to the large bony plates in the head can be difficult to recognize.

Dental overgrowths associated with malocclusions should be corrected gradually to prevent dysphagia and pain caused by inadvertent exposure of pulp horns. Often, incisor malocclusion cannot be completely resolved, but regular maintenance may prevent it from worsening.

32.19 DENTAL DISEASE

Dental disease is grouped into four basic types: abnormal occlusal wear pattern, periodontal disease, dental caries, and disease of the dental pulp. All of these types of basic dental disease are interrelated, and horses with one of these types of disease also have, to varying degrees, the other types of disease.

Proper alignment of the dental arcades is critical to the normal wear of the dentition. Historically, abnormal dental wear patterns have been described as elongations of the crown, descriptive terms for which include *hooks, ramps, waves, step mouth, tall teeth*, and *excessively high transverse ridges*.[49] Elongations are usually found on a normal tooth that opposes an abnormal tooth in the opposite arcade, such as a damaged, misplaced, or missing tooth. This abnormal tooth, as well as the elongation, should be evaluated. Most elongations are reduced with float or a grinding instrument. When reducing an elongation, care should be exercised not to cause iatrogenic damage to the tooth, such as pulpal exposure, thermal injury to the pulp or fracture of the crown.

Periodontal disease is often a painful dental condition and is described as the leading cause of “quidding” in horses. A mild form of periodontal disease primarily affects young horses, 2½ to 5 years old, that are shedding deciduous teeth (caps) and erupting permanent incisors and premolars. A more severe and progressive form of periodontal disease is seen in mature horses and is the result of the chronic effects of diastemata, or spaces that develop between teeth that are not aligned properly in the arcade. Diastemata promote periodontal disease by allowing feed to become trapped between teeth. Diastemata can form secondary to developmental disease, such as when dental buds are spaced too far apart or are abnormally angulated so that the teeth in the dental arcade are not properly compressed. This is usually a progressive condition that when left untreated worsens. Spaces between teeth or teeth out of alignment also predispose to abnormal wear patterns on the affected and opposing dental arcades.

Treatment of horses with periodontal disease involves treating both the cause and the effects of the disease. Periodontal disease caused by feed trapped at the gingival margin of a diastema often improves after the diastema is thoroughly cleansed using dental picks and/or irrigation. Correction of any associated abnormal wear pattern is also indicated. In more refractory cases, opening or widening of the diastema with a special burr or a right angle grinder may be necessary. This procedure may allow the horse's masticatory actions to more easily channel food in and out of the diastema, thus preventing or reducing entrapment, stagnation, and decay of feed.

685

686

The severity of periodontal disease can be decreased using high-pressure irrigation to clean periodontal pockets. After the pockets have been irrigated, the diastema is packed with a perioceutic agent such as doxycycline gel or a powdered antibiotic. This technique places a high concentration of antibiotic in contact with the infected and inflamed tissues, and the packing acts as a temporary barrier to recontamination. This form of therapy may need to be repeated regularly to produce long-term, positive results.

Caries usually involve the cemental layer of the tooth. Peripheral cemental caries is seen secondary to periodontal disease. The most common type of cemental caries involves the infundibular portion of the incisors or maxillary

cheek teeth (Fig. 32-18). The incisors have one infundibulum and the upper cheek teeth have two, and each infundibulum has a cup, or open portion, at the occlusal surface. The occlusal surface of the tooth is covered with cementum for several months after the tooth erupts, and as the tooth wears, the cementum-filled infundibulum is exposed at the occlusal surface. Some degree of decay is always present at the occlusal surface of an infundibulum, because feed and other products of mastication are compressed into the ghost of the vascular canal.

Fig. 32-18 Cadaver specimen of the maxillary dental arcade. Note the black areas of dental decay on the occlusal surfaces of M1 and M2 *(arrows)*.

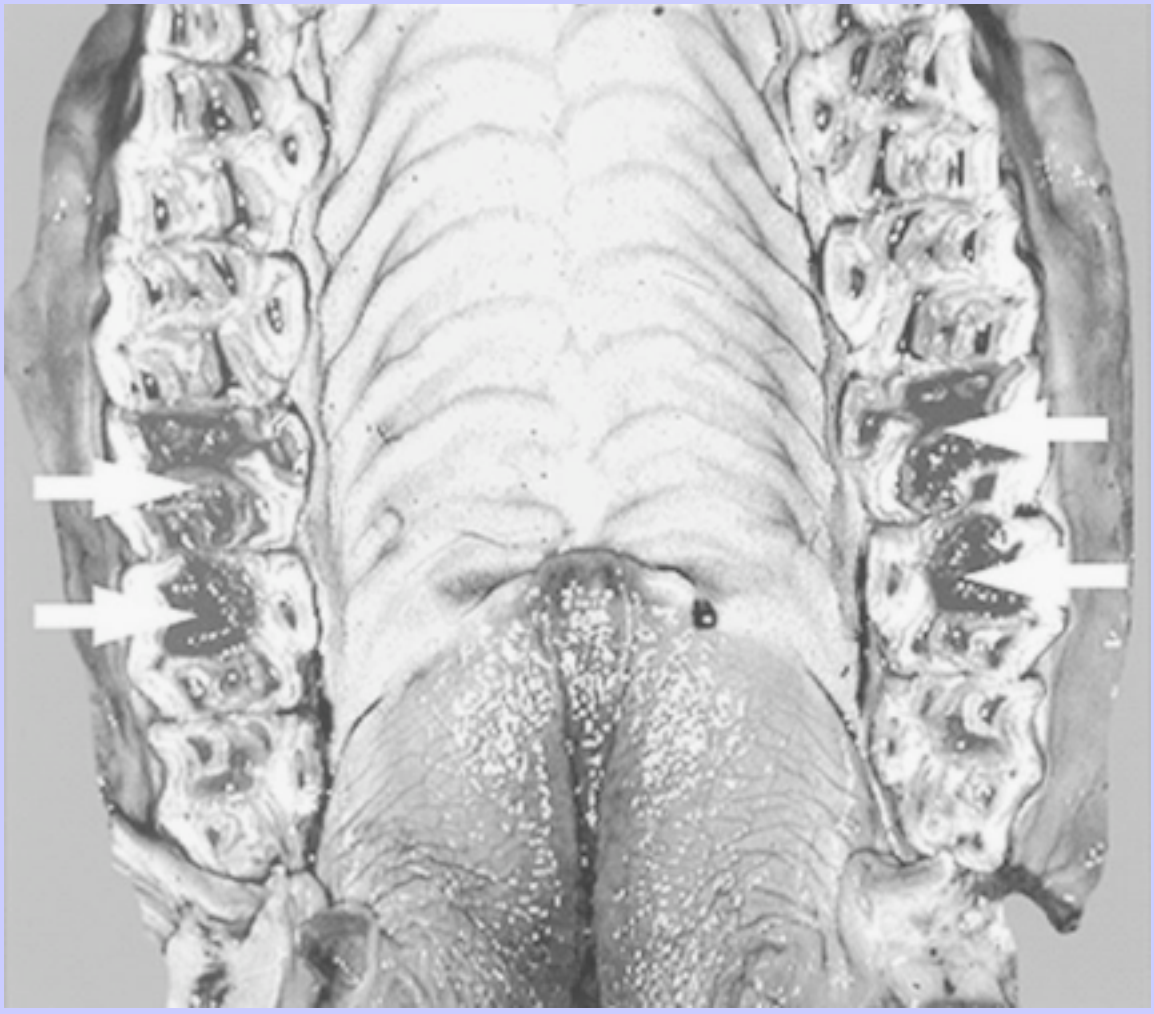


Fig. 32-19 Lateral view of cadaver equine skull illustrating wave mouth.

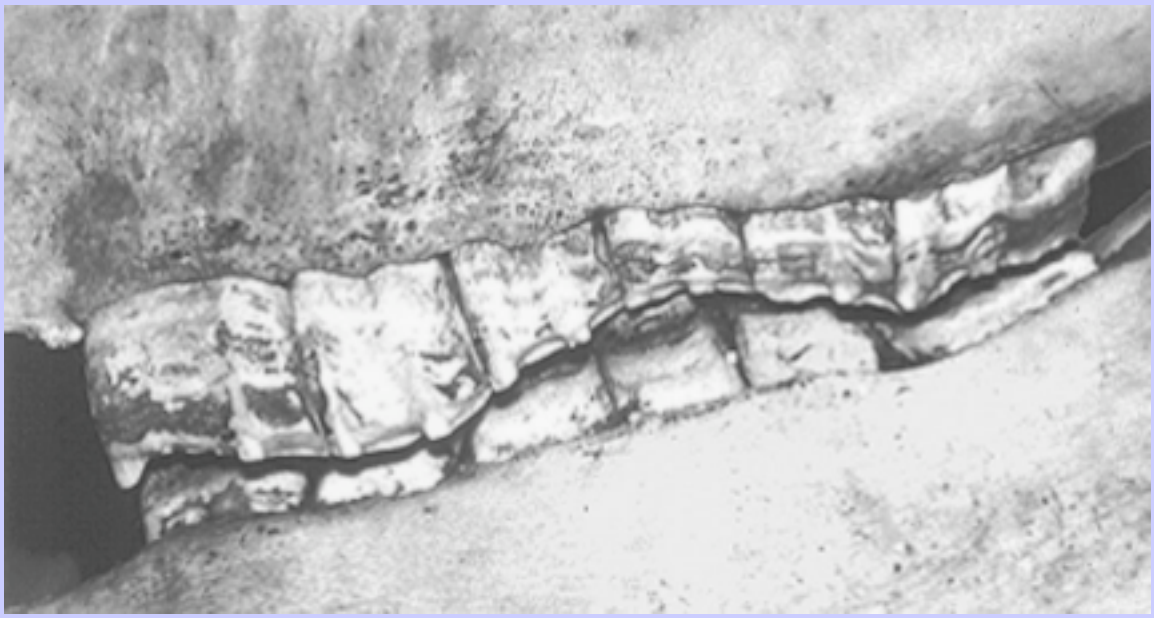


An infundibulum contains dead cementum that is completely encased in a layer of enamel, which prevents the infundibular caries from causing widespread inflammation or infection. True dental pulp infection secondary to infundibular caries occurs only if caries penetrate this protective enamel layer. Developmental malformations of the infundibulum may weaken this enamel barrier, predisposing the dentine and pulp to exposure from infundibular caries. Infundibular caries may weaken a tooth whose infundibula are congenitally deformed or have an abnormally large vascular channel, predisposing the tooth to excessive attrition or midsagittal fracture of the crown.

Infundibular caries is usually innocuous but can predispose to dental elongations on the opposing arcades (e.g., wave mouth,Fig. 32-19). These abnormal wear patterns should be reduced regularly. To strengthen the tooth and delay the progression of infundibular caries, abnormally large infundibular vascular channels can be cleaned, partially packed, and sealed with a dental composite material. As advanced diagnostic methods, such as CT, become more readily available to the equine practitioner, these abnormal infundibula can be more easily recognized.

Infection of the dental pulp occurs primarily in horses 4 to 10 years old. Horses with infection of the pulp are presented because of clinical signs of associated inflammatory changes at the apical region of the tooth. The clinical signs of pulpal infection vary and depend on the involvement of structures adjacent to the apex of the affected tooth. Horses with infection of one of the lower first four cheek teeth develop swelling on the ventral aspect of the mandible over the apex of the affected tooth, and within this swelling, a draining tract usually develops. The last two lower cheek teeth are embedded in the portion of the mandible surrounded by the large muscles of mastication, so infection of one of these teeth causes the surrounding muscles to swell. Exudate accumulated between the mandible and musculature may be seen during ultrasonographic evaluation of the soft tissues of the mandible.

The apices of the upper two or three cheek teeth are closely associated with the facial bones; therefore when one of these teeth becomes infected, facial swelling usually results. The apices of the caudal three or four upper cheek

teeth reside within the maxillary sinuses; when one of these teeth becomes infected, purulent nasal discharge caused by secondary sinusitis usually results.

Because pulpal infection destroys the tissue responsible for the production of secondary dentin, the pulp horns and root canals of the affected teeth fail to fill with dentine as they normally would. In the later stages of pulpal infection, the affected tooth usually exhibits some degree of decay at the site of the pulp horn on the occlusal surface. This weakened, decayed area may predispose to fracture of the crown.

Administration of antimicrobial drugs has been successful in the treatment of horses with apical dental infection in its early stages, but the most common treatment of horses with an apically infected tooth is removal of the affected tooth and treatment of associated bone or sinus infection. Teeth can be removed by one of three methods: extraction via an oral approach, repulsion via an apical approach, or elevation via a lateral buccotomy approach.

32.20 SALIVARY GLANDS AND DUCTS

Saliva hydrates and lubricates the oral cavity, facilitates swallowing, prevents tooth demineralization, and regulates oral microbial flora.[50] Diseases of the salivary glands of horses are uncommon but include sialoadenitis, salivary calculi, salivary mucocele, trauma and neoplasia. During oral examination the openings of the salivary ducts should be noted. The ducts of the paired parotid salivary glands enter the mouth at the parotid papillae, located next to the upper last premolars (i.e., 109 and 209). The ducts of the paired mandibular salivary glands open into the mouth on the lateral aspect of the sublingual caruncles. The ducts (approximately 30 in number) of the paired sublingual salivary glands are seen as small pores in the sublingual recess.

Slobbering or drooling may indicate excessive production of saliva (i.e., ptyalism) or accumulation of saliva in the mouth from dysphagia. Heavy metal toxicity, poisoning with a parasympathomimetic agent, neurologic disease, or stomatitis may cause ptyalism. Dysphagia can be caused by esophageal obstruction (choke), an oral foreign body, or some neurologic diseases, such as rabies.

Sialoadenitis, or inflammation of a salivary gland, may be the result of obstruction of a salivary duct from accumulated exudate or mucus, feed particles such as grass awns, an orally introduced foreign body, or a sialolith. Sialoliths occur infrequently but are found almost exclusively in the parotid salivary duct. Obstruction of the duct with a sialolith causes salivary retention, which can lead to glandular atrophy or acute sialoadenitis, swelling of the gland, and rupture of the duct. A sialolith causes a hard, usually smooth enlargement at some point along the course of the parotid salivary duct. The horse usually shows no signs of pain when the enlargement is palpated. The sialolith is usually apparent during radiographic evaluation of the skull, but it can be obscured by adjacent bone. Diagnosing the presence of a sialolith is usually straightforward because the condition is easily differentiated from other conditions that produce similar clinical signs, such as trauma, apical dental infection, or facial tumor. Surgical removal of the sialolith and primary closure of the duct and surrounding tissue usually yield good results.

A salivary mucocele is an accumulation of salivary secretions in a single or multiloculated cavity adjacent to a ruptured salivary duct. A ranula is type of mucocele that develops secondary to obstruction of a sublingual salivary duct. Treatment of horses with a mucocele consists of creating a salivary fistula into the oral cavity or excising the mucocele and destroying salivary gland, either with a chemical inserted into the duct or by ligation of the duct.

Laceration or iatrogenic injury to a salivary duct can lead to a salivary cutaneous fistula. The fistula can be resolved by reapposing the severed duct with sutures, by creating a new oral opening for the duct, or by destroying the salivary gland. The parotid salivary gland can be ablated by flushing a solution of 10% formalin into the duct or by

ligating the duct proximal to the fistula. Wounds involving the salivary glands can usually be resolved successfully by cleansing, debriding, and suturing the wound.

Primary neoplasms of the salivary glands of horses include benign mixed tumors, adenocarcinomas, and acinar cell tumors. Neoplasms that invade the salivary gland from an adjacent area or melanomas of old grey horses that metastasize to the salivary gland are more common than primary salivary neoplas

32.21 EQUINE ORAL NEOPLASMS

Equine oral neoplasms are rare, making up a very small percentage of facial or mandibular neoplasms. Oral neoplasms can be divided into three basic types: odontogenic, osteogenic, and secondary (soft tissue).[51]

Odontogenic neoplasms are derived from remnants of dental epithelium. The five types that have been reported in the oral cavity of horses are ameloblastomas, ameloblastic odontomas, complex odontomas, compound odontomas, and cementomas. Histologic examination of odontogenic neoplasms can be confusing because of variation in appearance of tissue obtained at different sampling sites and age-related changes in the neoplasm's appearance. Because of their rarity, ill-defined biologic behavior, poorly defined radiographic features, and histologic variations, odontogenic neoplasms can be difficult to classify.

Primary bone neoplasms of horses are rare, and most (osteoma, ossifying fibromyoma) are benign. More than 80% of equine osteosarcomas occur in the head region. Like odontogenic neoplasms, primary bone neoplasms of horses are difficult to classify. In addition to gross and histologic examination, correlating history and clinical, radiologic, and biochemical findings is often essential to establish a diagnosis.

Secondary neoplasms of the oral cavity include squamous cell carcinoma, lymphosarcomas, papilloma, and melanomas that have extended into the oral cavity from an adjacent site or metastasized into the oral cavity from a remote site. Squamous cell carcinoma is the most frequently reported oral neoplasm in the horse. Generally these neoplasms are seen in old horses; there is no gender or breed predilection. Neoplasms of the tongue are rare and include lymphosarcomas, multiple myeloma, rhabdomyosarcoma, and paraneoplastic bullous stomatitis.

Options available to control progression of oral neoplasms include radiotherapy, hyperthermia, chemotherapy, cryosurgery, immunotherapy, autogenous vaccines, photodynamic therapy, laser therapy, and surgical resection. Results of these treatments vary according to the type of tumor and circumstances, such as whether the neoplasm has invaded bone.

32.22 DISORDERS OF THE ESOPHAGUS

Anthony T. Blikslager

Samuel L. Jones

32.23 ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

The most cranial aspect of the esophagus is located on the median plane immediately dorsal to the trachea. However, at approximately the midcervical region (C4 to C5), the esophagus typically shifts to the left of the trachea and lies just deep to the external jugular vein.[52,53] It is here that intraluminal obstructions or the tip of a stomach tube may be visualized, and this is the region where trauma can readily result in esophageal perforation. When a stomach tube is passed, it is critical that the tube be palpated to ensure the tube is in the esophagus because

jugular pulses can be confused with the appearance of the tip of the tube. In addition to its proximity to the external jugular vein, the esophagus is also located adjacent to the vagosympathetic trunk and the common carotid artery.[52] The esophagus is innervated by branches of the vagosympathetic trunk, and blood is supplied to the cervical esophagus by branches of the carotid arteries. The thoracic esophagus, which lies ventral to the trachea until the tracheal bifurcation, where it resumes a dorsal position, receives its blood supply from the bronchoesophageal artery. Venous drainage is via the external jugular veins in the cervical esophagus and the esophageal vein in the thoracic esophagus.

The muscular wall of the esophagus increases in thickness as the esophagus courses distally, while the lumen gets smaller.[52] The esophagus is not covered by a serosa except for a very short segment that traverses the abdominal cavity between the diaphragm and the stomach.[53] Instead, the outer wall of the esophagus is composed of adventitia that is loosely attached to surrounding tissues. This loose connection allows movement of the esophagus during swallowing and during movement of the neck. The cranial two-thirds of the esophageal wall consists of skeletal muscle, whereas the distal third of the esophagus is composed of smooth muscle. Although the muscular layers are composed of an outer and an inner layer, similar to the remainder of the gastrointestinal tract, the skeletal muscle layers are oriented obliquely to one another.[52] This, and an abundant submucosa, enables extensive dilation of the esophagus as a bolus of food moves toward the stomach. In addition, the velocity of esophageal contraction is faster in the skeletal muscle segment of the esophagus compared with the distal smooth muscle segment.[54] The muscle layers become oriented in more of an outer longitudinal and inner circular configuration in the caudal esophagus.[52] In the resting collapsed state, redundant esophageal mucosa and submucosa become oriented in longitudinal folds. The mucosa is composed of stratified squamous epithelium that is continuous with the stratified epithelium of the cardiac portion of the stomach.[52]

The cranial esophageal sphincter is formed by the cricopharyngeus muscle and maintains a resting intraesophageal pressure of approximately 85 mm Hg and a postdeglutition pressure as high as 200 mm Hg. Although the caudal esophageal sphincter is anatomically indistinct, resting intraesophageal pressure in this region is maintained at approximately 13 mm Hg, and postdeglutition pressure in the caudal esophagus may be as high as 100 mm Hg. The pressure in the caudal esophagus is maintained at approximately 10 mm Hg higher than the intraluminal pressure of the stomach.[54,55] Although the higher pressure in the distal esophagus has been implicated as the cause for the inability of most horses to vomit and for gastric rupture, other factors such as a poorly developed vomiting reflex may be more important.[56]

32.24 DIAGNOSTIC CONSIDERATIONS

Esophageal disease should be a differential diagnosis in any horse that demonstrates excessive salivation. Such signs also indicate the need to assess hydration, electrolyte levels, and acid-base status. In a study in which horses had continual loss of saliva via an experimentally placed esophagotomy, abnormalities included hypochloremia, hyponatremia, and hypokalemia.[57] This results from the relatively high levels of these electrolytes in saliva. Furthermore, because horses depend on dietary intake of potassium, hypokalemia would be exacerbated in a horse that was also unable to eat because of esophageal obstruction. Loss of salivary fluid and bicarbonate also results in dehydration and metabolic acidosis. However, metabolic alkalosis subsequently occurs presumably as a result of renal compensation for electrolyte loss, particularly chloride.[57]

Further examination of horses with esophageal disease may reveal evidence of swelling or emphysema in the region of the cranial or cervical esophagus that should prompt a thorough oral examination and further diagnostics such as radiography and endoscopy to define the nature of any esophageal abnormalities. If the esophagus has been

perforated or ruptured, subcutaneous emphysema is usually evident. The lungs should be carefully auscultated for evidence of aspiration pneumonia. Radiographs of the chest are required for a full pulmonary assessment.

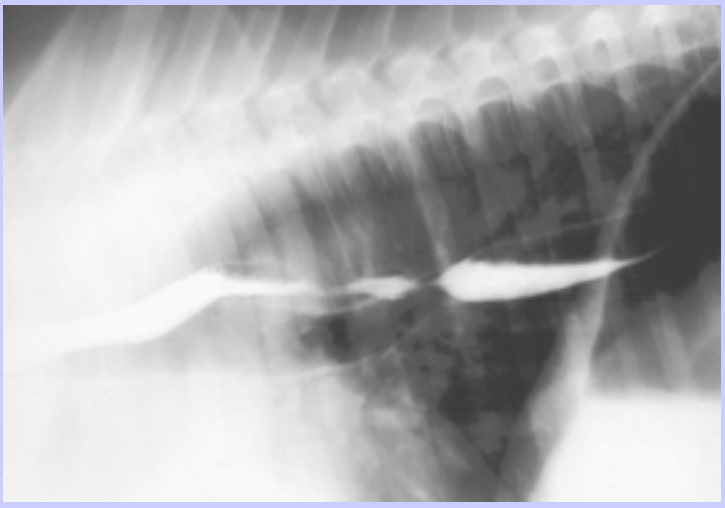
Radiographs of the esophagus should initially include plain films that may reveal evidence of an obstruction or areas of gas opacity within facial planes indicative of esophageal perforation.[58] However, facial and subcutaneous emphysema must be differentiated from other causes, including tracheal perforation.[56] The esophagus is often gas-distended cranial to an obstruction up to the cranial esophageal sphincter. Plain films may be diagnostic, but contrast radiographs are frequently required to fully define the nature of esophageal abnormalities.[58] Administration of barium paste or liquid will reveal linear opacifications as a result of the linear mucosal folds and may help outline intraluminal obstructions or strictures (Fig. 32-20).[58] A double-contrast study is a useful radiographic technique for defining esophageal wall abnormalities, particularly postobstruction mucosal ulceration, and is performed by placing a cuffed nasogastric tube in the cranial esophagus and injecting 300 to 500 mL of liquid barium followed by a similar volume of air. Care should be taken when evaluating such radiographs, because swallowing can create the false impression that there is a stricture.[59] The incidence of swallowing can be decreased by administration of xylazine. Liquid barium is preferable if swallowing function is compromised because it is less harmful to pulmonary tissues than paste, and water-soluble iodinated contrast material is particularly damaging to the lung because of its hypertonicity.[56] However, if an esophageal perforation is suspected, water-soluble contrast material is preferable.[56]

Endoscopic evaluation of the esophagus should be performed as part of a complete evaluation of esophageal injuries and abnormalities. After sedation of the patient, the endoscope should be passed all the way into the stomach before the esophagus is examined; it will be more readily viewed as the endoscope is withdrawn.[58] Inflation of the esophagus must also be performed intermittently as the wall of the esophagus collapses around the end of the endoscope. The longitudinal folds of the esophageal mucosa will be readily appreciated and can be flattened out as the esophagus is distended to more clearly view the entire circumference of the esophagus. Swallowing may create artifacts such as the appearance of strictures, so the esophagus should be carefully reinflated after each swallow to carefully evaluate such findings.[59]

688

689

Fig. 32-20 Barium contrast esophagram outlining esophageal luminal structure. Courtesy Dr. K.E. Sullins.



A recent study evaluated structures that could be evaluated via thoracoscopy of the mediastinum, including the thoracic component of the esophagus. Although this procedure caused pneumothorax, a 15-minute period of evaluation allowed observation of a number of structures including the esophagus.[60] Portals placed at the eighth, tenth, and twelfth intercostal spaces were useful for completion of this procedure and could provide additional information aside from radiographic and endoscopic evaluation of the thoracic esophagus.

32.25 ESOPHAGEAL OBSTRUCTION

Esophageal obstruction, either primary (simple choke) or secondary to other disease processes, is the most common esophageal disorder seen in horses. Although primary obstructions may be caused by foreign bodies, including corncobs, potatoes, apples, carrots, medicinal boluses, stones, riding crops, or wood fragments, primary obstructions are most often caused by roughage, particularly leafy alfalfa hay, coarse grass hay, bedding, and even grass.[61–71] Prior esophageal trauma or poor mastication caused by dental abnormalities may predispose horses to esophageal impaction. Obstructions from roughage may be precipitated by wolfing or gulping food, particularly if the horse is exhausted and/or mildly dehydrated such as after a long ride, or weakened from chronic debilitation. Secondary impactions are caused by intramural or extramural abnormalities that mechanically impede food passage. Examples of intramural obstructions include tumors (squamous cell carcinomas), strictures, diverticula, cysts, and vascular ring anomalies.[72–78] Mediastinal or cervical masses (tumors or abscesses) may cause extramural obstructions.

The clinical signs associated with esophageal obstructions are similar whether they are classified as primary or secondary and are rarely specific. Horses with esophageal obstruction are often anxious and stand with the neck extended. Gagging or retching may be noted, particularly with acute proximal obstructions. Bilateral frothy nasal discharge containing saliva and food material, coughing, odynophagia, ptyalism, and dysphagia are usually the primary clinical signs, the severity of which varies with the degree and location of the obstruction. Distention of the cervical esophagus may be evident at the site of obstruction. Other clinical signs may be observed related to complications stemming from the obstruction, such as dehydration, weight loss, aspiration pneumonia, or esophageal rupture.

Thorough physical examination, including a complete oral examination, must be performed to rule out other causes of hypersalivation, dysphagia, and nasal discharge. Palpation of the jugular furrow may reveal a mass associated with the impaction. In most horses the esophagus is located in the left jugular furrow, but it may be found in the right furrow in some animals. Crepitus or cellulitis may be evident, suggesting rupture of the esophagus. Auscultation of the lungs is important to determine whether pneumonia or pleural fluid is present because of aspiration or intrathoracic esophageal rupture. Passage of a nasogastric tube is a good way to determine whether and where an obstruction is present but provides little information about the nature of the obstruction or the condition of the esophagus.

Ultrasonography of the cervical region is extremely useful not only to confirm the presence of a cervical esophageal impaction, but also to provide critical information about the location and extent of the impaction and esophageal wall thickness and integrity. Ultrasonography may also provide information about the cause of the obstruction. Radiography, particularly air or barium contrast studies, may be useful to assess an esophageal impaction but may be more useful for evaluating the esophagus after rather than before relief of the impaction to demonstrate stricture, dilation, diverticula, esophageal rupture, or masses.[79,80] Care should be taken when interpreting radiographic studies in sedated horses, particularly after passage of a nasogastric tube or other esophageal manipulations that may contribute to esophageal dilation.[81] Impacted food material can be detected in

the esophagus by a typical granular pattern, and gas is often observed to accumulate proximal to the obstruction. Foreign bodies may be identified by contrast radiographic studies.

Definitive evaluation of esophageal obstructions often requires endoscopic examination. Most cases of esophageal obstruction occur at sites of natural narrowing of the esophageal lumen, such as the cervical esophagus, the thoracic inlet, the base of the heart, or the terminal esophagus. Therefore an endoscope longer than 1 meter may be required for complete evaluation. Endoscopic evaluation is useful before relief of an impaction to localize the impaction and to investigate the nature of the impaction if a foreign body is suspected. Foreign bodies may be retrievable via transendoscopic tethering.[69] Critical diagnostic and prognostic information is obtained after resolution of the impaction to determine whether mucosal ulceration, esophageal rupture, masses, or strictures are present.

The primary goal of treatment for esophageal impaction is to relieve the obstruction. Parenteral administration of acepromazine (0.05 mg/kg IV), xylazine (0.25 to 0.5 mg/kg IV) or detomidine (0.01 to 0.02 mg/kg IV), oxytocin (0.11 to 0.22 IU/kg IM), and/or esophageal instillation of lidocaine (30 to 60 mL of 1% lidocaine) may help reduce esophageal spasms resulting from pain or increased esophageal tone.[66,81–83] However, recent conclusive studies revealed that detomidine, acepromazine, or a combination of xylazine and butorphanol had the greatest effect on esophageal motility when evaluated by a monomer in conscious horses.[84] However, in vitro studies revealed a relaxant effect of oxytocin on esophageal muscle, suggesting it may be useful for relief of esophageal obstruction.[85]

Resolution of an impaction may require physical dispersal of the material. A nasogastric tube can be used to displace the impacted material in conjunction with external massage if the obstruction is in the cervical region. Often it is necessary to carefully lavage the esophagus with water via an uncuffed or a cuffed nasogastric tube while the head is lowered to aid in breaking up the impaction. Some clinicians advocate a dual tube method whereby a tube is placed through each nasal passage into the esophagus for ingress and egress of the lavage fluid. Because of the risk of aspiration of water and/or food material, esophageal lavagfe is sometimes done under general anesthesia with a cuffed nasotracheal tube.

In refractory cases, intravenous administration of isotonic fluid containing 0.9% NaCl and KCl (10 to 20 mEq/L) for 24 hours at a rate of 50 to 100 mL/kg/day in conjunction with esophageal relaxants such as oxytocin may promote hydration and softening of the impaction and will help prevent or alleviate any electrolyte or acid-base imbalances resulting from salivary losses of chloride, sodium, and potassium. Refractory cases may require esophagotomy to relieve the impaction. Strict restriction of access to food and water, including access to bedding material, must be enforced until the obstruction is resolved and the esophagus has regained function.

Dilation proximal to the site of obstruction, mucosal injury from trauma, and esophagitis are sequelae to esophageal impaction that predispose patients to reobstruction. The rate of reobstruction may be as high as 37%. Depending on the duration of the obstruction and the degree of trauma or dilation, the risk of reobstruction is high for 24 to 48 hours or longer; therefore food should be withheld for at least 24 to 48 hours after resolution of the obstruction. After 48 to 72 hours or when the esophageal mucosa has recovered as assessed by endoscopy, soft food (moistened pellets and bran mashes) can be fed. The patient can be gradually returned to a high-quality roughage diet over a period of 7 to 21 days depending on the degree of esophageal damage induced by the impaction and the nature of any underlying disease. The prognosis for survival is good (78%), but some horses may require permanent dietary modification if persistent chronic obstruction is a problem.[68]

Complications of esophageal impaction include metabolic alkalosis from prolonged loss of salivary chloride and sodium, esophageal ulceration, stricture, perforation, aspiration pneumonia, and megaesophagus. Esophageal endoscopy and/or ultrasonography should be performed immediately after the impaction is relieved to determine whether any complications of the impaction have developed or if an inciting cause of the obstruction is present.

Endoscopic evaluation is critical to determine the postobstruction treatment and followup. Reevaluation should be performed intermittently every 2 to 4 weeks after resolution of the impaction if esophageal dilatation or mucosal injury is noted. Additional evaluation via radiography may be warranted to assess motility and transit times.

If the obstruction was present for 48 hours or longer, dehydration, hyponatremia, hypochloremia, and hypokalemia may occur and should be corrected via oral electrolyte solutions or intravenous administration of 0.9% NaCl and KCl (10 to 20 mEq/L). If aspiration is suspected, administration of broad-spectrum antibiotics that are effective against gram-positive and gram-negative organisms, including metronidazole for anaerobes, is advisable. Sucralfate (20 mg/kg orally [PO] q6h) may hasten healing if esophageal ulceration is evident, but this is controversial. Some clinicians suggest that administration of a nonsteroidal antiinflammatory drug such as flunixin meglumine (1 mg/kg PO or IV q12h) or phenylbutazone (1.1 mg/kg PO or IV q12h) for 2 to 4 weeks after resolution of the impaction may reduce the development of strictures.

32.26 ESOPHAGITIS

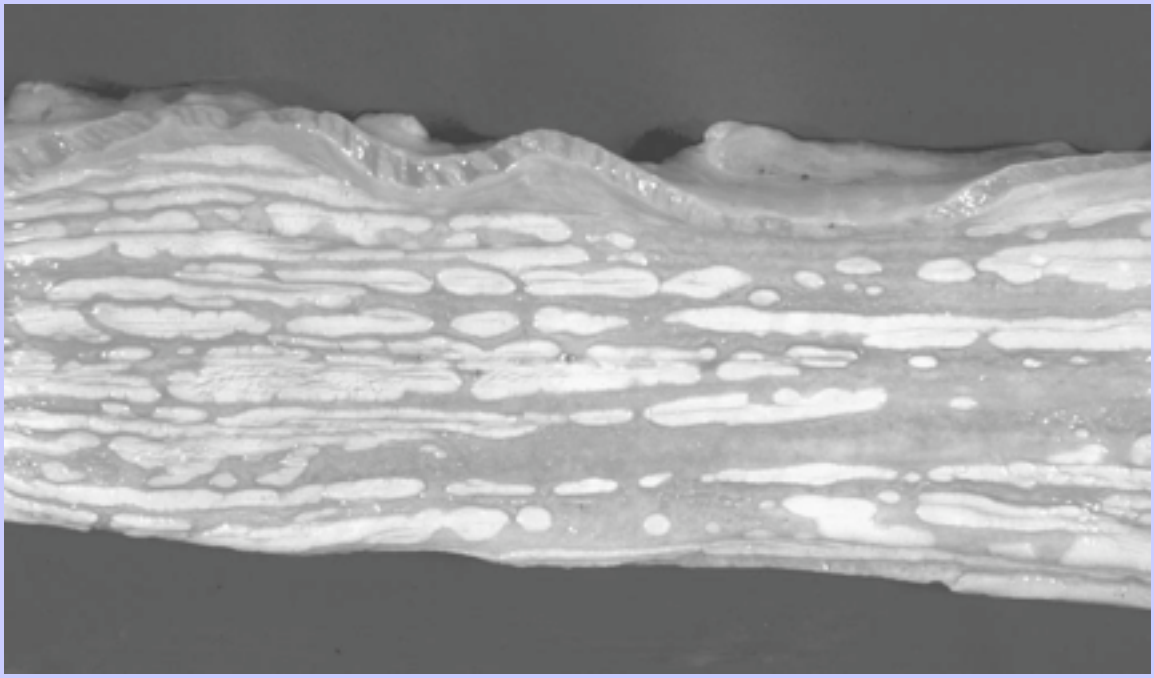
Inflammation occurs during many conditions of the esophagus. *Esophagitis* refers to a clinical syndrome of esophageal inflammation, which may or may not be ulcerative. Causes of esophagitis in horses include trauma (foreign bodies, nasogastric tube), infection (mural abscesses), and chemical injury (medicines, cantharidin).[86,87] An important category of esophagitis is reflux esophagitis, caused by reflux or delayed clearing of gastric contents into the distal esophagus and subsequent chemical injury to the mucosa (Fig. 32-21). Similar to ulceration of the squamous portion of the stomach in horses, a major cause of ulcerative esophagitis is epithelial damage resulting from exposure to acid, which is synergistically exacerbated by bile salts.[62,88] The major protective mechanisms of the esophageal mucosa include salivary and food material buffers, normal peristaltic motility, and the barrier formed by the gastroesophageal sphincter. Thus, esophagitis may be seen in conjunction with gastric ulcer disease, motility disorders, increased gastric volume from gastric outflow obstructions, gastric paresis, intestinal ileus, or impaired lower esophageal sphincter function.

The clinical signs of esophagitis are nonspecific and similar to those of esophageal obstruction and gastric ulcer disease. In fact, esophagitis may occur concurrently with esophageal obstruction or gastric ulcer disease, so clinical signs may overlap extensively with these diseases. Gagging, or discomfort when swallowing, may be evident, and hypersalivation and bruxism are signs of esophageal pain. Partial or complete anorexia may be noted such that horses with chronic esophagitis may have significant weight loss. Motility dysfunction secondary to esophagitis may cause recurrent esophageal impaction. Clinical signs of underlying disease that predispose to esophagitis may predominate or mask the signs of esophagitis. Horses with gastrointestinal motility disorders such as anterior enteritis are at high risk for developing reflux esophagitis because of the presence of both gastric acid and bile salts in the fluid reflux. However, signs attributable to esophagitis secondary to ileus may not be noted because of the profound signs caused by the intestinal disorder. Foals with gastric outflow obstructions commonly have reflux esophagitis.

690

691

Fig. 32-21 Severe ulceration of the esophagus in a weanling foal that had severe duodenitis and gastric outflow obstruction. Courtesy Dr. M.J. Murray.



Diagnosis requires endoscopic examination of the esophagus. Diffuse, patchy, linear, or coalescing erosion or ulcerations may be noted. Significant edema or hyperemia may also be observed. It is important to determine whether underlying disease, such as infection, neoplasia, diverticula, or esophageal stricture is present. In addition, the stomach must be examined because reflux esophagitis is commonly accompanied by gastritis or gastric ulcer disease. Contrast radiography may be helpful if endoscopy is not available to detect esophageal ulceration and can be used to assess esophageal motility and transit time.

The principles of therapy for reflux esophagitis include control of gastric acidity and correction of any underlying disorder that is contributing to gastroesophageal reflux. Thus, treatment with histamine-2 (H_2)–receptor antagonists such as ranitidine or proton pump antagonists such as omeprazole is important for resolution of the disease. Some clinicians advocate sucralfate administration to aid healing of esophageal ulcers. However, the efficiency of sucralfate binding to ulcerated mucosa in the squamous epithelium of the gastrointestinal tract has recently been brought into question.

Foals with reflux esophagitis secondary to delayed gastric outflow caused by gastroduodenal ulcer disease or gastric paresis may benefit from prokinetic drugs that act on the proximal gastrointestinal tract. Metoclopramide (0.02 to 0.1 mg/kg SC q4-12h) reduces gastroesophageal reflux by increasing lower esophageal sphincter tone, gastric emptying, and gastroduodenal coordination. Caution should be exercised when giving metoclopramide to horses because they are prone to extrapyramidal neurologic side effects. Cholinergic drugs such as bethanechol (0.025 to 0.035 mg/kg SC q4-24h or 0.035 to 0.045 mg/kg PO q6-8h) may improve gastric emptying and are effective for treating reflux esophagitis. For esophagitis from trauma or pressure injury after esophageal impaction,

judicious use of nonsteroidal antiinflammatory drugs may be warranted to reduce esophageal inflammation and pain.

Dietary modification may be necessary in patients with esophagitis, depending on the degree of ulceration or if motility is impaired. Horses with less severe esophagitis should be fed frequent small meals of moistened pellets and fresh grass. Severe esophagitis may necessitate withholding food and complete esophageal rest for several days. Although the prognosis for esophagitis is good in the absence of underlying disease, the risk of stricture formation is high if severe circumferential or coalescing ulcerations are present. Animals with esophagitis from severe trauma or infection may also be prone to stricture formation.

32.27 MOTILITY DISORDERS OF THE ESOPHAGUS

Esophageal hypomotility is the most common motility dysfunction of the equine esophagus and results in esophageal dilation or megaesophagus. Although megaesophagus in horses is most commonly acquired, there are reports of idiopathic megaesophagus in young horses that is likely congenital (Fig. 32-22 and Color Plate 1).[89–92] Acquired megaesophagus in adult horses is usually caused by either primary or secondary esophageal obstruction. Esophageal impactions of relatively short duration cause proximal dilation of the esophagus that is generally reversible. However, if the duration of the obstruction is long, the motility of the esophagus may be permanently impaired. Acquired megaesophagus in foals is often secondary esophagitis resulting from gastric outlet or duodenal obstruction. Other causes of acquired megaesophagus include extraesophageal obstruction by tumors or abscesses, pleuropneumonia, and vascular ring anomalies. In addition, acquired megaesophagus may result from neurologic, neuromuscular, or muscular disorders. Neurologic diseases that cause vagal neuropathy, such as equine protozoal myeloencephalitis, equine herpesvirus myeloencephalitis, and idiopathic vagal neuropathy, have been associated with megaesophagus in horses. Pleuropneumonia may be associated with vagal neuropathy, resulting in megaesophagus. Megaesophagus is also an early sign of equine dysautonomia[93] and may be noted in patients with botulism. Myasthenia gravis is a well-known cause of megaesophagus in other species but has not been reported in horses. Also in other species, electrolyte disorders, cachexia, primary myopathies, myositis, and Addison's disease may affect esophageal motility but have not been associated with megaesophagus in horses.

691

692

Fig. 32-22 Megaesophagus in a 10-month-old Paint horse foal that had two duodenal strictures that appeared to have been present for several months. The trachea *(T)* lies dorsal to the dilated esophagus *(E)*. Courtesy Dr. M.J. Murray.

Esophageal inflammation, particularly reflux esophagitis, may affect motility and cause megaesophagus. However, because esophageal hypomotility may predispose to reflux esophagitis, it may be difficult to determine whether the esophagitis or the megaesophagus is the causative disorder. Iatrogenic megaesophagus can be induced by the α_2-adrenergic agonist detomidine, but this is transient and reversible.[94] However, the use of this drug may complicate clinical evaluation of esophageal motility. Because esophageal hypomotility is a functional obstruction, the clinical signs of esophageal hypomotility or megaesophagus are similar to those of esophageal obstruction. Thus, the clinical signs include ptyalism, dysphagia, and nasal discharge of saliva and food material. The cervical esophagus may be sufficiently dilated to be evident externally. Weight loss is a common sign, and clinical signs attributable to an underlying disease may be evident.

Diagnosis of esophageal hypomotility requires transit studies. Transit time of a bolus from the cervical esophagus to the stomach can be measured by fluoroscopy or contrast radiography.[58,93] Other signs of esophageal hypomotility and megaesophagus include pooling of contrast material and an absence of peristaltic constrictions. Endoscopy may reveal a dilated esophagus and an absence of peristaltic waves. Evidence of underlying disease causing obstruction or esophageal dilation may be observed. The esophagus should be evaluated for evidence of esophagitis that is either causing esophageal motility dysfunction or is a result of impaired esophageal clearance of gastric fluid. Esophageal manometry may be useful to document abnormal postdeglutition contraction pressures, contraction time, and propagation times.[55,89] Other diagnostic tests such as a CBC and chemistry to help identify an underlying cause should be performed. A careful neurologic evaluation should be performed. Signs of neurologic disease and abnormal cerebrospinal fluid analysis suggest an underlying neurologic disorder. Myopathy may be detected by electromyography.

Treatment of esophageal hypomotility or megaesophagus should be aimed at treating the underlying cause. Dietary modification should be aimed at improving esophageal transit of food. Slurries of pellets should be fed. In addition, it may be beneficial to feed from an elevated position to promote transit. In patients with reflux esophagitis associated with megaesophagus, metoclopramide or bethanechol may be beneficial to increase lower esophageal tone, promote gastric emptying, and reduce gastroesophageal reflux. The prognosis depends on the underlying cause and the degree of dilation. Although many cases of megaesophagus associated with reflux esophagitis respond well to treatment, many other forms of megaesophagus including congenital megaesophagus have a poor prognosis.

32.28 CONGENITAL DISORDERS

Congenital disorders of the esophagus are rare. Reported congenital abnormalities include congenital stenosis,[95] persistent right aortic arch, congenital strictures, esophageal duplication cysts,[96,97] and idiopathic megaesophagus.[98] In the one report on congenital stenosis, double-contrast radiography revealed concentric narrowing of the thoracic esophagus in the absence of any vascular abnormalities at the base of the heart. Successful treatment included having the foal stand with the forelimbs elevated off the ground after each feeding.

Persistent right aortic arch is a congenital anomaly in which the right fourth aortic arch becomes the definitive aorta instead of the left aortic arch, which results in constriction of the esophagus by the ligamentum arteriosum as it extends between the anomalous right aorta and the left pulmonary artery.[75] Clinical signs may include dysphagia, drooling of saliva, and distention of the cervical esophagus as a result of partial obstruction of the thoracic esophagus.[99] Endoscopic examination typically reveals dilatation of the esophagus cranial to the obstruction with

evidence of diffuse esophagitis. In addition, evaluation of the thorax usually reveals the presence of aspiration pneumonia. Successful surgical treatment of persistent right aortic arch has been reported in one foal.

Esophageal duplication cysts cause typical signs of esophageal obstruction, including salivation, dysphagia, and swelling of the cervical esophagus as they enlarge. Such signs can make them difficult to differentiate from simple obstruction (choke). However, an aspirate of the mass may aid in the diagnosis by revealing the presence of keratinized squamous cells.[100] Cysts may communicate with the lumen of the esophagus. Surgical treatments have included complete surgical resection and surgical marsupialization. The latter appears to be more successful and to result in fewer complications. Complications of surgical resection have included laryngeal hemiplegia secondary to surgical trauma to the recurrent laryngeal nerve in the region of the esophagus, and esophageal fistula formation.

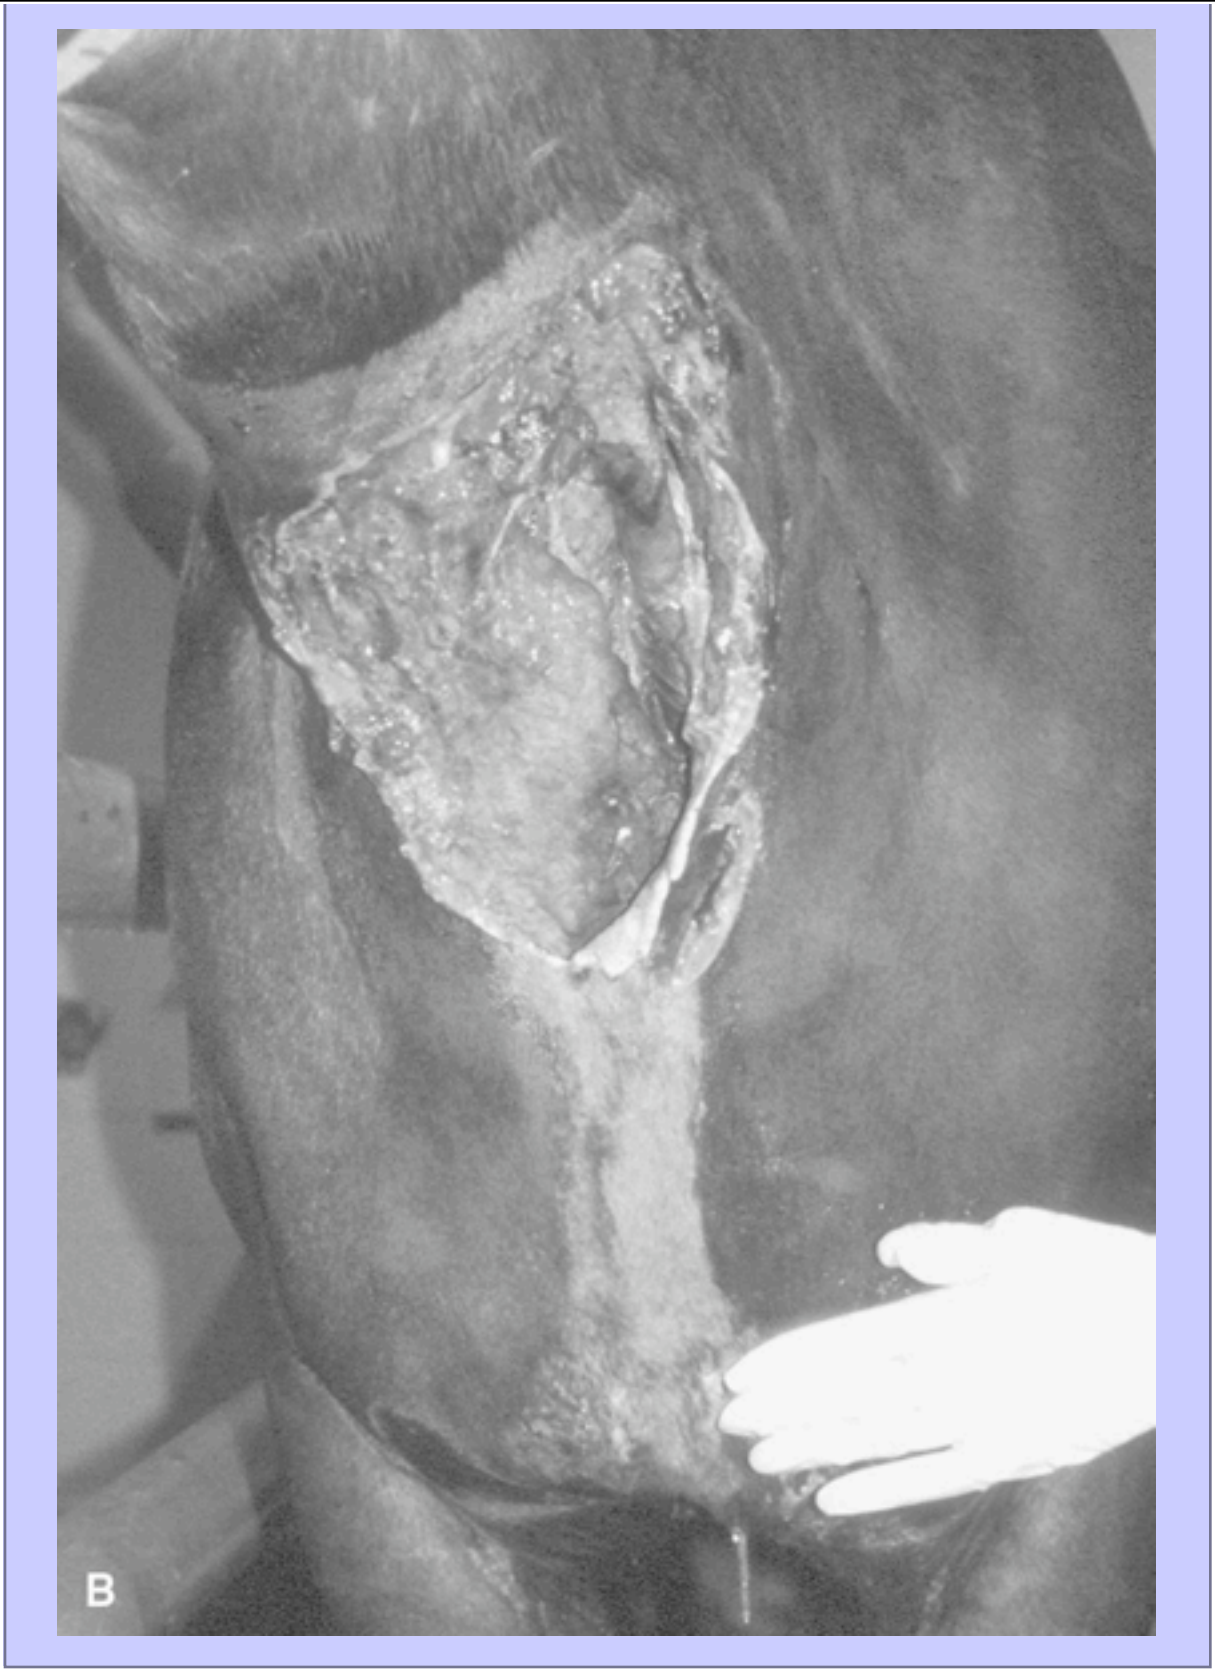
692

693

32.29 ESOPHAGEAL PERFORATION

Perforation typically occurs in the cervical region in response to external trauma or rupture of an esophageal lesion such as an impacted diverticulum. The esophagus is particularly vulnerable to external trauma in the distal third of the neck because it is covered by only a thin layer of muscle at this point.[101] Iatrogenic perforation may occur in response to excessive force with a stomach tube against an obstruction or a compromised region of the esophagus. Esophageal perforations may be open or closed and tend to cause extensive necrosis of tissues surrounding the wound because of drainage of saliva and feed material within fascial planes (Fig. 32-23). This may lead to extensive cellulitis and endotoxemia. Closed perforations of the esophagus are particularly troublesome, as wound discharge may migrate all the way to the mediastinum and pleural space via fascial planes and may cause abscessation (Fig. 32-24). In addition, extensive subcutaneous and fascial emphysema frequently develops and is usually evident on cervical radiographs.

Fig. 32-23 Esophageal perforation in a horse. **A**, An open esophageal laceration was detected on presentation in the midcervical region. The wound was treated by lavage and debridement, and the horse was fed via a tube inserted into the esophagus through the wound. **B**, Approximately 14 days later, dissection of esophageal contents within surrounding fascial planes has resulted in extensive sloughing of tissue.



B

Treatment should include conversion of closed perforations to open perforations if possible,[102] extensive debridement and lavage of affected tissues, broad-spectrum antibiotics, tetanus prophylaxis, and esophageal rest. The latter may be achieved by placing a feeding tube into the esophagus via the wound. Alternatively, a nasogastric tube should be placed using a small tube (12-Fr diameter). For open perforations, once the wound has granulated and contracted to a small size, oral feeding may be attempted. Extensive loss of saliva via esophageal wounds may lead to hyponatremia and hypochloremia. In addition, transient metabolic acidosis occurs because of salivary bicarbonate loss, followed by progressive metabolic alkalosis. Although there are reports of esophageal wounds healing well by second intention, it takes a prolonged period of time.[103] In addition, some perforations never completely heal and form permanent esophagocutaneous fistulas that may require surgical correction. The development of esophageal strictures is not common because wounds are usually linear and not circumferential. However, traction diverticula may develop. Other complications of esophageal wounds include Horner's syndrome and left laryngeal hemiplegia.

In a retrospective study on esophageal disorders, only 2 of 11 horses with esophageal perforations survived long term, and in a report on esophageal trauma secondary to nasogastric intubation, 4 of 5 horses were euthanized. The prognosis is therefore poor in horses with esophageal perforations, largely because of the extent of cellulitis, tissue necrosis, shock, and local wound complications.

693

694

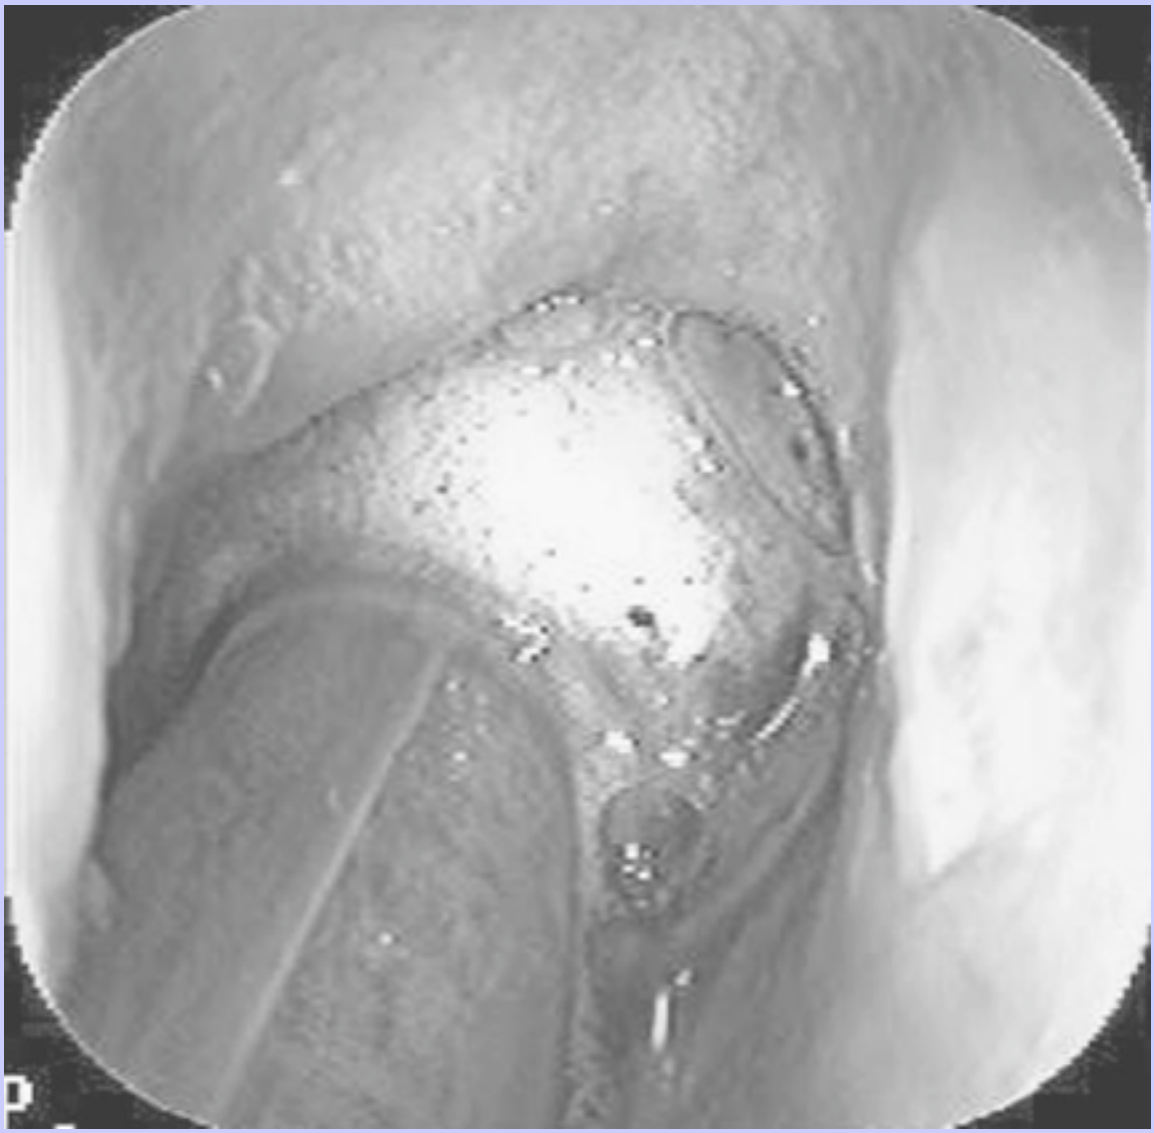
32.30 ESOPHAGEAL STRICTURE

Strictures most commonly occur as sequelae to esophageal obstructions that result in circumferential erosion or ulceration of the esophageal mucosa, although strictures may result from oral administration of corrosive medicinal agents and trauma to the neck.[104] Congenital strictures have also been reported. Strictures that result from mucosal and submucosal trauma are termed *esophageal webs* or *rings*. Strictures may also originate in the muscular layers and adventitia of the esophagus (mural strictures) or in all of the layers of the esophagus (annular stenosis).[105] Horses with these lesions have a presentation similar to that of horses with simple obstructions because strictures result in partial obstruction and accumulation of feed material in the lumen. Esophageal webs or rings can be observed endoscopically, whereas mural strictures or annular stenosis may require double-contrast esophagrams to confirm their presence.

In one study on esophageal stricture after simple obstruction, maximal reduction in esophageal lumen occurred within 30 days of esophageal obstruction. Although surgery has been employed to reduce such strictures, initial medical management is warranted because strictures may resolve with conservative therapy, and the esophagus continues to remodel for up to 60 days after ulceration. In one report, seven horses with esophageal obstruction—induced stricture were treated conservatively by feeding a slurry diet and administering antiinflammatory and antimicrobial medications, and five of seven were clinically normal within 60 days. One of the five successfully treated horses had a 10-cm area of circumferential ulceration, suggesting extensive mucosal injury may resolve without permanent stricture formation. If there is insufficient resolution of strictures within 60 days, other methods to increase esophageal diameter should be investigated. Bougienage has been used successfully in small animal patients and human beings. The technique involves passage of a tubular dilatable instrument down the esophagus and stretching of the stricture. Some authors have suggested that this may be accomplished by passing a nasogastric tube with an inflatable cuff (Fig. 32-25).[106] However, the procedure has to be performed frequently to have any success and is not well tolerated in the horse. Alternatively, several surgical techniques have been used to resolve strictures, including resection and anastomosis,[107,108] temporary esophagostomy with fenestration of the stricture, esophagomyotomy for strictures of the muscularis and adventitia,[109,110] and patch grafting with local musculature.[111] However, such surgeries are fraught with complications, largely because of the propensity of the traumatized esophagus to restricture. The esophagus lacks a serosal layer and does not rapidly form a fibrin seal, as does the remainder of the intestinal tract, so anastomoses tend to leak. In addition, tension on the esophagus during swallowing and movement of the neck impairs healing of anastomoses.

Fig. 32-25 Attempted dilation of esophageal stricture using bougienage. In this case, a cuffed Silastic tube was passed to the site of stricture aided by endoscopy, and the cuff was then inflated to distend the site of structure. Courtesy Dr. M.J. Murray.



32.31 ESOPHAGEAL DIVERTICULA

There are two types of diverticula: traction (true) diverticula and pulsion (false) diverticula. Traction diverticula result from wounding and subsequent contraction of periesophageal tissues, with resultant tenting of the wall of the esophagus. Pulsion diverticula arise from protrusion of esophageal mucosa through defects in the muscular wall of the esophagus and usually result from trauma or acute changes in intraluminal pressure (Fig. 32-26). Traction

diverticula appear as a dilatation with a broad neck on contrast esophagography, whereas pulsion diverticula typically have a flask shape with a small neck on an esophagram.[112] Whereas traction diverticula are usually asymptomatic and of little clinical significance, pulsion diverticula may fill with feed material, ultimately leading to esophageal obstruction.[113] However, a movable mass in the midcervical region may be noticed before onset of complete obstruction.[56] Pulsion diverticula may be surgically corrected by inverting or resecting prolapsed mucosa and closing the defect in the wall of the esophagus.[77,112,113] Inversion of excessive mucosa may predispose horses to esophageal obstruction and should therefore be reserved for small diverticula.

32.32 NEOPLASIA

Neoplasia of the esophagus is rare, but squamous cell carcinoma[114,115] and leiomyosarcoma[116] have reportedly affected the esophagus either as the primary site or in association with a lesion in the squamous portion of the stomach. The predominant clinical signs are weight loss, colic, and recurrent esophageal obstruction. The tumor is typically detected antemortem on esophagoscopy and radiography, but a definitive diagnosis may require a biopsy during laparotomy.[72,116] When neoplasia affects the lower esophageal sphincter, gastroesophageal reflux may contribute to ulceration of esophageal mucosa. The prognosis for malignant neoplasia of the esophagus is grave.

32.33 DISORDERS OF THE STOMACH

Michael J. Murray

32.34 GASTRIC ULCERATION

Just as the term *colic* describes a clinical presentation and encompasses a large number of disorders, the term *equine gastric ulcer syndrome* (EGUS) describes a clinical finding, the cause of which is likely to be multifactorial and different from case to case. The umbrella of EGUS includes lesions in the squamous or glandular mucosal linings of the stomach, focal or multifocal ulceration, generalized gastritis, gastric emptying disorders, gastroesophageal reflux disorders, and obstructive disorders. In foals, signs attributable to gastric disease can be the result of primary duodenal disease (see Color Plates 1-12).

32.34.1 Prevalence and Incidence

Gastric ulceration is a widespread phenomenon, affecting a large number of foals and horses. The overall prevalence of gastric ulceration in foals up to 60 days old has been reported to range from 25% to 50%, and most lesions were observed in the squamous mucosa.[117,118] In the majority of foals with lesions, clinical signs of ulcers were not apparent, and in one study[119] most lesions observed in foals less than 60 days old healed without treatment.

More than half of apparently normal horses had gastric lesions in one endoscopic study,[120] and lesions were more prevalent and severe in horses exhibiting clinical signs consistent with gastric ulceration (poor appetite, poor body condition, recurrent abdominal discomfort). Horses in training for racing appear to be at particular risk for developing gastric lesions, because 70% to 90% of racehorses have had gastric lesions documented endoscopically[120–125] or at necropsy.[126]

The incidence of gastric ulcers in horses exposed to ulcerogenic stresses has been reported to range from 70% to 86%.[127–129] Ulcers developed within 5 to 7 days in some reports. In one report ulcers developed in the majority of horses in simulated race training within 7 days,[130] and it was reported that 11 of 15 horses exercised using a mechanical exerciser developed gastric ulcers within 7 days.[131] Most studies have been done in horses in race training, but in one study that simulated conditions of traveling to a recreational horse show, 7 of 10 horses developed gastric ulcers within 5 days.[129] The latter two studies demonstrated a high incidence rate and rapid onset of gastric ulcers in horses not in race training regimens.

695

696

In the endoscopic studies referenced in the previous paragraphs, the majority of gastric lesions in adult horses reportedly occurred in the squamous mucosa. To some extent this observation has been influenced by the limitations of the endoscopic examination, in which only the portion of the stomach not obscured by ingesta or gastric secretions was observed. In studies in which the antrum and pylorus were specifically examined, lesions were found in the antral mucosa in 47% and 58% of horses.[132,133] In some horses with moderate to severe antral ulcers, the gastric squamous mucosa was normal.

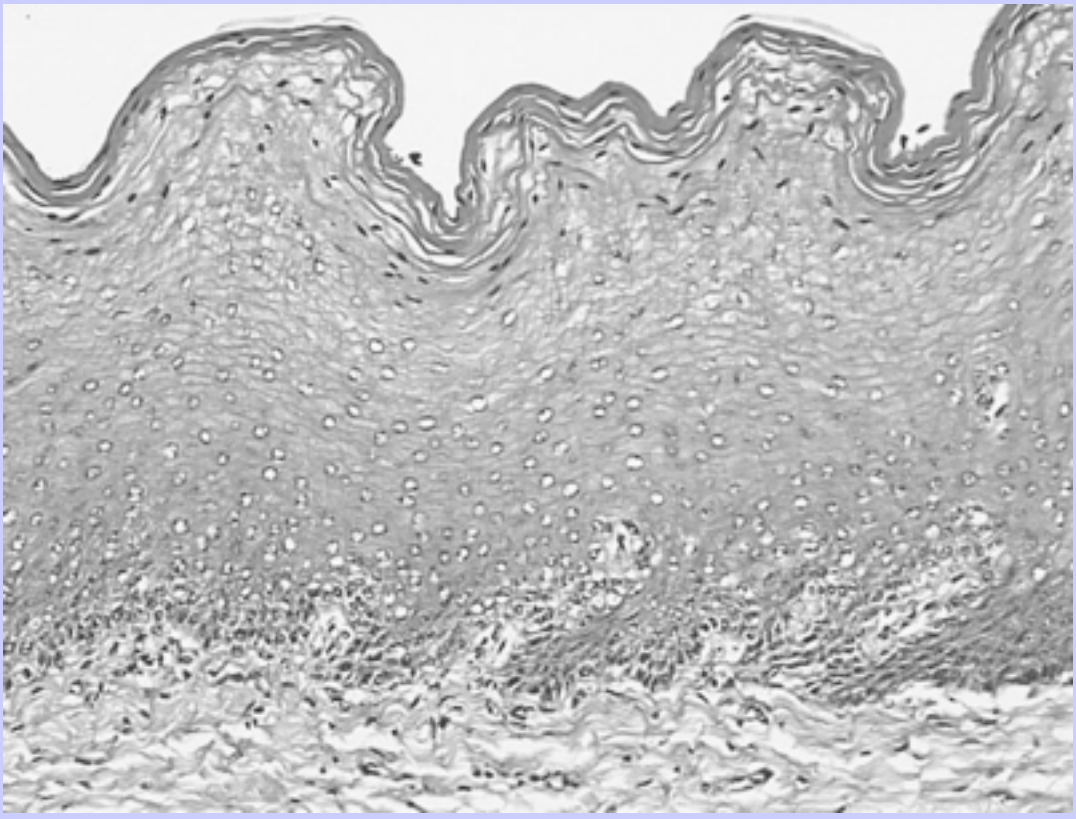
32.34.2 Pathophysiology

Damage to the gastric lining results from a combination of the physical properties of the gastric mucosa, the physiology of gastric acidity in the equine stomach, and the horse's response to potentially ulcerogenic stress factors. The predominant factor in peptic injury to alimentary mucosa is hydrochloric acid, although the proteolytic enzyme pepsin,[134] bile acids,[135] and short-chain fatty acids[136] may facilitate or exacerbate hydrochloric acid—induced mucosal injury.

The dorsal portion of the equine stomach is lined by a stratified squamous epithelial mucosa, which, like esophageal mucosa, has minimal intrinsic resistance to peptic injury (Fig. 32-27).[137] The equine gastric squamous mucosa is highly susceptible to acid-induced injury, with damage to this tissue detected within 30 minutes of in vitro exposure to solutions acidified by HCl.[138] The equine gastric glandular epithelium (Fig. 32-28) is histologically and physiologically similar to the lining of the stomach of other animals and human beings, and this mucosa has evolved elaborate mechanisms to protect itself from peptic injury. These include the mucus-bicarbonate barrier, prostaglandins, nitric oxide, growth factors, mucosal blood flow, and cellular restitution.[139,140]

Perhaps the key factor in whether the gastric squamous mucosa is injured by HCl is the duration of contact of HCl with the mucosa, which is influenced by eating behavior, exercise, and perhaps other factors, which collectively are recognized as “ulcerogenic stresses.” Risk factors, acting singly or interacting together, contribute to the ulcerogenic stress experienced by a horse, and the expression of the ulcerogenic stress as a gastric ulcer depends on individual characteristics of the animal as well as the risk factors themselves.

Fig. 32-27 Photomicrograph of equine gastric squamous epithelial mucosa. There are multiple layers of epithelium arranged in parallel with the luminal surface. The most superficial layers of cells are cornified, and superficial to these cells are layers of keratin. (Hematoxylin and eosin stain.)



Foals and horses and secrete HCl continuously,[141] and gastric acidity is greatest when foals do not nurse[142] or horses do not eat.[143] Gastric pH can fall to highly acidic levels (<2) within minutes of cessation of nursing or eating hay. Any disruption of feeding or nursing, whether it is imposed or caused by a clinical disorder, will prolong gastric acidity and increase the time that the squamous mucosa is exposed to HCl.

Prolonged periods of high gastric acidity (pH < 2) were created in horses using a protocol of alternating 24-hour periods of feed deprivation with free-choice timothy hay,[144] which consistently resulted in erosion and ulceration, often severe, in the gastric squamous epithelial mucosa in horses.[143] Erosions, sometimes bleeding, were seen after 48 hours cumulative feed deprivation, and ulcers were consistently seen after 96 hours. Concurrent administration of the H_2-receptor antagonist ranitidine during feed deprivation significantly minimized the area of lesions in the gastric squamous epithelial mucosa, demonstrating the direct contribution of HCl in the pathogenesis of these lesions.

Feeding practices and management of horses can influence gastric acidity and peptic injury to the gastric squamous mucosa. Changing horses from pasture to stall confinement with free choice timothy hay for 7 days resulted in erosion and ulceration of gastric squamous mucosa.[143] Imposed feed deprivation in the management of cases of colic can result in erosion and ulceration of the gastric squamous mucosa. Similarly, horses that are partly or completely anorectic because of their illness will likely develop erosions or ulcers in their gastric squamous mucosa.

Given the very high prevalence of gastric ulcers in horses in training, exercise is an important risk factor for EGUS. The reasons for the high prevalence and incidence of EGUS in association with exercise have not been fully explained, but in one report it was shown that treadmill exercise was associated with increased exposure of the dorsal part of the stomach to highly acidic gastric contents.[145] This occurred secondary to, and as a possible consequence of, increased intraabdominal pressure during exercise. These changes were observed when horses increased speed from a walk to a trot. It is interesting to note that several horses in that study developed gastric ulcers.

The high prevalence and severity of gastric ulcers in racehorses has contributed to the perception that EGUS is primarily a disorder of racehorses and other horses in intensive training, However, results of a recent study demonstrated that activities considered to be normal by the recreational horse enthusiast are associated with an increased incidence of gastric squamous mucosal ulcers.[131] Ten horses were exposed over 5 days to conditions that simulated activities that are typical for the recreational use of horses, including transportation to an unfamiliar stable environment, twice-daily feeding, and light exercise (lunge line), and return transportation to the premises of origin. Ten age-matched herdmates remained on the premises of origin during the trial. Gastroscopy was performed at the beginning (day −1) and the end of the trial (day 5). The appearance of all horses' stomachs was normal at the beginning of the trial. Two control horses and seven transported horses developed ulcers in the squamous mucosa of the stomach by day 5. The ulcer scores of the transported horses increased significantly from day −1, whereas ulcer scores in the control horses did not change significantly from day −1.

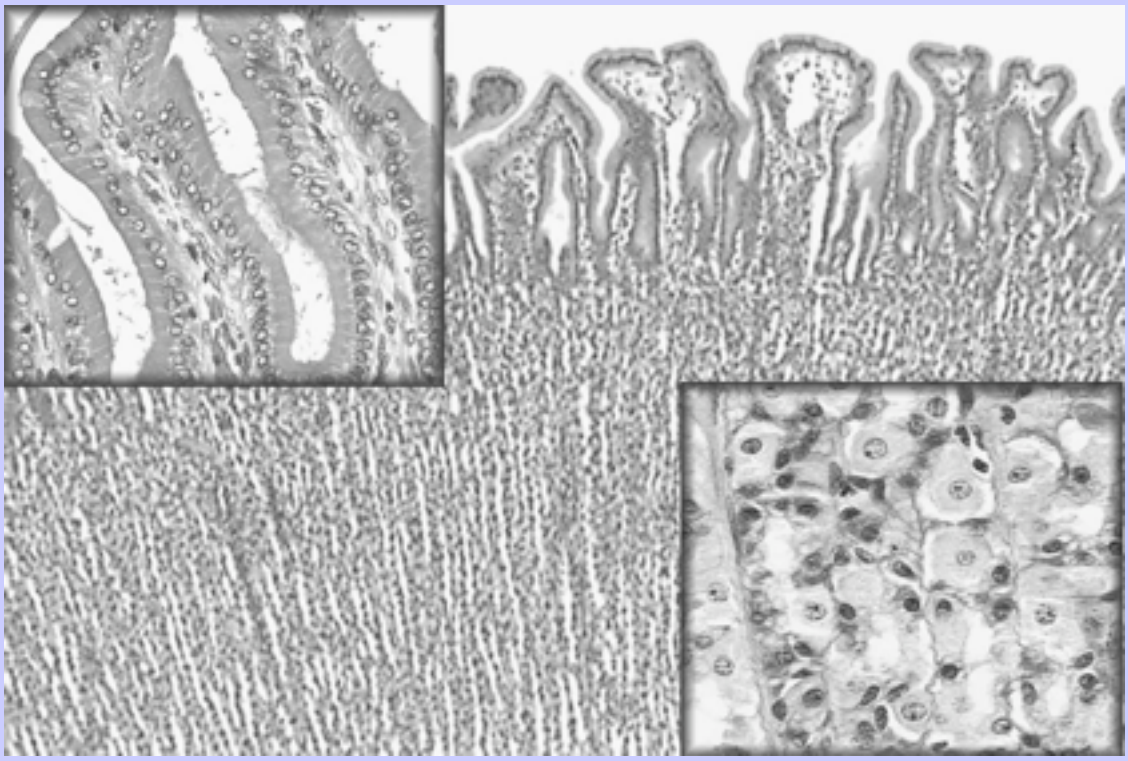
697

Fig. 32-28 Photomicrograph of equine gastric glandular mucosa. In contrast to the squamous mucosa, the glands are parallel to one another and perpendicular to the luminal surface. There are multiple cell types within the mucosa, with surface epithelial cells and mucus-secreting cells toward the lumen, and parietal cells, chief cells, enterochromaffin-like cells, G-cells, and D-cells deeper in the mucosa. The insert at the top left shows a high-power magnification of cells lining gastric pits on the surface of the epithelium. The insert at the lower right shows a high-power magnification of cells lining the gastric glands deeper in the mucosa. Hematoxylin and eosin stain.



The pathophysiology of lesions in the gastric glandular mucosa of foals and horses is not well understood. Nonsteroidal antiinflammatory drugs can induce gastric ulcers, but this is an infrequent cause of ulcers in most horses. Most lesions in the gastric glandular mucosa are observed in the antrum and adjacent to the pylorus. The role of hydrochloric acid in the development of ulcers in the glandular mucosa, particularly in the antrum, is unclear. In the feed deprivation model, in which prolonged increased gastric acidity induces gastric squamous mucosal ulcers, lesions were not induced in the glandular mucosa.[143] In human beings, *Helicobacter pylori* is considered to be the predominant cause of gastric erosions and ulcers,[146] but *Helicobacter* organisms have not

been reported to have been cultured from equine gastric mucosa. However, antibodies to *Helicobacter* proteins have been demonstrated in sera from foals and horses,[147] and through use of PCR techniques the *Helicobacter*-specific *16s rRNA* gene was identified in equine gastric mucosa.[148] Spiral organisms were identified in equine gastric mucosa by immunofluorescence, using a highly specific antibody to a *Helicobacter* protein (David Scott, personal communication, 2005). The role of an equine *Helicobacter* in the pathophysiology of ulcers in the mucosa of the antrum and pylorus is speculative, but consideration must now be given to this organism as a potential pathogen in the horse.

32.34.3 Clinical Syndromes

The magnitude of adverse health effects in the majority of foals and horses with gastric lesions remains somewhat speculative because the disease often goes unrecognized. In one report, though, the prevalence of gastric ulceration was significantly greater in horses with clinical problems such as colic, poor appetite, and poor bodily condition than in asymptomatic horses.[120]

32.34.3.1 FOALS

The clinical signs that typically are associated with gastric ulcers in foals (e.g., bruxism, dorsal recumbency, salivation, interrupted nursing, diarrhea, and colic) are, in fact, observed in the minority of foals with endoscopically observed ulcers.[118] Therefore when clinical signs are seen, the clinician should consider that severe ulceration exists. Diarrhea was the most frequently associated clinical signs in one report.[149] Colic, bruxism, dorsal recumbency, or ptyalism should alert the veterinarian to the probability of severe ulceration. Ptyalism occurs as a result of esophagitis, which often results from gastroesophageal reflux caused by gastric outlet obstruction or pseudoobstruction. Thus, ptyalism in foals often reflects a serious problem in the stomach and/or duodenum. Weanlings and older foals with chronic gastric ulceration often have intermittent diarrhea and abdominal discomfort, poor growth, rough hair coat, and a pendulous abdomen.

In foals with clinical signs, squamous mucosal lesions often are severe (see Plate 12). Most glandular lesions that result in clinical signs are located in the vicinity of the pylorus, although in young foals (<30 days old) with stress ulcers lesions are often located in the glandular mucosa in the body of the stomach (see Plate 8).

32.34.3.2 ADULTS

Although most adult horses with gastric lesions do not demonstrate overt clinical signs, low-grade discomfort that results in subtle signs may go unnoticed. Indeed, horses that I have treated solely on the basis of endoscopic findings have frequently demonstrated improved attitude and appetite, yet attitude and appetite were not considered problems before treatment began.

In horses, gastric lesions have most frequently been associated with colic, poor appetite, and poor bodily condition.[120,150] Other signs associated with ulcers have included attitude changes, stiffness, a tucked-up abdomen, and poor performance.

It should be noted that all the signs attributable to gastric ulcers have also been reported in horses that were referred for gastroscopy but did not have ulcers. Thus, although many signs appear typical for horses with ulcers, none is pathognomonic. Nonetheless, gastric ulcers should be strongly considered in horses with recurrent colic and other vague disorders for which a diagnosis has not been determined.

Hemorrhage (i.e., either active bleeding or darkened, coagulated blood) can occur with deep gastric ulcers in horses. However, bleeding from ulcers in the gastric squamous mucosa does not cause anemia or hypoproteinemia in adult horses, and if these abnormalities are present, another cause must be determined. 697 698

32.34.4 Diagnosis

Diagnosis of gastric ulceration is based on the presence of age-related characteristic clinical signs, endoscopic findings, and response to treatment. The diagnosis of gastric ulceration in the majority of foals and horses can be definitively determined only by gastroscopic examination. In young foals (<30 days) with an immature colonic flora, the presence of fecal occult blood may be indicative of gastroduodenal ulceration. In older animals, hemoglobin is too extensively degraded by colonic microorganisms for blood originating in the stomach to be detected by fecal occult blood tests.

The use of sucrose as a marker of equine gastric mucosal permeability has been reported in research studies in horses. As a disaccharide, ingested sucrose is digested to its constituent sugars, glucose and fructose, which are absorbed through the small intestine. The presence of ingested sucrose in the blood reflects absorption of the disaccharide through a breach in the gastric mucosa. In one report, horses were administered 454 g of table sugar by nasogastric tube, and urine sucrose was increased after 120 minutes in horses with gastric ulcers, particularly moderate to severe ulcers.[151] Because the need for collection of urine for this test will restrict its utility, a method for detection of sucrose in equine plasma has been developed.[152] To date, a validation of this method as a diagnostic test for gastric ulcers in horses has not been reported.

32.34.5 Treatment

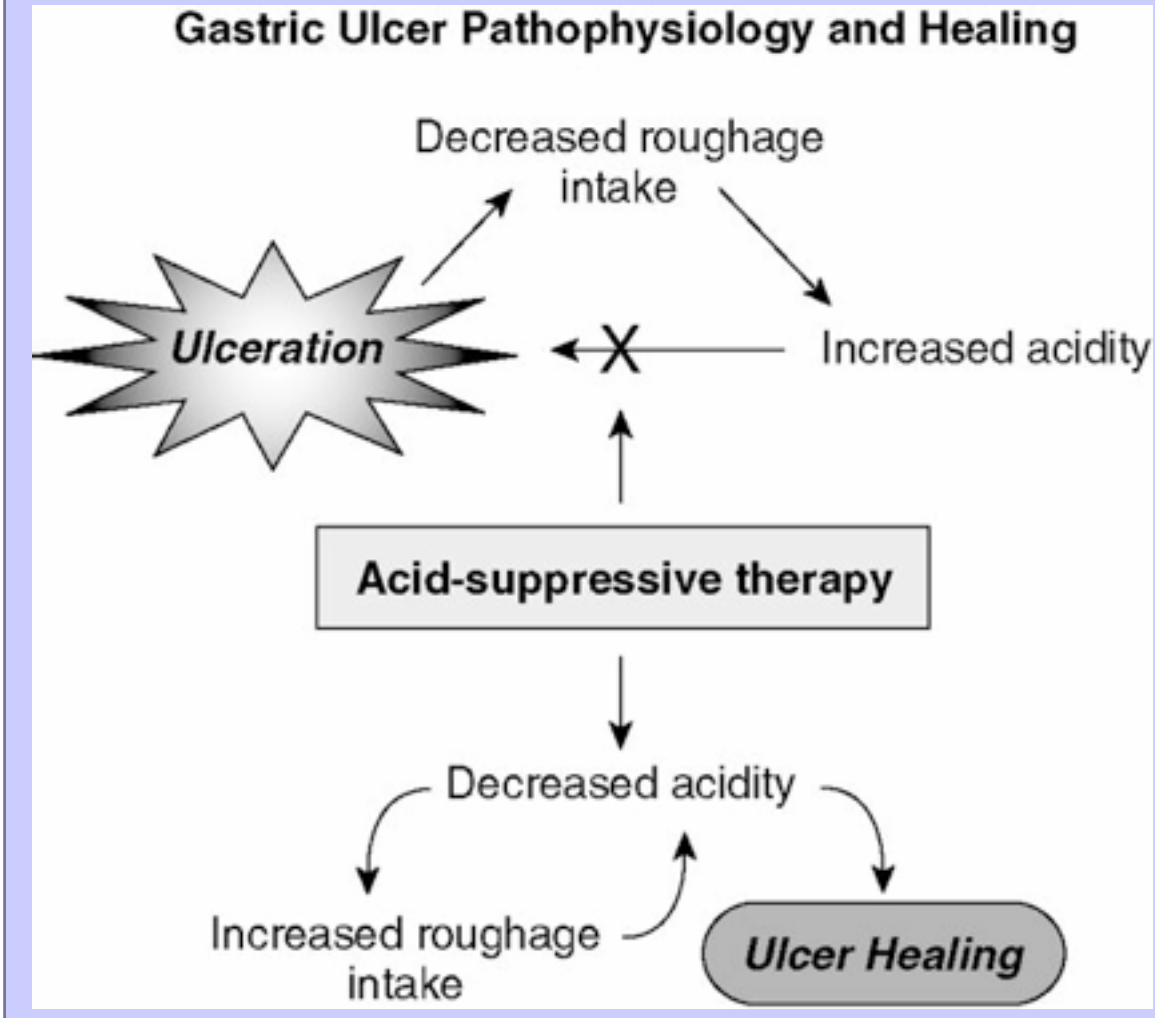
Processes that promote ulcer healing are stimulated by injury to the gastric mucosa. These include increased capillary blood flow, generation of new capillaries (neovascularization), induction of growth factor receptors, and proliferation of epithelium along a capillary scaffold.[153,154] With erosions in the stomach lining, some epithelium remains in the erosion bed and healing can occur within a few days because the epithelium is regenerated relatively rapidly. With severe ulcers that extend through the entire epithelium and lamina propria, a bed of granulation tissue forms in the ulcer bed, and healing results primarily from contraction of the ulcer margins. This type of healing can require weeks to complete.

Gastric ulcers can heal without treatment, even in the face of continued ulcerogenic stress, but in such conditions new ulcers typically form as old ulcers heal.[155] Also, the healing is often incomplete. For example, in racehorses it is typical to observe ulcers with proliferative margins and granulation tissue in the ulcer beds mixed with what appear to be newly formed, bleeding ulcers. In most cases, unless the ulcerogenic stress is removed the stomach will remain ulcerated. This means taking the horse out of training and probably turning it out onto pasture, because even taking the horse out of training but maintaining stall confinement can be ulcerogenic.[155] Successful treatment of gastric ulcers is predicated on addressing the underlying cause and treating with medications that create an environment that is favorable to ulcer healing. Acid-suppressive treatment often is required to break the cycle of inappetence that causes increased gastric acidity, which results in ulceration, which then prolongs and exacerbates the inappetence (Fig. 32-29).

Decisions concerning whether to treat gastric lesions, what medication to use, and for how long are best made on the basis of results of a gastroscopic examination, the type of activity for which the horse is used, and whether the horse will continue in that activity or be rested. If response to treatment is used as a diagnostic aid, clinical

conditions such as poor appetite, colic, or diarrhea (foals) that result from gastric ulcers should improve in 24 to 48 hours of initiating acid-suppressive therapy. If improvement in clinical signs is not observed, gastric ulceration, if present, should be considered to be a secondary, not a primary, problem.

Fig. 32-29 Diagram representing the pathophysiology of ulceration of the equine gastric squamous mucosal epithelium and the permissive effect of acid suppression on ulcer healing.



The primary objective in the treatment of gastric ulcers is to alleviate discomfort, and this is best done by inhibiting or neutralizing acid secretion. Decreasing gastric acidity also creates an environment that is permissive for healing of the gastric mucosal epithelium. Once ulcers form, there are changes in the tissue that promote healing. Suppressing acidity creates an environment within the stomach that permits ulcer healing.

Several acid-suppressing drugs are approved for treating gastric ulcers in horses (Box 32-2).

The H_2 antagonists cimetidine, ranitidine, famotidine, and nizatidine interfere with histamine stimulation of HCl secretion by competitively blocking the H_2 receptor on the parietal cell. Both cimetidine and ranitidine have been shown to suppress gastric acid secretion in horses and neonatal foals.[141,142,144,156,157] Effectiveness of these drugs in blocking acid secretion is dependent on plasma concentrations, and the magnitude and duration of acid inhibition are highly variable in horses. Both the degree and duration of suppression of gastric acidity by H_2 antagonists vary among horses,[157,158] presumably as a result of differences in drug absorption. A dose of 6.6 mg of ranitidine per kilogram given PO every 8 hours provided adequate suppression of acidity in most horses in research studies. This dosage schedule resulted in a median 24-hour gastric pH of 4.6 in horses with free access to hay (compared with a pH of 3.1 in horses fed, but not given ranitidine).[144] However, because of the individual variability in response among horses, the duration of effect may be only 1 to 2 hours. Using lower doses often results in no response.

32.34.5.1

Box 32-2 Therapeutic Agents Registered for Use in Treating Gastric Ulcers in Foals and Adult Horses

32.34.5.1.1

PROTON PUMP INHIBITOR

Omeprazole (GastroGard [USA, Argentina, Canada, Europe], UlcerGard [USA], GastroShield [Australia]): 4 mg/kg, once daily for treatment, 1 mg/kg/day for prevention

32.34.5.1.2

HISTAMINE TYPE-2 RECEPTOR ANTAGONIST

Ranitidine (Ulcerguard [Australia]): 6.6 mg/kg q8h PO for treatment

Effective doses of cimetidine have not been examined as extensively as those of ranitidine, but an effective oral dose may be as high as 50 mg/kg/day. Lower doses are often given, and sometimes with clinical improvement, but in my experience ulcers have often persisted.

Formulations for parenteral administration of H_2 antagonists are available but are approximately three times the cost of oral products. Ranitidine should be given IV at 1 to 1.5 mg/kg every 8 hours, and cimetidine at 6.6 mg/kg three to four times daily. The parenteral route of administration can be very beneficial in foals and horses that cannot tolerate or use orally administered medications.

Omeprazole is a proton pump inhibitor that blocks gastric acid secretion by inhibiting the parietal cell H^+, K^+-ATPase (proton pump) that secretes HCl.[159] Omeprazole is a potent inhibitor of gastric acidity in horses. The antisecretory effects of omeprazole persist far longer than the drug's plasma level, because binding to the H^+, K^+-ATPase of the parietal cell persists for up to 24 hours after a single dose.[160] This prolonged duration of action enables once-daily dosing.

A paste formulation of omeprazole* has been registered in the United States, Canada, Europe, and elsewhere for use in treating gastric ulcers in foals and horses. In clinical trials, ulcer healing in horses and foals treated once daily with omeprazole paste at a dose of 4 mg of omeprazole per kilogram of body weight was substantially superior to healing in sham-treated horses.[161,162] It is important to note that in one set of these trials,[162] ulcer

healing occurred in more than 77% of omeprazole-treated horses that were in race training, a result that has not been noted in horses treated with H_2 antagonists.[163] Thus, omeprazole brings a new perspective to the treatment of gastric ulcers in horses. Once-daily treatment and a paste formulation should enhance treatment compliance, and the potency of acid suppression permits horses to remain in their activities while being effectively treated for ulcers.

Another important feature of omeprazole paste was the confirmation of its ability to prevent both occurrence and recurrence of ulcers in horses in race training, in which conditions are most ulcerogenic.[164,165] The daily dose used for prevention was one fourth that used for treatment (1 mg of omeprazole per kilogram vs. 4 mg/kg, respectively). In an 8-day study of horses in mild to heavy exercise, once-daily omeprazole paste† at a dose of 1 mg/kg prevented gastric ulcers in 45 of 51 treated horses (12% incidence), compared with an incidence of 73% in 51 untreated horses.[168a]

Antacids can effectively reduce gastric acidity, but only briefly. In a study examining administration of 180 mL of Maalox‡, gastric pH was increased for at most 45 minutes.[157] In another study 240 mL of Maalox TC§ increased gastric pH for 2 hours.[166] Thus, liquid antacid products must be given both in large volumes (240 mL) and very frequently, and these products are not suitable for ulcer treatment. Feed additives that contain antacids are popularly considered to be helpful in controlling gastric ulcers in horses, but there are no supportive data. Also, an acid-neutralizing effect is most desirable when the stomach is empty, not when it is full, because gastric pH naturally is high when horses ingest feed. Antacids containing aluminum may have some effect on healing of gastric glandular lesions, because aluminum hydroxide has been shown to enhance gastric mucosal nitric oxide, which should promote mucosal blood flow.[167]

Sucralfate, the major components of which are sucrose octasulfate (SOS) and aluminum hydroxide, is helpful in the treatment of peptic ulcers in people,[168] although healing rates for sucralfate in treatment of duodenal ulcers were much longer than for H_2 antagonists. The mechanism of action likely involves adherence to ulcerated mucosa, stimulation of mucous secretion, enhanced mucosal blood flow, and enhanced prostaglandin E synthesis. These are all factors relevant to glandular mucosa, and it is doubtful that sucralfate is effective in treating ulcers in the equine gastric squamous mucosa. In fact, I have observed lesions to develop in the squamous mucosa while horses were being treated with sucralfate.

Sucralfate can be administered concurrently with an H_2 antagonist. Concurrent administration may reduce H_2 antagonist absorption by 10%, but this has not appeared to affect efficacy in horses.[169] It is important to note that sucralfate can substantially interfere with the absorption of other drugs, particularly fluoroquinolones, and therefore its use with other medications should be determined on a case-by-case basis.

Few studies have directly compared the effectiveness of different ulcer treatments in horses. In a study of racehorses at a California race track, treatment with cimetidine was compared with treatment with registered omeprazole paste on healing and prevention of gastric ulcers.[124] Horses were treated with cimetidine 20 mg/kg three times daily for treatment or prevention of ulcer recurrence or omeprazole 4 mg/kg once daily for treatment and 2 mg/kg once daily for prevention of recurrence in a randomized controlled trial. There was significant reduction in ulcer severity in horses treated with omeprazole, and ulcer severity did not significantly increase after horses received the prevention dose of omeprazole. Cimetidine did not reduce ulcer severity or prevent recurrence of ulcers after treatment with omeprazole. In a randomized controlled trial conducted in Australia with 60 racehorses in training, ulcer healing was significantly better in horses treated daily with omeprazole paste* (4 mg of omeprazole per kilogram) than in horses treated with a commercial ranitidine product† (6.6 mg

of ranitidine per kilogram three times daily).[170] Furthermore, there was additional ulcer healing in horses treated with omeprazole paste after 28 days of treatment with ranitidine.

A study that included 798 racehorses examined the effect of several medications used to treat EGUS.[171] Two hundred and twenty-seven horses had been treated for at least 2 weeks at the time of gastroscopy with registered omeprazole paste[a] (4 mg/kg/day or 2 mg/kg/day), omeprazole in unregistered compounded products, H_2 antagonists (drugs and dosages not specified), sucralfate, or "buffers." The risk of having moderate to severe EGUS in horses treated with registered omeprazole paste[a] at 4 mg/kg/day or 2 mg/kg/day (0.18) was significantly less ($P < .001$) than in untreated horses, but the risk of having moderate to severe EGUS in horses treated with the other products was no different from that in untreated horses.

699

700

In some cases prokinetic drugs may be required to enhance gastric emptying. Use of a prokinetic drug is indicated when there is suspected gastroesophageal reflux, gastric outlet obstruction or pseudoobstruction, or duodenal ulceration or inflammation. Drugs available for this purpose include bethanechol and metoclopramide.

I have used bethanechol successfully to enhance gastric emptying and minimize gastroesophageal reflux with few mild adverse effects. Bethanechol was reported to enhance gastrointestinal motility while not increasing gastric acid output in horses.[172] In cases of acute gastric atony, 0.025 mg/kg SC every 4 to 6 hours has been effective in promoting gastric motility and emptying, followed by oral maintenance doses of 0.35 to 0.40 mg/kg three or four times daily. Adverse effects can include diarrhea, inappetence, salivation, and colic, but they occur infrequently. Bethanechol can be administered chronically (weeks to months) in horses with pyloric fibrosis and stenosis, although there are no data regarding its long-term effectiveness.

Reported experience with metoclopramide in the equine is limited to its use in postoperative ileus (POI). Doses ranging from 0.10 to 0.25 mg/kg three or four times daily are used by some clinicians to treat suspected delayed gastric emptying, although one report indicated that constant infusion at a rate of 0.04 mg/kg/hr was superior to interval dosing in enhancing postsurgical small intestinal motility.[173] Sudden neurologic excitation is an adverse reaction to metoclopramide but is more common toward 0.25 mg/kg. In one foal I treated, administration of metoclopramide over several days resulted in tachycardia, bilateral facial sweating, miosis, and enophthalmos. These signs resolved when the drug was discontinued.

32.35 REFLUX GASTRITIS

Reflux gastritis frequently accompanies conditions in which there is small intestinal ileus with large volumes of enterogastric reflux that must be evacuated by nasogastric intubation. This fluid typically has a pH of 5 to 7 and contains substantial biliary and pancreatic secretions. Often gastroscopy reveals that extensive erosion of the

squamous mucosa occurs in association with this reflux. The erosions extend from the margo plicatus dorsally, primarily along the cranial and right sides of the stomach. Presumably squamous mucosal erosion results from the effect of bile acids on the gastric squamous mucosa combined with accumulation of gastric hydrochloric acid.[138] Often in such cases, islands of regenerative squamous epithelium can be observed in the eroded or ulcerated fundus within 2 to 3 days, and in another 2 to 3 days the squamous epithelium can completely regenerate. Horses with reflux gastritis may be slow to regain a normal appetite after feeding resumes, and in some cases administration of an acid-suppressive drug has resulted in a quick improvement in appetite. Intravenous administration of an H_2 antagonist may prevent these lesions from developing or hasten healing, but treatment may not be necessary in all cases.

32.36 GASTRIC IMPACTION

True gastric impaction occurs infrequently and may result from ingestion of certain feed stuffs or eating when there is impaired intestinal motility. Potential predisposing feeds include beet pulp, bran, straw, wheat, and barley. Beet pulp and bran can become desiccated within the stomach and may not become rehydrated by water or gastric secretions. Dental disorders may predispose some horses to gastric impaction if roughage is incompletely masticated. Feeding a horse that has signs of colic may predispose to gastric impaction because there may be poor gastric emptying associated with generalized decreased gastrointestinal motility.

Definitive diagnosis of gastric impaction is difficult. Gastric impaction is occasionally diagnosed during exploratory laparotomy as the primary cause of colic in horses.[174] Other than at surgery, definitive diagnosis of gastric impaction can be difficult. If the horse has not eaten for several hours, yet poorly macerated or digested feed material is recovered from the nasogastric tube, a gastric impaction may be suspected. On rectal examination, the spleen may be displaced caudally and medially, but this finding is not specific for gastric impaction or dilation. Gastric impactions can be confirmed by gastroscopy, although one cannot differentiate a normally full stomach from an impacted stomach. The key to making this diagnosis is the failure of the stomach to empty appreciably in 12 to 24 hours. Radiography may also reveal a distended stomach that distorts the diaphragm cranially.

Gastric impactions can be effectively treated medically by administering dioctyl sodium succinate (DSS), 5% solution, 4 to 8 oz, in 4 to 6 L of water. The DSS acts as a surfactant and allows water to penetrate the impacted, desiccated ingesta, facilitating their removal from the stomach. Alternatively, one can lavage the stomach with water repeatedly by pumping 2 to 4 L of water via nasogastric tube and recovering the infused water and ingesta by gravity flow or aspiration through the nasogastric tube. This is particularly effective in treating bran mash impactions, because of the small particle size of the bran. Mineral oil is less effective in treating gastric impactions because the interior of the impacted ingesta is desiccated and compacted. The mineral oil slides around the impaction and does not penetrate it; thus it does not facilitate passage of the impacted ingesta through the pylorus. When diagnosed at surgery, gastric impactions can be effectively treated by the injection of 2 to 4 L of saline transmurally into the stomach, followed by gentle massage of the stomach and the impacted mass. The impaction usually resolves within 12 to 24 hours. Treatment with bethanechol, 0.02 mg/kg SC every 6 to 8 hours to promote gastric emptying may be helpful in conjunction with these therapies. Bethanechol may have reduced effectiveness in a distended stomach, but it should not contribute to stomach rupture and therefore can be used safely.

Gastric impaction can also accompany grass sickness, in which case the prognosis for survival is poor. Grass sickness occurs in the United Kingdom and in areas of South America. The disease does not occur in the United States, but horses recently imported from the United Kingdom have been diagnosed with grass sickness in the United States.

32.37 GASTRIC RUPTURE

Gastric rupture occurs as a sequela to gastric distention from ingesta, fluid, or gas. The adult equine stomach can hold 20 to 25 L when maximally distended. Gastric rupture can occur from simple excessive distention, but also the integrity of the wall of the stomach may become compromised because of decreased blood flow. Distention of the small intestine has been demonstrated to significantly reduce mural blood flow, and this likely occurs in the stomach with distention. In some cases, it has appeared that rupture occurred as a result of an infarction of a portion of the stomach wall, without apparent substantial distention. Gastric perforation from ulceration happens rarely in adult horses. Because of extensive contamination of the peritoneal cavity with stomach contents, treatment is not possible and humane destruction of the horse is required.

32.38 ABSCESSES

Abscesses in the wall of the stomach are infrequent findings and occur most frequently in foals. Abscesses can form secondary-to-severe gastric ulceration, *Rhodococcus equi* bacteremia, foreign body penetration, or septic peritonitis. Signs of gastric abscessation are variable and similar to those of abscessation in other organs: fever, neutrophilia, hyperfibrinogenemia, anemia, weight loss, and possibly colic. Diagnosis may be made endoscopically, radiographically, or ultrasonographically. In some cases use of labeled WBC scintigraphy may identify an intraabdominal abscess in the region of the stomach. Usually by the time a diagnosis is made, the abscess is very advanced and often it is adhered to multiple abdominal viscera. Treatment should include long-term antimicrobial drugs, but outcomes are usually poor.

32.39 GASTRIC TUMORS AND MASSES

Gastric tumors, neoplastic and nonneoplastic, occur infrequently. Squamous cell carcinoma is the most common neoplastic disorder that affects the equine stomach (Fig. 32-30).[175] The tumor originates from the gastric squamous epithelium and can metastasize to the abdominal cavity and viscera and/or extend into the esophagus. It typically affects horses in their teens or older. Presenting signs include chronic weight loss, anemia, nasal reflux, or colic. Diagnosis can be made by gastroscopy, laparoscopy, barium contrast radiography, or peritoneal fluid analysis when the tumor has metastasized into the abdomen. Metastatic masses may be felt on rectal palpation. When the tumor obstructs the cardia, it is difficult, if not impossible, to pass a nasogastric tube, and saliva and ingesta accumulate within the esophagus. There is no effective therapy.

Primary gastric adenocarcinoma has been described, and metastatic lymphosarcoma, mesothelioma, and bile duct carcinoma have involved the stomach.

Nonneoplastic masses that have been observed in the equine stomach include *Draschia megastoma* masses, proliferative granulation tissue, and adenomatous masses in the antrum and pylorus. Rarely, proliferative squamous mucosa may appear as a mass attached to a stalk (Fig. 32-31). These can occur in a healing ulcer as an ulcer bed contracts while there is rapid proliferation of granulation tissue.

Fig. 32-30 Endoscopic view of a gastric squamous cell carcinoma.

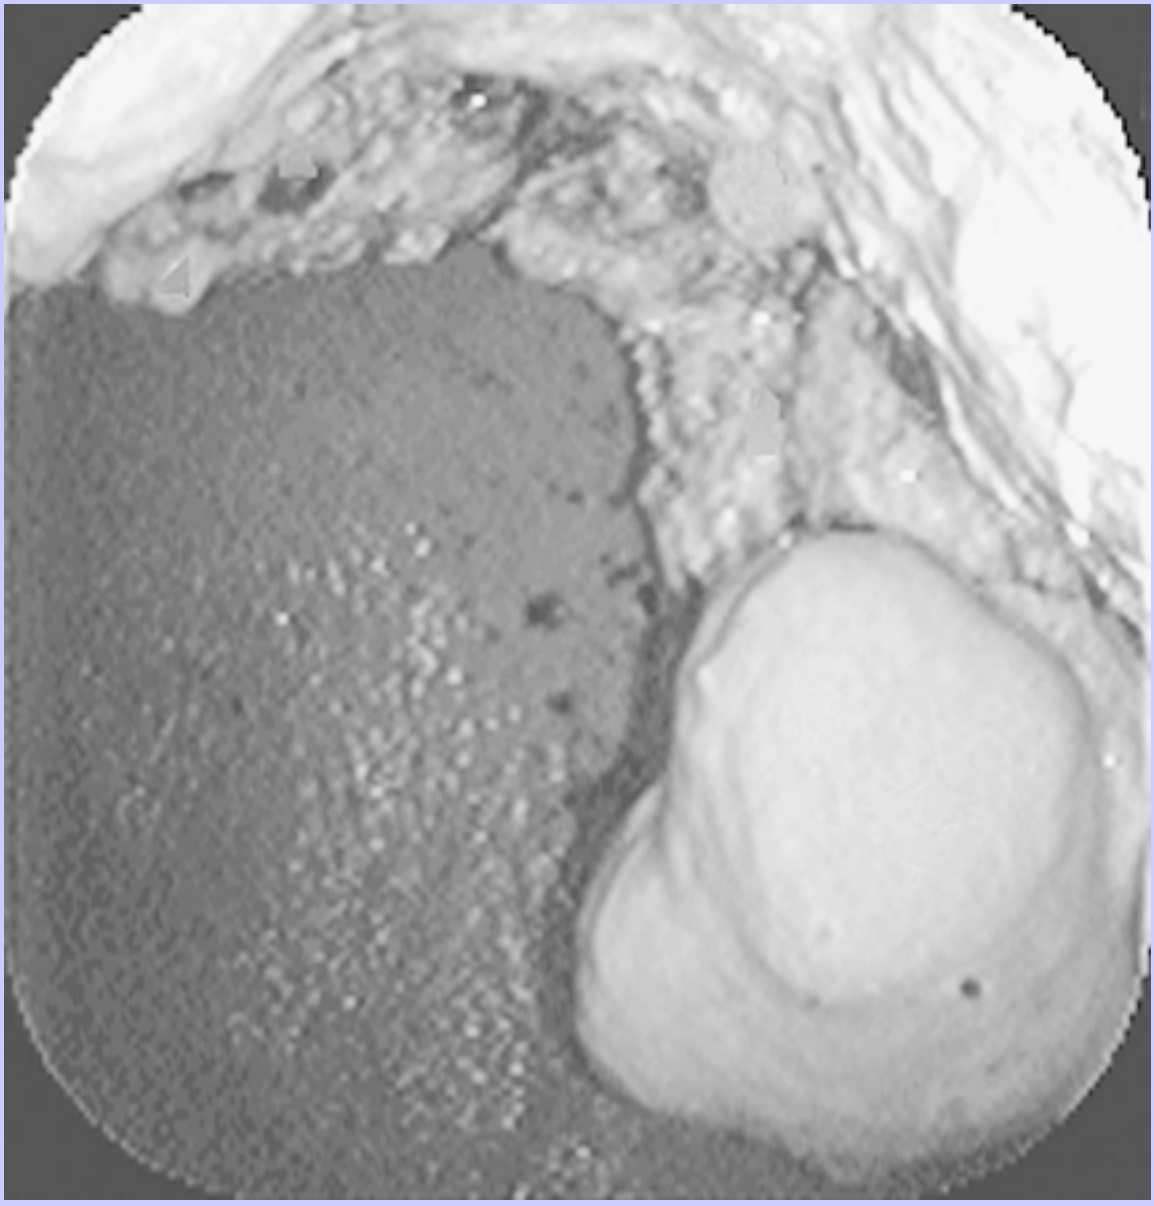

Fig. 32-31 Endoscopic view of the stomach of a horse in which there is a mass *(arrow)* protruding from the squamous mucosa along the lesser curvature. The mass appeared to be a proliferation of granulation tissue, around which margins of a healing ulcer had contracted. Photo courtesy of Dr. Guy Lester, Murdoch University, Murdoch, Western Australia.

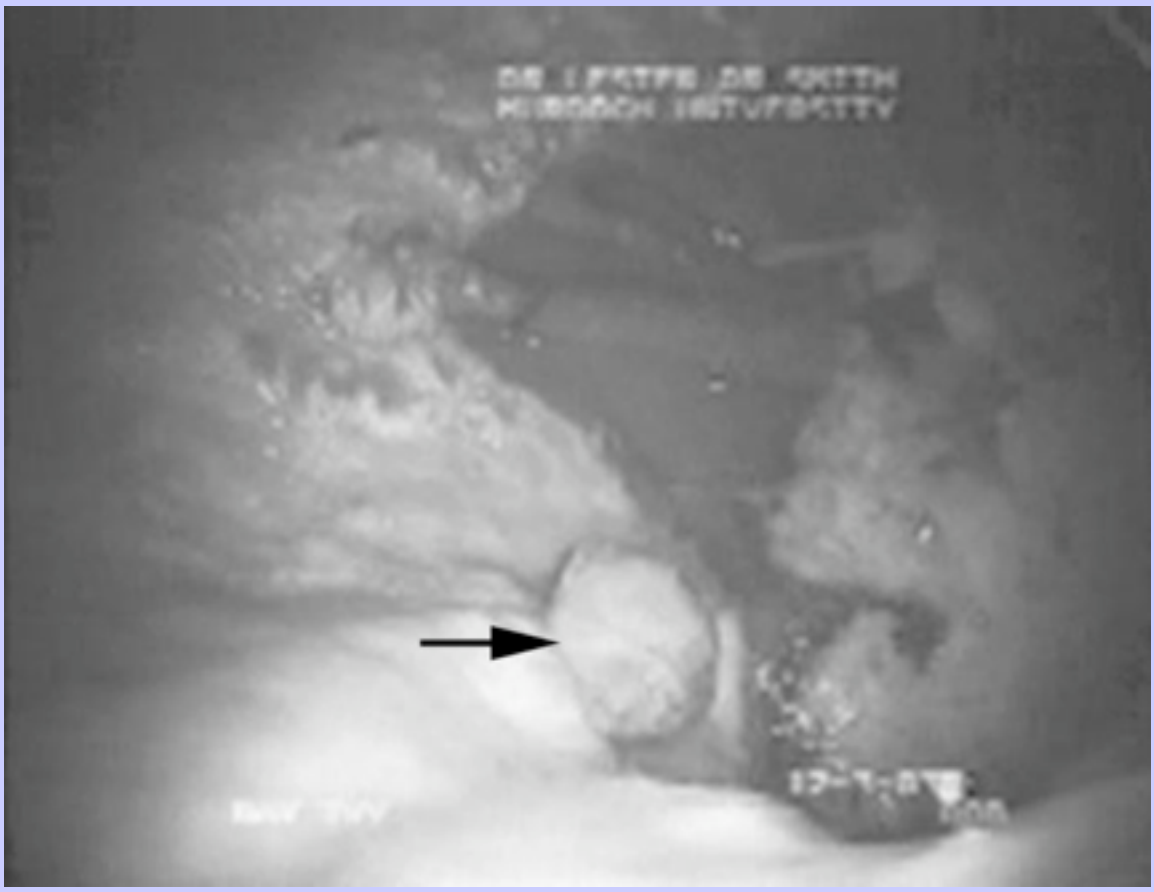
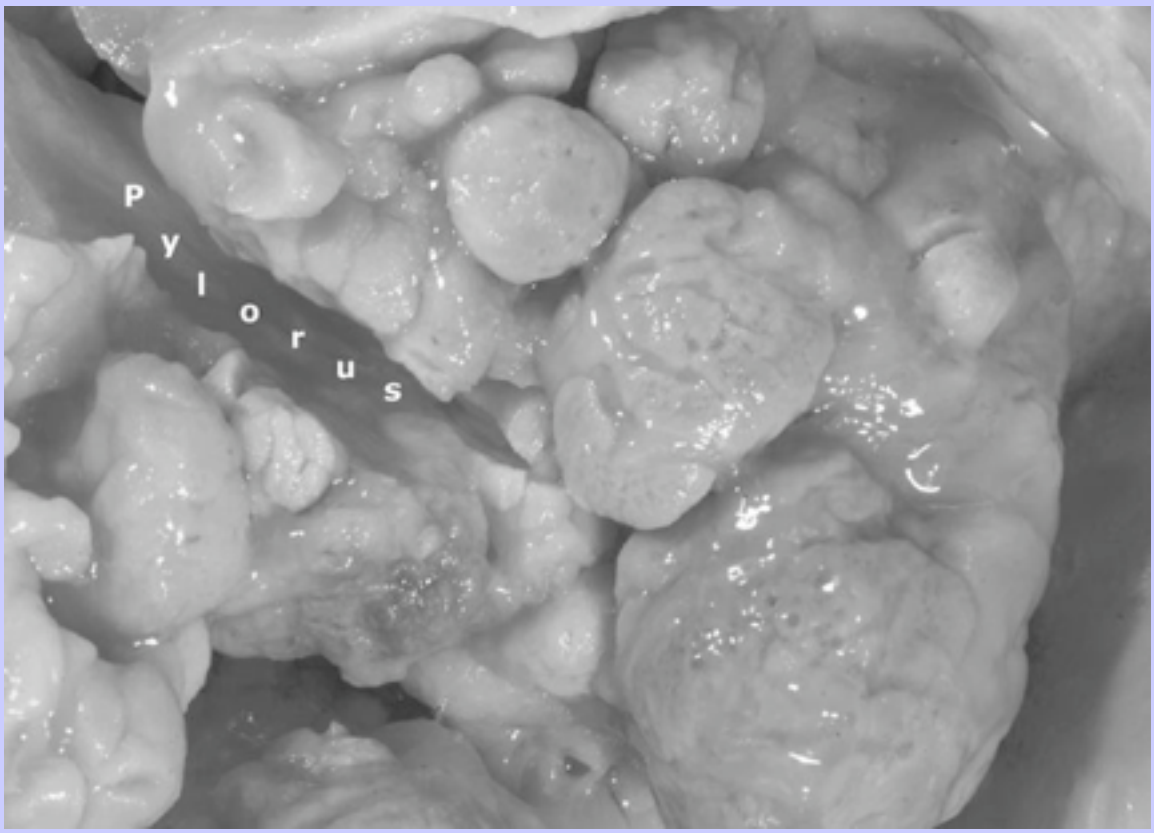


Adenomatous masses in the antrum and pylorus have been reported,[176] and I am aware of several more cases. These appear as large, irregular polypoid lesions (Fig. 32-32) and can obstruct most of the antrum. The cause of these lesions is unknown. Horses with these lesions have been presented with mild, intermittent colic. There is no effective treatment.

32.40 PYLORIC STENOSIS

Pyloric stenosis can occur secondary to chronic ulceration and fibrosis or muscular hypertrophy. The majority of cases occur as a result of chronic ulceration at the pylorus. I have diagnosed pyloric stenosis in foals, yearlings, and adult horses up to 20 years old.[177]

Fig. 32-32 Postmortem photograph of several masses in the pyloric antrum that were identified on histologic examination as gastric polypous adenomas. The masses almost completely obstructed the antrum and pylorus, and there was muscular hypertrophy of the pyloric canal, resulting in stenosis. Photo courtesy of Dr. Udo Hetzel, University of Liverpool, Liverpool, England.



701

702

Diagnosis of pyloric stenosis is best made by endoscopy. Usually there will be active ulceration and inflammation, and the pyloric opening will appear small and fixed. If a biopsy forceps is pushed into the stomach lining at the pylorus, the wall of the stomach will appear to be rigid owing to scar tissue in the stomach wall. With primary muscular hypertrophy, no ulceration of mucosal inflammation should be present.

Treatment of pyloric stenosis caused by fibrosis from chronic ulceration is difficult. The fibrosis, and therefore the stenosis, may be permanent, although I have treated cases in which the pylorus became less rigid and more compliant when the primary ulceration and associated inflammation were resolved. The treatment objectives are to promote ulcer healing and enhance gastric emptying. Long-term acid-suppressive treatment may be required. In some cases vigorous debridement of the chronically ulcerated mucosa may promote generation of healthy granulation tissue, leading to ulcer healing. Gastric emptying can be promoted by bethanechol (0.02 mg/kg SC q8h or 0.35 mg/kg PO q8h).

If medical management is not effective, surgical bypass of the pylorus (gastroenterostomy) is indicated. Whereas pyloromyotomy has been effective in treating cases with primary muscular hypertrophy, the degree of fibrosis that is present in most cases precludes this approach.

32.41 INTESTINAL INJURY AND HEALING IN THE HORSE

Nathaniel A. White, II

There are numerous causes of intestinal injury during equine acute abdomen. Classic pathophysiologic explanations use ischemia, ulceration, and inflammation from infection, parasites, trauma, toxins, or immune complexes to categorize and explain intestinal injury. For the clinician, understanding the underlying pathophysiology of injury is important for recognition and treatment of horses with colic. For many of these intestinal disorders the signs can be similar, making clinical differentiation difficult.

Cellular injury was once characterized by the morphologic change it caused. The new paradigm includes cell injury, which is as much functional as it is structural. The response to a stimulus is mediated by numerous autocrine and paracrine messengers, which include cytokines, chemokines, prostaglandins, neuropeptides, and proinflammatory substances such as interleukins (ILs), tumor necrosis factor alpha (TNF-α) complement, histamine, bradykinin, serotonin, and interferon (IFN).[178–180] In the intestine, inflammatory responses to these messengers can be orchestrated by mucosal cells, fibrocytes, macrophages, mast cells, endothelial cells, neurons, muscle cells, and polymorphonuclear cells.[178] The chain of events is complex, with the relationship of all the different cell responses not yet fully understood. It is clear that the inflammatory response from any insult initiates a multitude of chemical and immune reactions, which, depending on the severity of the insult, can cause both local and systemic effects.

Several mechanisms can stimulate an inflammatory response, including ischemia, reperfusion after ischemia, inflammation from bacterial or viral infection, and inflammation from parasites, trauma (surgical), or toxins. The resulting tissue injuries vary and may be differentiated by their effect on the different layers of the intestine and by the vascular and nervous response. Though the mucosa or serosa is often affected first, the inflammatory response frequently involves the remaining layers of the intestine, the submucosa, and smooth muscle. The inflammatory response may also vary depending on the specific cause. For example, ischemia can be caused by strangulation of the blood supply, distention of the intestinal wall, or poor perfusion resulting from systemic shock. Although the response of individual intestinal cells may be similar for each, each stimulus appears to evoke different sequences of cell response, thereby causing different clinical signs and varying response to treatment. In some instances injury to the intestine may be secondary to another disease process, but the damage to the intestine can still initiate a systemic response resulting in a systemic inflammatory response syndrome (SIRS) with multiple organ failure.

32.42 INTESTINAL INFLAMMATION: GENERAL CONCEPTS

The cascade of events initiated by infection or ischemia has been extensively studied. Inflammatory mediators increased during bowel inflammation are released from numerous cell types, including mucosal cells, endothelial cells, fibrocytes, myocytes, mesothelial cells, and neurons.[178] There is also evidence that the compounds making up the tissue ground substance and cytoskeleton can also initiate an inflammatory response and help transmit signals or cells between immunocytes and afferent neurons. Theoretically all cells in the intestine can act as effector cells, both producing cytokines to send messages to other cells and being activated to respond to the insult by chemokines.[178,180,181] Cytokines, growth factors, and adhesion molecules can all initiate an inflammatory

response.[178,179] This response also alters cell apoptosis, resulting in delayed removal of mucosal cells and neutrophils or early death of immunocytes or specific cells in organs.[182] Cytokines such as IL-1β and TNF-α, platelet-activating factor (PAF) complement (C5a), IFN-γ, and histamine are all reported to be involved in inciting intestinal inflammation.[183] Describing all the effects and interactions of the inflammatory cytokines and eicosanoids is beyond the scope of this chapter, but it is apparent these substances can stimulate and inhibit the inflammatory reaction by directing cell communication and cell response to injury. As a result the disease process should be viewed as a sequence of altered cell functions, which are integrated and designed to protect the intestine from permanent injury.

The cells primarily observed to take part in intestinal injury are mucosal cells, endothelial cells, neurons, fibroblasts, mast cells, eosinophils, neutrophils, and macrophages. Rather than responding independently, these cells likely all respond to the initial insult, each with its inherent cytokine production or cell activation, which stimulates or suppresses other cell responses. Envisioned as a group acting simultaneously, the sequence likely proceeds from an initial stimulus to mucosal or serosal cells or in the case of ischemia the vascular endothelium or enteric neurons.

Mucosal cells react by releasing cytokines to activate macrophages and lymphocytes in the lamina propria.[181] These cells release cytokines and adhesion molecules, which in turn activate other cells while initiating local defenses. Simultaneously, endothelial cells respond to the cytokine message by releasing cytokines to attract neutrophils and eosinophils and subsequently enable them to migrate through the endothelium into the interstitium. Afferent neurons detect cytokine increases and initiate neuropeptide, cytokine, or eicosanoid release from the efferent neurons, resulting in activation of numerous cells including those already activated by the initial cell messengers.[184–188] Fibrocytes, responding to the initial cytokine messages and growth factors, subsequently release 702
cytokines and growth factors such as Il-1α, Il-1β, TNF-α, transforming growth factor, and platelet-derived growth 703
factor. All can be proinflammatory or can help to repair the mucosa.[189,190] Metalloproteinases released in response to inflammatory cytokines alter the basement membranes and collagen in the different layers, allowing migration of cells to the extracellular space and stimulating other cells to release chemoattractants.[178] Muscle cells, once thought to be neutral in the inflammatory cycle, appear to be able to release cytokines, thereby participating in the inflammatory reaction.[178,191] Increased adhesion molecule production in the muscle after surgical manipulation has been linked to neutrophil infiltration and subsequent bowel dysfunction.[192–194]

Although all the cells in the intestine participate in the inflammatory response as effector cells, they can also act as suppressors. Each appears to communicate with other cells locally to cause or suppress the inflammatory response. Production of nitric oxide by endothelial cells can reduce neutrophil adhesion, whereas increased release of growth factor by fibroblasts and the vascular endothelium speeds healing of the mucosa.[189] The response to receptor activation can take only seconds to minutes to upregulate cytokine production. Lack of suppression, perhaps because of chronic or overwhelming stimulation or severe damage to cells, which release the inhibitor messengers, allows amplification of inflammation and permanent cell damage.

The role of each cell type as effectors and messengers is slowly being unraveled. The role of some cells is better understood than that of others. Reperfusion, cytokines, and complement initiate endothelial cell changes. Subsequent production of cytokines and prostanoids by endothelial cells attracts neutrophils and macrophages.[195] Endothelial cells also stimulate the inflammatory response by altering capillary permeability, promoting neutrophil adhesion, and altering blood flow. The interaction between the endothelial cell and neutrophils or eosinophils is a pivotal response in causing intestinal injury. This response is made possible by PAF, leukotrienes (LTB_4), and adhesion molecules produced by endothelial cells and neutrophils.[180,195] Neutrophil migration into affected tissues

subsequently causes severe damage including damage to cells and tissue ground substance, which further promotes the inflammatory response.

Although all intestinal cells can be involved in the inflammatory process, the nervous system is now known to be integral in the inflammatory response. Release of potassium, adenosine triphosphate (ATP), bradykinin, and prostaglandin E_2 all stimulate afferent neurons.[184,196] Neuropeptides released from neurons in response to afferent signals caused by products of cell injury including cytokines, eicosanoids, and histamine.[184,197] Substance P, neurokinin, calcitonin gene-related protein (CGRP), and vasoactive peptide (VIP) have all been found increased levels in inflamed tissues, suggesting that they act as messengers to histiocytes or immunocytes, which subsequently release cytokines.[184,186] The paracrine response differs in different tissues, but inflammatory responses by mast cells, neutrophils, T cells (cytokine release), B cells, macrophages, fibroblasts, and muscle cells are in part caused by neuropeptide stimulation. The coordination of this response is not totally understood, but neuropeptides serve as proinflammatory mediators or suppressors.[188,198] This system allows for immediate response of cells to a stimulus without humoral involvement and likely can cause persistent inflammatory reactions in response to inflamed tissue.[184]

Local inflammation of the intestine is known to cause changes in other organs distant to the intestinal damage, specifically the lung.[199] Circulating cytokines and activated neutrophils rapidly initiate an inflammatory response in the lung after intestinal inflammation. This response is well known in experimental models and humans but has not been reported during intestinal disease in the horse. Other organs are likely affected, creating signs of multiple organ involvement as part of SIRS.[200]

32.42.1 Ischemia and Reperfusion

Ischemia is a deficiency of blood flow in tissue or an organ. The lack of energy production in the cell starts a degenerative process. Within 5 minutes there are alterations in mitochondria, characterized by swelling and disorganization of cristae.[201] Mitochondrial changes precede cytoplasmic and membrane changes, which occur in the first 30 minutes by activation of phospholipases, cytokine production, and accumulation of arachidonic acid. If ischemia persists, the cell degradation continues with failure of the membrane ion pumps, allowing calcium to move into the cytoplasm.[202] This calcium accumulation within the cell activates proteases, which cause cell membrane damage and nuclear clumping. Calcium uptake in the mitochondria is increased, which inhibits oxidative phosphorylation, thereby decreasing the cell's source of energy.[202]

In the intestine, microscopic changes become evident at 30 minutes when the mucosal epithelial cells and serosal mesothelial cells separate from their basement membranes.[203] This appears to be a mechanical separation caused by water movement from the vasculature into the subepithelial space. Metalloproteinases may also be involved in altering the basement membrane. The space, created by the initial separation, named *Grunehagan's space*, occurs at the tip of the villus in the small intestine (Fig. 32-33).[203] If ischemia continues, the cell damage progresses as the mucosal cells progressively slough off the lamina propria toward the intestinal crypts (see Fig. 32-33). The change is similar in the colon, with epithelial cells sloughing off the surface of the mucosa (see Fig. 32-33). However, the slough is somewhat slower in the colon as it proceeds into the crypts. The serosa reacts in a similar fashion, with mesothelial cells lifting off the basement membrane before there is visible cell membrane or cytoplasmic change. Other than vascular congestion, there is minimal change in the architecture of the supporting tissues in the mucosa or the serosa for the first 60 minutes of total ischemia. After 180 minutes of

ischemia the lamina propria and mucosal vascular tuft have lost their architecture. The tissue is necrotic and becoming homogeneous, with lack of nuclear definition and cell structure.

Estimating the time required to create ischemic lesions depends on the experimental methods used. Different types of anesthesia in the horse and other animals have resulted in different rates of mucosal degeneration during ischemia. For example, experiments using animals anesthetized with inhalant anesthetics are different from those that required animals breathing air, most likely from higher tissue oxygen concentrations at the beginning of the experiment.[203–205] Also, some cell types, such as muscle, appear more resistant to ischemia, which probably depends on the intracellular energy reserves of the cells. There are also differences in the response to low-flow ischemia versus total arteriovenous obstruction. Nevertheless, lesions caused by ischemia progress with reperfusion.

If reperfusion—either resumption of blood flow or increased flow after low-flow conditions—occurs while cells are still viable, a cascade of events is set in motion by the delivery of oxygen to the previously ischemic tissue.[195,206] The resultant injury is called *reperfusion injury* and relies on renewed oxygen in the tissue, with participation of endothelial cells and afferent receptors to create the subsequent inflammatory response. Although it makes sense that oxygen is needed to resuscitate the previously ischemic cells, the innate defense system in many cell types is to respond to the ischemic change with an inflammatory response. This response appears to help initiate a defense against bacterial invasion and is aimed at removing the damaged cells from the system. If enough cells have been damaged, the reperfusion effect can cause enough inflammation to prevent cells from surviving, thereby delaying healing.

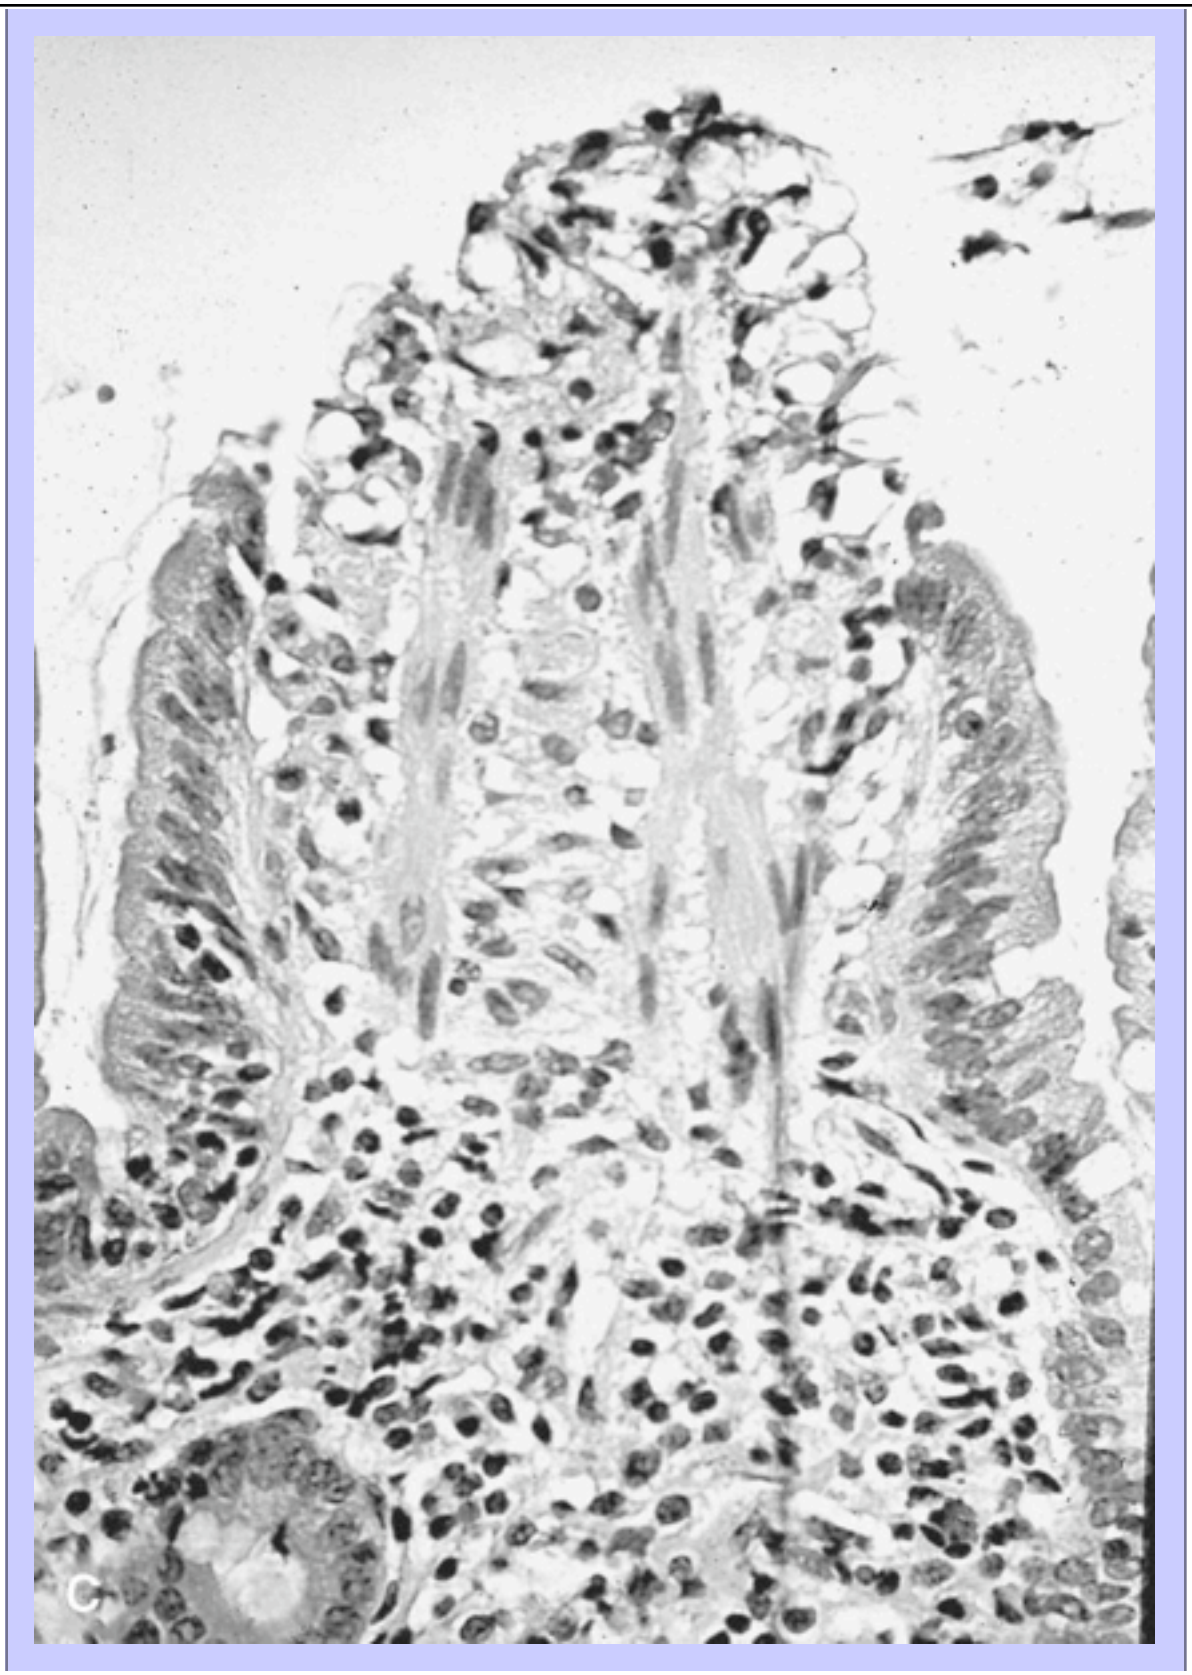
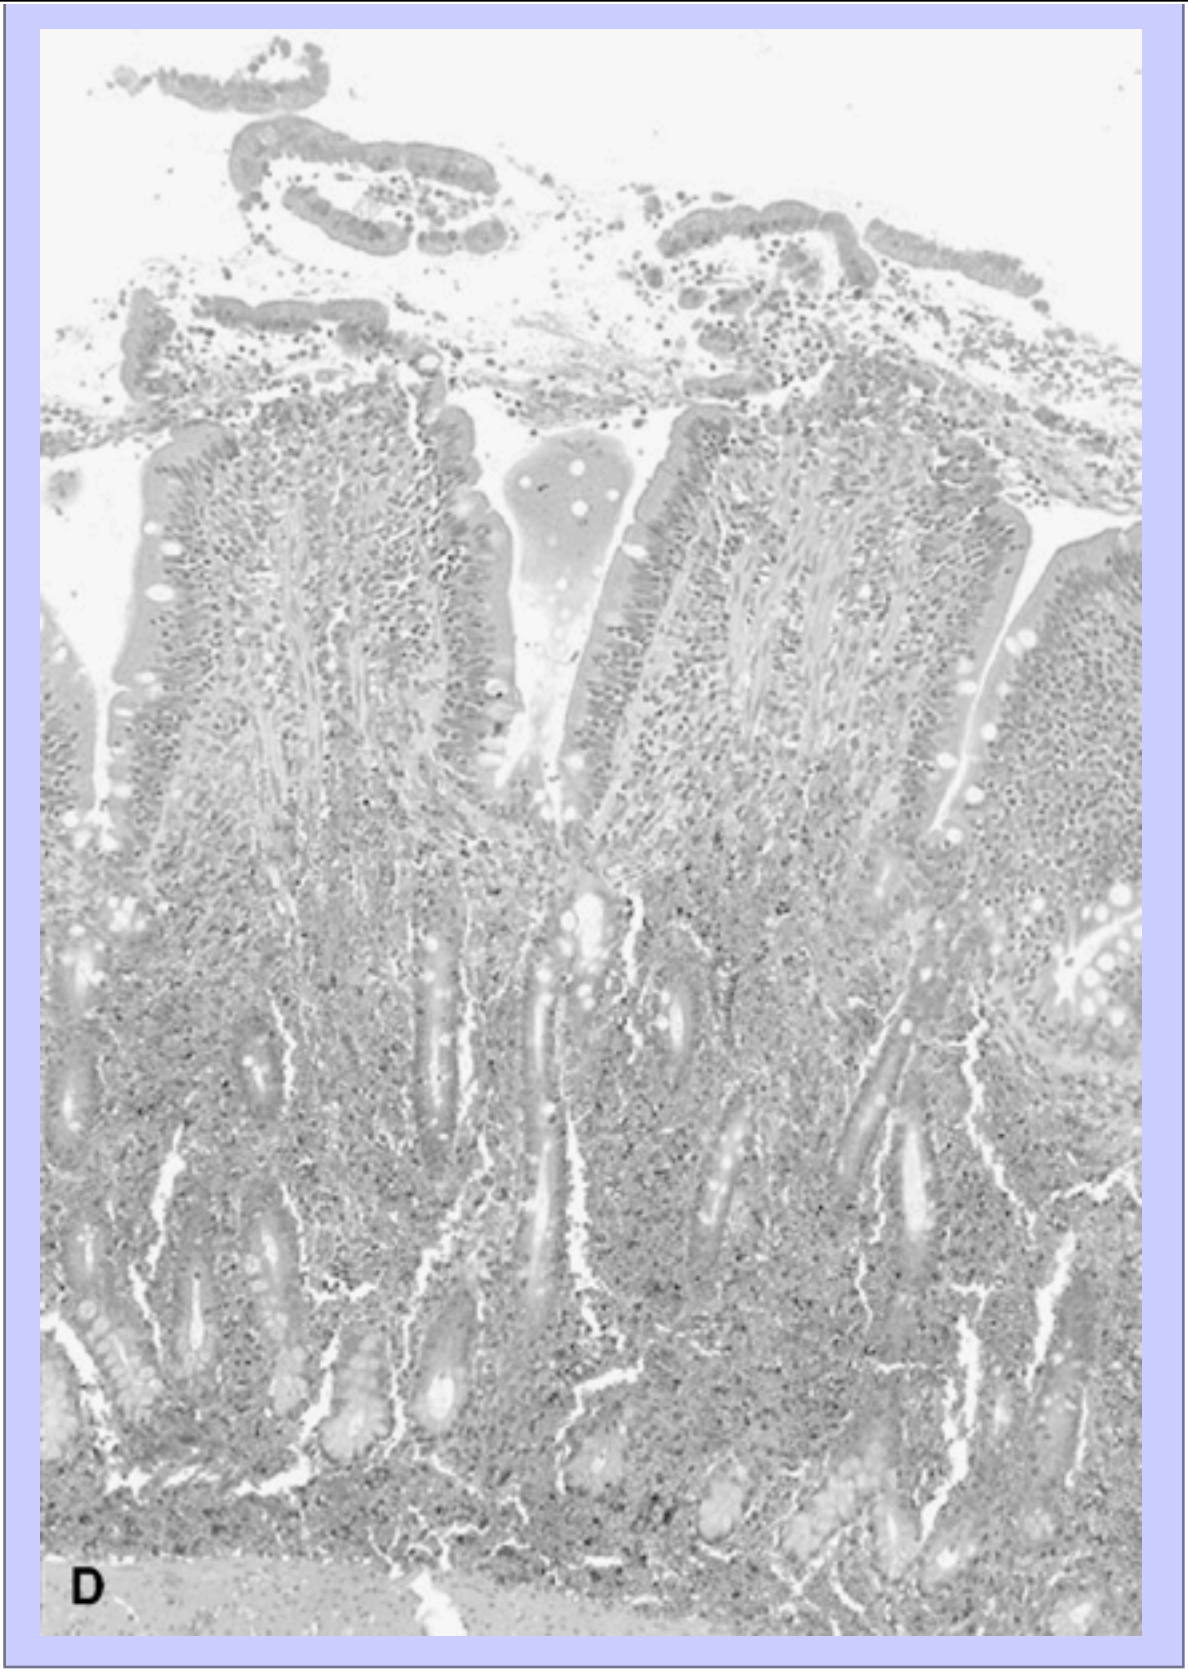
B





D

Reperfusion injury starts as a change in intracellular metabolism in previously ischemic tissue. It does not require exposure to a microbe or toxin, but it does rely on cell production of cytokines and leukotrienes as signals to numerous blood and tissue cells required to complete the process. One primary initiator of reperfusion injury in the intestine is the production of oxygen radicals (O_2•). Oxygen has the ability to take on an extra electron during enzymatic processes in the cell. Most cells including endothelial cells and the small intestinal mucosal cells contain xanthine dehydrogenase, which when converted to xanthine oxidase catalyzes hypoxanthine to xanthine.[206] Hypoxanthine is increased in the cytoplasm of cells during ischemia. Calcium and proteases initiate xanthine dehydrogenase conversion to xanthine oxidase, a process that can be stimulated in endothelial cells by IL-1, TNF-α, and C5a, as well as neutrophil adherence. Oxygen is used in the reaction and ends up with an extra electron, making an O_2• or superoxide.[205]

Once released, O_2• can initiate a number of chemical reactions that cause cell membrane damage directly and by stimulating phospholipase activity. During O_2• production nitric oxide (NO) production is decreased, thereby allowing neutrophil adhesion and migration. Superoxide interaction with iron or catalase causes production of hydroxyl radicals (OH•) or hydrogen peroxide (H_2O_2) respectively. Both are cytotoxic. The OH• alters or destroys cell membranes. Affected cells rapidly express cytokines and leukotrienes, which act as chemoattractants for neutrophils. After the initial free radical production, cell injury progresses as two main events. Calcium, already increased in the cell, increases further, effectively blocking further energy production in the mitochondria and activating proteases, causing further degradation of the cell nucleus and cytoplasm.[202] Second, radicals formed from molecular oxygen can cause cell membrane damage, thereby initiating a similar cellular response. The formation of chemical mediators takes only seconds to minutes after reperfusion and rapidly sets the inflammatory cascade in motion.

Although the mucosal cells and serosal mesothelial cells are damaged early in ischemia and are able to release cytokines to alert other cells locally, endothelial cells appear to be the primary initiators of reperfusion injury.[179] They participate in cytokine production and are involved with neutrophil adhesion and migration from blood into tissues. Endothelial cells are also involved with the changes in blood flow after reperfusion.[188] The platelets and neutrophils accumulate in and obstruct capillaries, altering blood flow. Endothelial cell swelling or contraction causes constriction of blood vessel lumens (Fig. 32-34). Changes in endothelial cells in response to histamine, complement, leukotrienes, and PAF increases capillary permeability, allowing fluid and protein to move into the interstitium.[188] Even though the metabolic state of the tissue during initial reperfusion initially results in overall increased blood flow, the increased vascular permeability increases interstitial pressure, causing capillary collapse. Combined with endothelial cell change, vascular constriction and collapse of the tissue vasculature results in a "no-reflow phenomenon," promoting further tissue ischemia.

Endothelial cell membrane changes allow expression of adhesion molecules and receptors, which are necessary for neutrophil adhesion and migration through the capillary and venule endothelium (Fig. 32-35). This migration of neutrophils causes the most prominent inflammation in the tissue, because activated neutrophils release elastase, oxygen radicals, and other serine proteases, which attack collagen, ground substance, and cell membranes.[207] The respiratory burst, a buildup of oxygen free radicals in neutrophils during activation, is responsible for most of the inflammation and tissue damage seen during reperfusion. It is also apparent that reperfusion injury can expand the initial injury into the surrounding viable tissue and that it can cause irreversible tissue damage.[208–210] Reperfusion injury can also cause injury distant from the local damage and has been observed in the lung because of cytokine and activated neutrophil circulation.[211] Although not reported in

the literature, the resulting lesion can be seen in the lungs of horses that succumbed to severe intestinal strangulation, obstruction, and shock.

Cell necrosis is recognized as a pathologic feature during ischemia and reperfusion. Recently, however, alterations in apoptosis (programmed cell death) have been found to increase during ischemia and reperfusion in experimental studies of the heart, brain, liver, adrenal glands, kidney, and intestine.[212–214] Alternatively, epithelial cells undergoing hypoxia and reoxygenation modulate neutrophils to delay apoptosis, suggesting a role in initiating SIRS.[215] Significantly increased apoptotic cells in muscle, mucosa, neurons, and glia in naturally obstructed or strangulated equine intestine suggests apoptosis is stimulated by and may promote the inflammatory response.[216,217] Apoptosis is also increased in intestine distant to the primary lesion, supporting systemic stimulation by cytokines.[218] The amount of apoptosis observed in experimental animals and in horses with intestinal obstruction suggests this process is excessive during reperfusion and may result in both morphologic and functional changes.

The importance of oxygen radical generation as a mechanism of injury in strangulating lesions has been questioned in the horse.[219] However, both clinical signs and lesions from clinical cases suggest that intestinal damage progresses after reperfusion. Use of a low-flow to no-flow model of ischemia with subsequent reperfusion responded to treatment to counteract injury from superoxide production and neutrophil accumulation.[220] This suggests that free radical production is part of the cascade of events causing an inflammatory response in the small intestine after bowel strangulation. Lack of malondialdehyde and conjugated diene production in the large intestine suggests less of a role for tissue-generated oxygen radicals and that reperfusion injury is primarily caused by the oxygen radical release from migrating neutrophils as seen in xanthine oxidase—deficient rats.[207,221,222]

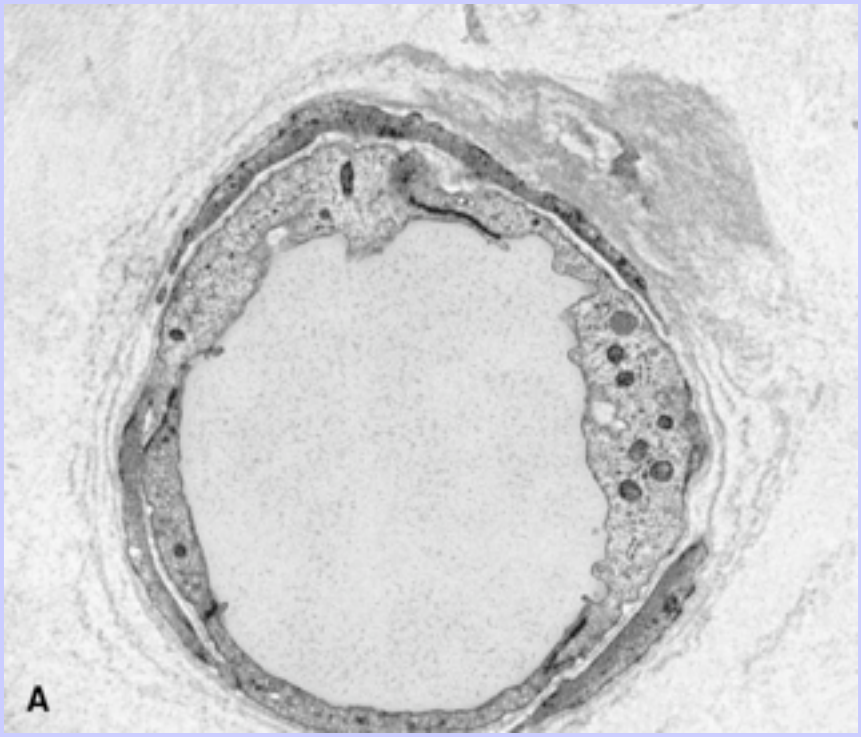
Recent research suggests that endothelial cells are not the only cells that act as “local effectors” of inflammation during reperfusion. Signs of inflammation are present in all parts of the intestine including the muscle and myenteric plexus.[191,223–225] Alterations in muscle mitochondrial morphology have been identified in equine jejunum after low-flow ischemia.[226] Similarly, during large colon volvulus the neurons in the myenteric plexus undergo degeneration and decrease in number compared with normal conditions.[224] Evidence of ischemic injury and inflammation occurs in both muscle and myenteric plexuses. This is relevant in horses with colon volvulus, in which survivors had significantly more neurons than nonsurvivors.[224] Perhaps of greater importance is the long-term effect of the inflammation in the myenteric plexus after ischemia and reperfusion. One can speculate that the high rates of repeat colic episodes in horses after colon torsion or large colon impaction are related to damage to the enteric nervous system.[227]

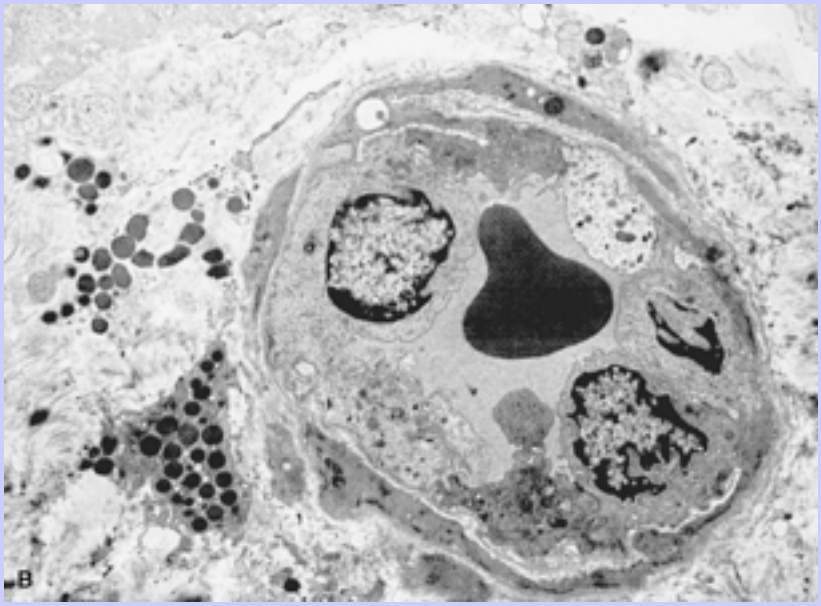
Reperfusion injury occurs after low-flow and no-flow ischemia. These models appear to emulate the clinical event, although the onset of ischemia in strangulation obstruction most likely starts as low-flow progressing to no-flow ischemia. Although the time frame of reperfusion injury is somewhat understood from the experimental models, the functional effects of dynamic events set in motion by reperfusion such as “no reflow” as well as persistent inflammation in the serosa and around the intestinal nerve ganglia are not well understood. The relevance of these myenteric plexus lesions is also questioned, because they do not always correlate with severity of clinical signs.[224]

32.42.2 Low-Flow Ischemia

The effect of ischemia-reperfusion differs with the type of ischemia. Low-flow ischemia is defined as flow less than 25% of normal blood flow. At this flow rate, vascular and cell damage is minimal, with degeneration occurring over a long time period. When normal flow is returned by increasing vascular volume or release of the arterial obstruction, there is a hyperemic response doubling the normal blood flow to the affected intestine.[226] Cell damage accelerates during reperfusion, with marked changes in vascular permeability, mucosal damage, serosal damage, and signs of fluid accumulation in the submucosa, muscle, and serosa.[206,226,228,229] Edema in the submucosa and serosa causes vascular collapse, leading to decreased blood flow and eventually a "no-reflow" phenomenon in the serosa and mucosa, with flow to the affected segment decreased below normal.[230,231] The decreased flow is partially caused by endothelial cell swelling and neutrophil margination in the vasculature. Neutrophils migrate into all tissues but predominately the mucosal and serosal layers. As neutrophils migrate through the capillary or venule, they accumulate around the vessels. As reperfusion progresses, the greatest injury is observed in the serosa, with marked accumulation of neutrophils beneath the serosal basement membrane. Although neutrophil accumulation is most marked in the serosa, neutrophils can be found in all layers of the intestine. This type of low-flow ischemia is rarely documented in equine abdominal disease, but it likely exists in distended intestine in which there is low flow to the affected bowel wall. The flow is directly related to the intraluminal pressure, with pressures causing greater than 50% reduction in blood flow common in severe small intestinal distention.[232]

Fig. 32-34 Transmission electron photomicrographs of small vessels in the serosa (**A**) with normal endothelial cells before ischemia and (**B**) with swollen endothelial cells and accumulation of neutrophils narrowing the vessel lumen during reperfusion.

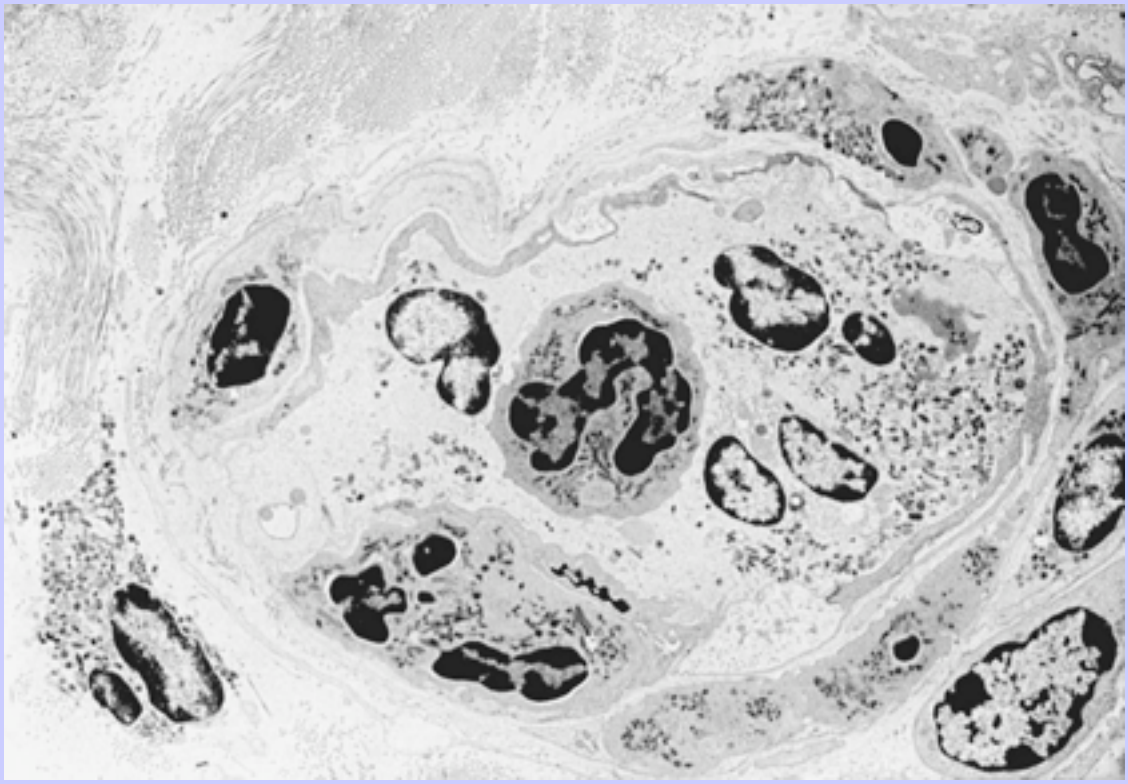




When examined in experimental models or when observed in clinical cases, most of these changes from acute low-flow ischemia are reversible and the affected intestine survives and heals. The effect varies greatly and is dependent on the length of ischemia. It is suspected that function is compromised temporarily, resulting in ileus, endotoxin absorption, or enteritis with excess secretion.[233] In the small intestine serosal scarring and adhesions are the most common long-term result and may increase the risk of colic episodes in the future. Even if lesions are not grossly evident and appear minor on microscopic examination, horses with colic, particularly those requiring surgery, likely have intestinal injury, which can ultimately result in permanent intestinal dysfunction. Hypothetically this is one possible reason for increased risk of colic after previous colic episodes or previous surgery for colic.[227,234]

706
707

Fig. 32-35 Transmission electron photomicrograph of neutrophils adhering to the endothelium and accumulating in the perivascular space after migrating through the endothelium.



Nonstrangulating infarction is the classic example of low-flow ischemia. In the horse, thromboembolic colic is reported to be caused by thrombosis of the mesenteric artery and its branches in horses infected with fourth stage larvae of *S. vulgaris*.[235] The mechanism of infarction is most likely reduction of blood flow from a thrombus in the artery or thromboembolism obstructing the peripheral vasculature. In nonstrangulating infarction the intestinal injury most likely results from long-term low-flow ischemia or low-flow ischemia with episodes of reperfusion injury. In clinical cases the injury is severe, often resulting in necrosis in all layers of the bowel, with obvious infarction.

Low-flow ischemia may also occur during shock.[194] Intestinal injury in bowel not directly involved in the primary lesion is suggestive that this injury is frequently present in horses with bowel strangulation obstruction.[194] In horses with obstructing or strangulating lesions, biopsies from nonaffected, grossly normal intestine have evidence of some degree of bowel injury including neutrophil infiltration.[209,210,216,236] Endotoxin administration also caused an inflammatory reaction in the intestines, with loss of mucosa and neutrophil infiltration in the mucosa.[237] This may be relevant to assessing horses in shock.

32.42.3 Total Arteriovenous Occlusion

Total ischemia caused by arteriovenous occlusion causes total vascular stasis. The most common cause of this form of ischemia is the mesenteric infarction caused by incarceration of bowel in hernias or constricted spaces. Early in the occlusion, capillary congestion is observed in all layers of the intestine. The intestine undergoes degeneration as previously described for ischemia. When total ischemia exceeds 2 hours in the small intestine and 3 hours in the large colon, the tissue changes during blood flow occlusion are extensive, and cell necrosis may preclude a response to reperfusion.[203–205,238–241] If the capillary damage is not too extensive during total ischemia, reperfusion causes further degeneration including mucosal cell loss, increased edema, and neutrophil migration (see Fig. 32-33). However, oxygen radical production seen with low-flow ischemia and reperfusion may not be responsible for the continued damage during total arteriovenous occlusion.[242] Furthermore, these events cannot be separated from the systemic shock, which can be cause secondary lesions seen in intestine distant to the lesion.[209] Despite the questions about the validity of reperfusion in the total ischemic event, continued intestinal injury during reperfusion is seen in both the small intestine and the large colon after total ischemia.[203,208,243] The epithelial cell loss after reperfusion is progressive and is likely caused by either countercurrent exchange creating a decreased oxygen concentration in the distant mucosa or by inflammation resulting from oxygen radical—induced inflammation from neutrophil activation.[207,223,244] The response in the serosa includes marked edema with initiation of neutrophil migration. Eventually a massive collection of neutrophils fills the outer border of the serosa.[245,246] During this type of ischemia and reperfusion, the damage from the inflammatory reaction can continue for days and if severe enough can prevent healing of the mucosa and serosa and is consistent with persistent ileus and shock.

32.42.4 Venous Occlusion

Venous obstruction without arterial obstruction causes increased pressure at the capillary, resulting in decreased blood flow and RBC and fluid extravasation into the interstitium. The result is separation of the tissues with an increased diffusion distance for oxygen and nutrients. The RBC accumulation causes tissue damage, and if it is severe enough a continuation of cell hypoxia becomes irreversible even with reperfusion. Injury during venous obstruction appears more severe than observed during subsequent reperfusion.[247] Small intestine can survive 2 hours of venous obstruction, although the resultant degeneration is severe and the intestine permanently scarred after healing.[204] The gross lesion is marked with obvious thickening of the bowel, which at first is red and eventually purple. With time the color turns black or green with subsequent necrosis and alterations in hemoglobin.

707 708

Based on both experimental work and observations in clinical cases, irreversible death of a segment of the intestine occurs after 2 hours in the small intestine and 3 hours in the large colon, although this obviously varies depending on the amount of residual blood flow to the affected tissue.[204,205,239] For the surgeon venous

occlusion is the most difficult type of lesion to assess, as intestinal thickness or amount of hemorrhage may not correlate with viability. Recent reports of survival of horses with hemorrhagic lesion at surgery suggest that this injury can be reversed more readily than a lesion caused by total arteriovenous occlusion. The sequence of mucosal degeneration remains the same in this type of ischemia, making the biopsy the most reliable method for determining if the intestine can survive and heal.[205]

32.42.5 Distention

Although distended intestine may appear to have normal color and motility after decompression, alterations in blood flow in the wall of the distended intestine are a form of low-flow ischemia. During intestinal distention intraluminal pressure causes collapse of the veins and capillaries, thereby decreasing the vascular capacity. This occurs even when blood pressure is normal. When small intestinal pressure is increased to 18 cm of water, as previously measured in clinical disease,[248] mesenteric blood flow to the intestine is decreased by at least 50%.[232,249] Increasing capillary back pressure while maintaining arterial pressure alters Starling forces in the intestinal wall. The result is secretion of fluid from the vasculature even with an increase in wall tension. Water and some protein escapes into the interstitium, causing submucosal and serosal edema. At higher intraluminal pressures there is more secretion than absorption of water, creating a cyclic increase in intraluminal pressure after bowel compliance has reached its limit.[250] Fluid and eventually protein leaks through the serosa into the peritoneal cavity.

If the pressure is maintained, intestinal compliance allows blood flow to gradually increase, acting as a form of reperfusion. Serosal and submucosal edema progresses during the period of distention. The mucosal and serosal lymphatics dilate, and RBCs and WBCs migrate into the serosa and submucosa (Fig. 32-36). There is minimal mucosal injury at pressures seen in clinical cases during simple obstruction of the small intestine or colon.

Subsequent decompression of the bowel causes reperfusion with a hyperemic response similar to that seen after low-flow or total ischemia. Blood flow to the affected bowel can initially double, but this effect is temporary, with subsequent blood flow decreasing below normal.[232] The mucosa appears relatively resistant to short-term distention, whereas the edema in the serosa causes capillary closure and increased vascular permeability. Serosal edema increases and more neutrophils migrate into the serosa, causing destruction of collagen and ground substance.[232,245] Intestinal smooth muscle is also affected with edema, and neutrophil migration is evident in the fascial planes around the myenteric plexuses (Fig. 32-37). Although bowel can frequently heal after this type of ischemic insult, the serosa is often thickened by fibrous tissue with the possibility of adhesion formation and mesenteric constriction.[251] The mucosa appears relatively resistant to the low-flow ischemia experienced with bowel distention, but the response is time dependent. Rarely does prolonged distention cause bowel necrosis. Bowel wall necrosis is more common when foreign bodies or impactions cause focal distention. Because the response to distention is both time and pressure dependent, the time frame for permanent damage is difficult to determine. The small intestine is more susceptible to distention injury compared with the large colon. Clinical measurement of intraluminal pressure during obstruction indicates that the large colon can tolerate at least twice the distention pressure with no adverse effects.[252,253]

Fig. 32-36 Photomicrograph of edema, lymphatic dilatation, and RBC and WBC accumulation in the serosa after 18 cm H_2O distention for 2 hours and reperfusion for 1 hour. Hematoxylin and eosin stain.

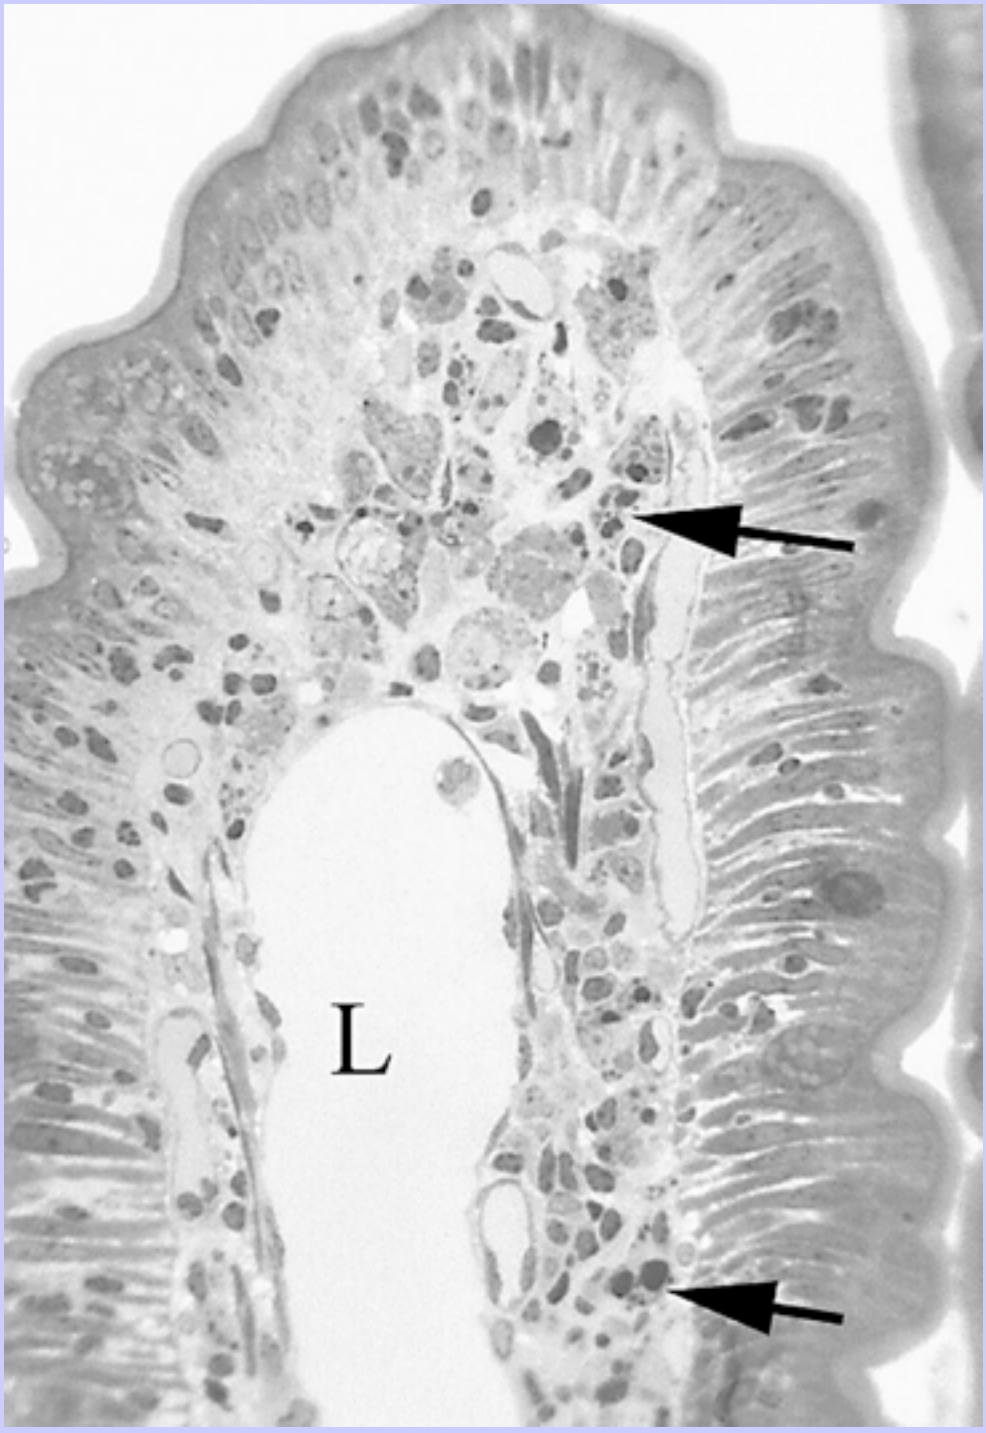


Fig. 32-37 Photomicrograph of neutrophil infiltrate *(arrow)* in the muscle and around a myenteric plexus after low-flow ischemia and reperfusion. Hematoxylin and eosin stain.

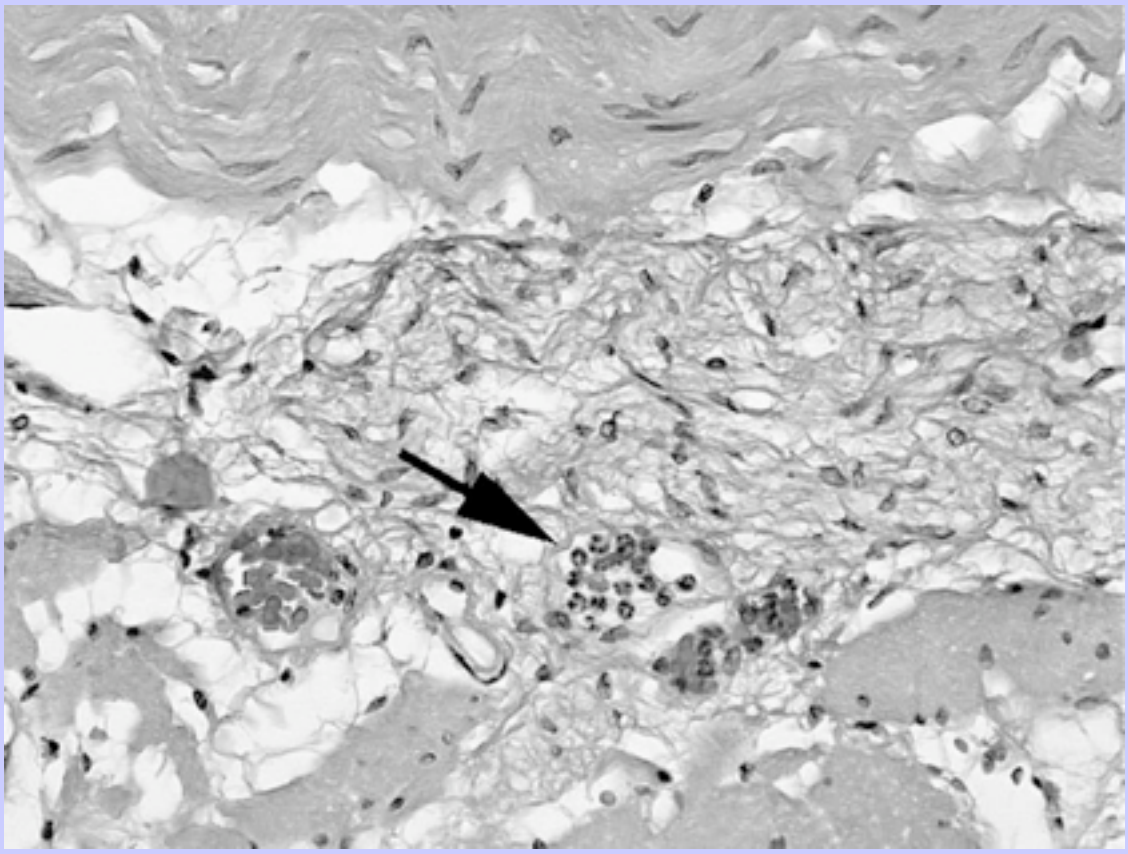


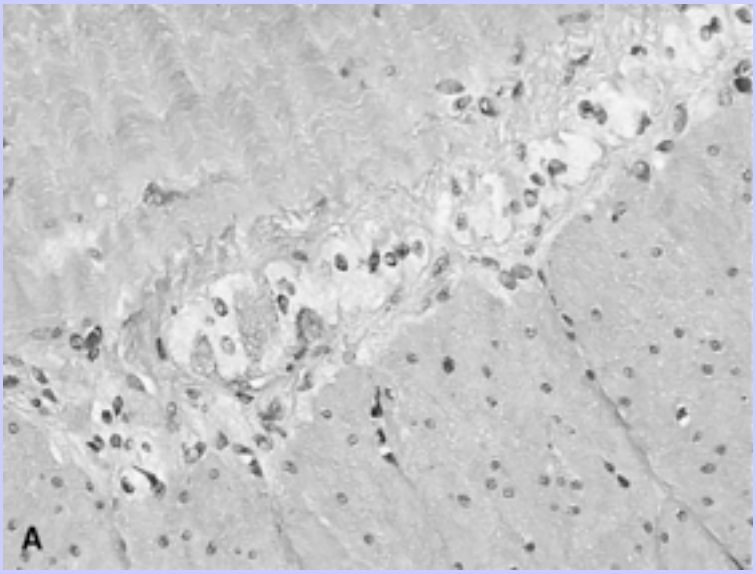
Intestinal dysfunction occurs after decompression of bowel that was previously obstructed. Ileus with gastric reflux is common in horses with previously distended small intestine, and the bowel pressure measured at surgery can predict the severity.[252,253] Abnormal motility with lack of response to prokinetic drugs is also observed after small intestine distention in vitro.[254] Although the injury from distention cannot be separated from conditions in the peritoneal cavity or failure of the cardiovascular system, the correlation of increased intraluminal pressures and survival indicates the importance of intestinal distention in causing injury.[230,232,248,251,252]

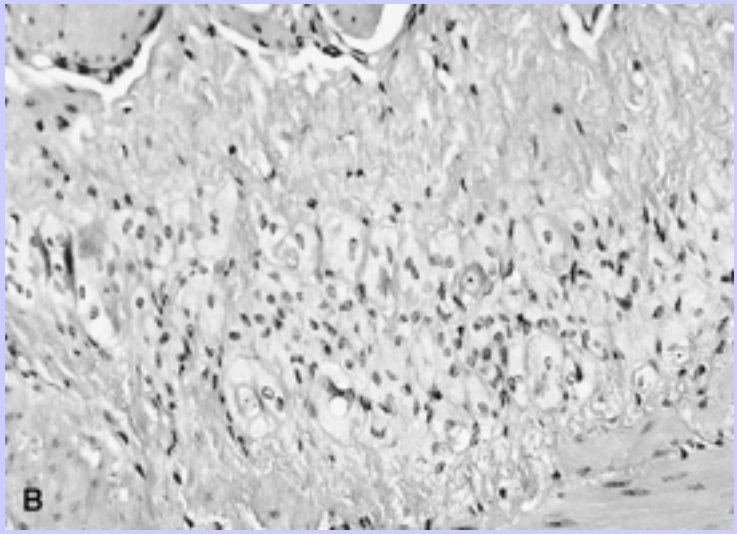
The enteric nervous system also appears to respond to intestinal distention. Chronic obstruction caused by impaction of the colon or cecum or colon displacement has been associated with a significant decrease in the number of neurons in the myenteric plexuses, whereas the number of myenteric plexuses was similar to that in normal horses.[224] This change in neuron number was also associated with increased thickness of the longitudinal muscle in the pelvic flexure or both circular and longitudinal muscle hypertrophy in the cecum.[255] This appears similar to pseudoobstruction in humans and to experimental denervation of intestinal segments in rats. The lack

of nervous inhibition is hypothesized to allow constant and uncoordinated muscular contractions with resulting hypertrophy and eventually poor transit of ingesta.

Myenteric plexuses from distended or obstructed large colons also had an increase in the number of glial cells (Fig. 32-38). This appears to be an inflammatory response by the enteric nervous system to the conditions involved with bowel distention. Alternatively the inflammation and neuron dropout may have been responsible for colon dysfunction in these horses examined because of colon obstruction.

Fig. 32-38 Photomicrographs of **A**, normal myenteric plexus with connective tissue surrounding an accumulation of neurons, and **B**, increase in glial cells in the myenteric plexus in a horse with chronic obstruction of the large colon. Hematoxylin and eosin stain.





32.43 INFECTION

Enteritis caused by infection is frequently a result of *Salmonella* species, *Clostridia* species, *Neorickettsia risticii*, or virulent *E. coli*. Viruses such as rotavirus can also cause infection in foals with subsequent clinical signs. These agents adhere to and attack mucosal cells. When bacteria bind to the mucosal cells, the release of endotoxin or exotoxins causes the mucosal cells to release cytokines, which signal immunocytes and neutrophils of impending invasion. The gut has a large number of lymphocytes and macrophages in the lamina propria, suggesting constant stimulus by agents or substances.[183,256] Although the mucosal cell has an innate ability to resist infection, the communication between the immunocytes and the mucosa is likely the chief defense. The infection can change mucosal function without destroying the mucosal barrier; increased TNF-α concentration has been shown to impair barrier function at the tight junctions.[257] The change can cause lack of absorption and/or massive secretion of fluid into the bowel, causing diarrhea.

Interaction of neutrophils with the apical membrane of epithelial membrane after paracellular migration stimulates adenosine receptors by production of 5′-AMP.[258] Subsequent functional secretion is caused by stimulation of adenyl cyclase and guanyl cyclase, which catalyze formation of cAMP or cGMP respectively. These cyclic nucleotides subsequently activate protein kinases, which block the NaCl absorptive process in the absorptive mucosal cell and stimulate Cl secretion in the crypt cell.[259] Inflammation with release of eicosanoids and bradykinin can also initiate the secretory process. The enteric nervous system can also induce inflammation and secretion in the bowel, which can be inhibited by nerve-blocking agents or indomethacin.[259,260] Neuropeptides from efferent nerves are hypothesized to initiate this response by affecting mucosal cells, fibroblasts, and endothelial cells.[178,261]

When bacteria cause injury by adhering to the mucosal surface and invading the mucosa, the response of the mucosal cells stimulates both the afferent nervous system and an immediate local immune reaction. Cytokines from local macrophages or injured epithelial cells serve as the messengers of recognition, which stimulate macrophages, neutrophils, and eosinophils to migrate to the region of invasion. Lymphocytes are also activated, releasing cytokines including IFN-γ. After an initial delay in mucosal cell apoptosis during bacterial adhesion and invasion, apoptosis is increased, theoretically to increase cell turnover and healing. TNF-α and nitric oxide appear to control mucosal cell apoptosis.[218]

709 710

The inflammatory response to invasion often causes massive mucosal necrosis, with loss of mucosal cells and a massive infiltrate of neutrophils and lymphoid cells. Fibrin exudate creates a cast on the mucosal surface of the bowel. The vasculature is exposed to the bowel lumen, allowing subsequent invasion of the bacteria, both pathogens and others, as well as bacterial toxins. The remaining mucosal cells are stimulated to secrete water via the stimulation of cAMP within the crypt cells. Water is also retained in the bowel because of the lack of absorptive cells; the result is diarrhea.

The infection can involve the other layers of the intestine, although it rarely involves the serosa. Still, some diseases such as hemorrhagic fibrinonecrotic duodenitis—proximal jejunitis (DPJ) affect all layers of the intestine. A causative organism has never been discovered to explain DPJ, but the lesion is similar to that seen with clostridial disease in young swine.[262] Similar to reperfusion injury, the inflammatory process creates dysfunction that can last for days. Although long-term complications from DPJ have not been reported, animals with severe cases have not survived because of the lack of healing and severe residual inflammation in the bowel wall.[262]

32.44 PERITONEAL INFLAMMATION

The serosal layer is made of a single-cell mesothelial layer mounted on a layer of connective tissue. This layer is important for maintenance of a lubricated barrier at the bowel surface, necessary for normal intestinal motility and peritoneal cavity fluid exchange. The mesothelial layer attaches to a basement membrane, which is adjacent to an elastic layer. The mesothelial cells vary in type. Some are short and have channels linking the peritoneal surface to the serosa. Others have long microvilli, which appear to help trap fluid on the surface of the peritoneum, providing the chief mechanism of lubrication on the bowel surface. Mesothelial cells react to circulating or intraperitoneal lipopolysaccharide (LPS), infection, and surgery by releasing TNF-α, IL-1β, IL-6, and macrophage inflammatory protein (MIP).[263] The response in the serosa is attraction and migration of neutrophils into the serosal connective tissue.

The initial response to serosal injury has been studied in laboratory animals using predominantly scarification of organs or fecal contamination of the peritoneal surface. The response to ischemia or distention of the equine small intestine is similar, though often more severe. During ischemia the mesothelium is rapidly lost, with subsequent serosal swelling with edema. During reperfusion the serosal vasculature becomes more permeable, and polymorphonuclear cells and mononuclear cells migrate through capillaries or venules and infiltrate into the serosal connective tissue layer. Neutrophils accumulate at the basement membrane around vessels and within lymphatics. Fibrin accumulates within the serosa and on the surface. WBCs release oxygen radicals and proteolytic enzymes, resulting in disruption of collagen, the primary ground substance of the serosa. The denuded serosal response includes increased vascular permeability, which allows the surface to be covered with a fibrin clot. After 24 to 48 hours there is massive accumulation of cells, which are predominately neutrophils, within the serosa and at the new surface.

Cytokines are involved in the response to serosal injury and the subsequent healing.[264,265] After intestinal anastomosis in rabbits, macrophages increased in number until about day four. Superoxide levels in these cells are high in the first 24 hours. Prostaglandins, cytokine secretion, and plasminogen activator inhibitor activity are known to increase during the first 3 days after peritoneal injury.[264] IL-1 and TNF-α are secreted by peritoneal macrophages after injury and appear to modulate peritoneal healing.[266] Peritoneal macrophages also secrete plasminogen activator. The secretion of both plasminogen activator and plasminogen activator inhibitor is stimulated by IL-1. After intestinal anastomosis there is a decrease in fibrinolytic activity for the first 5 days. Thereafter, plasminogen activator returns to the normal preoperative level. Normally fibrin will be dissolved by plasmin after plasminogen is activated by tissue plasminogen activator (TPA). The severity of the serosal injury is also related to the reduction of TPA and to the suppression of plasminogen activator normally produced by macrophages. If plasminogen is not activated or is absent, adhesions have a greater likelihood of becoming fibrous and permanent.

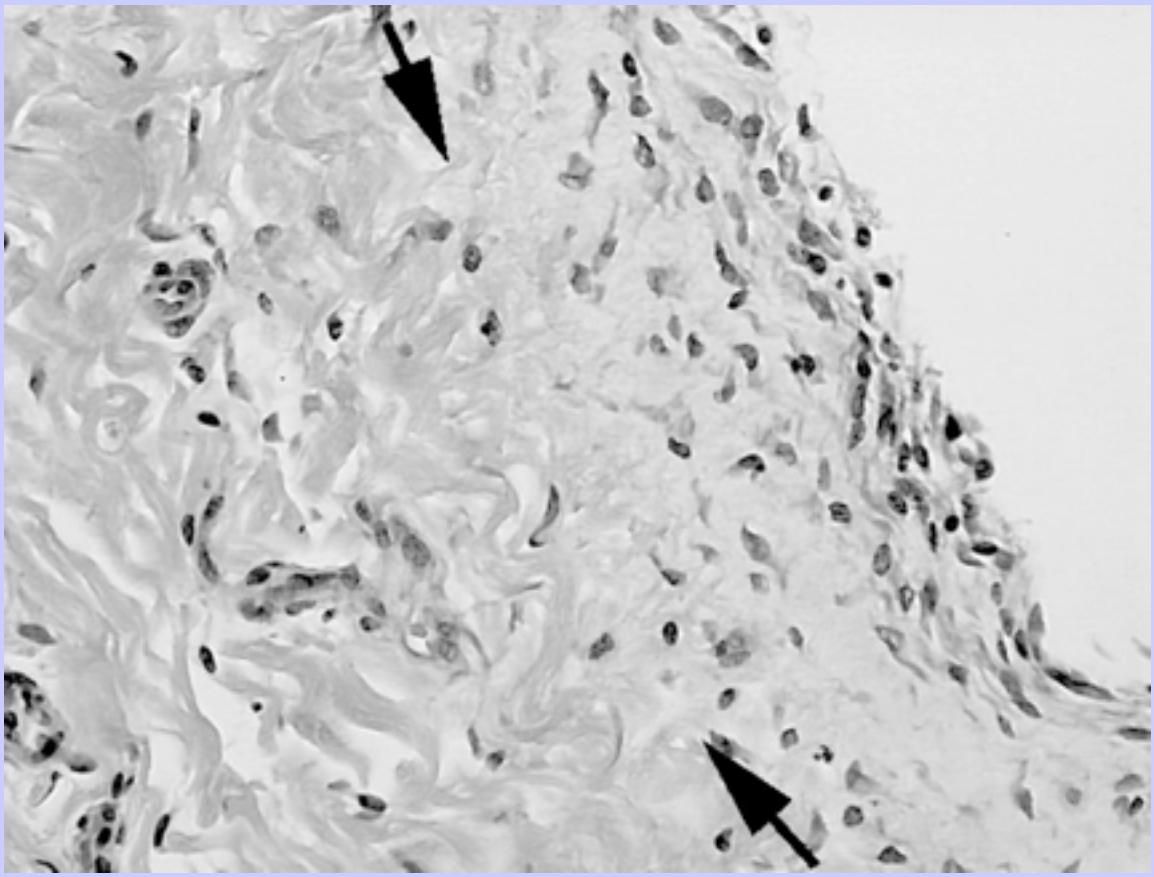
As healing progresses, fibroblasts migrate into the fibrin and a layer of granulation tissue forms both beneath and on top of the original basement membrane (Fig. 32-39). Mesothelial cells produce connective tissue growth factor in response to IL-1β, which simulates fibroblast proliferation.[190] During this stage IL-1 stimulates and prostaglandin E_2 inhibits fibroblast activity in the injured serosa. Primordial stem cells migrate to the surface and change to form a new mesothelium, a metaplasia likely under the control of growth factor from fibroblasts. The greater the inflammatory reaction within the serosa and on the surface, the more fibroplasia occurs, delaying mesothelium resurfacing and increasing the chance for adhesion formation or bowel scarring. Experimentally the severity of adhesions is correlated with increasing concentrations of TNF-α in peritoneal fluid, and antibodies against TNF-α can decrease adhesion formation.[266,267] Healing of the serosa may not result in bowel-to-bowel

adhesions but can still cause bowel and mesenteric scarring, which can cause luminal narrowing or kinking. The serosa also becomes thickened, which may result in bowel dysfunction or may interrupt the vascular supply, resulting in chronic obstruction.

In the horse the serosal injury is frequently caused by bowel distention. The cellular injury is similar to an inflammatory model except for the vascular sequelae. After small intestinal ischemia there is an initial vascular hyperemia in most of the bowel but a reduction of perfusion to the serosa.[231] This same effect occurs during bowel distention and is even greater after alleviation of distention. The edema formation in distended bowel takes place immediately and increases serosal tissue pressure, which exerts extravascular pressure and closes capillaries and venules.[231] This continues after bowel decompression, resulting in ischemic injury during reperfusion of the serosa. Reperfusion after decreasing bowel distention also causes serosal endothelial cell swelling and capillary plugging. This helps to explain the adhesions seen in bowel that was distended only proximal to an obstruction or strangulating lesion but was otherwise not involved in an ischemic lesion.

710
711

Fig. 32-39 Photomicrographs of the serosa with addition of a fibrous layer extending beyond the original level of the basement membrane *(arrows)* 10 days after bowel ischemia and reperfusion. (Hematoxylin and eosin stain.) The new serosa surface has yet to heal with a new mesothelial layer.



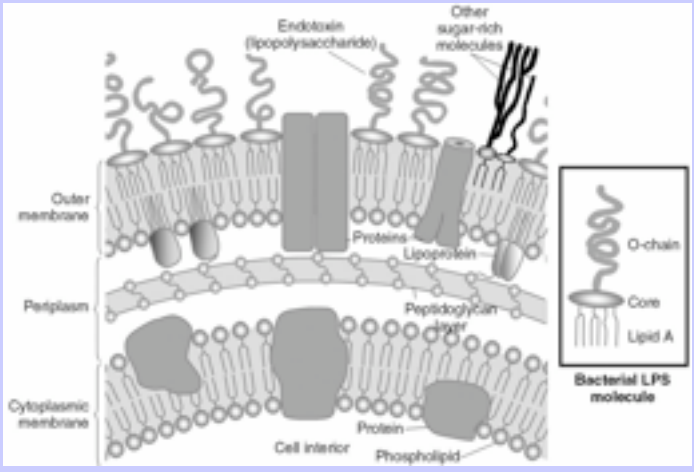
Adhesions resulting from septic peritonitis occur in response to a massive inflammatory response in the serosa. Similar to the response to ischemia, there is neutrophil migration and fibrin deposition in and on the serosa.[265] The inflammatory response may be so great that the proteolytic enzymes may prevent adhesion between bowel loops by breaking down fibrin. However, in most cases there is massive fibrin production, and bowel-to-bowel adhesions occur frequently.

32.45 BOWEL HEALING

After ischemic damage the mucosa heals rapidly.[268–270] Enterocytes migrate along the lamina propria, covering the surface within 24 to 38 hours. In the mucosa the crypt cells are responsible for rapid multiplication and physically forcing the older cells to the mucosal surface. Delayed healing is associated with a massive inflammatory response, which can stimulate delayed epithelial apoptosis and lack of cell replacement.[182,271] Connective tissue growth factor stimulates mucosal growth and may be responsible for excessive fibrosis in chronic inflammatory disease.[272]

Common use of nonsteroidal antiinflammatory drugs (NSAIDs), in particular flunixin meglumine, delays mucosal cell function during reperfusion.[270] Although replacement of the mucosal cell lining after ischemia is rapid, in vitro application of flunixin meglumine delays normal return of mucosal barrier function. Increased permeability to endotoxin in flunixin-treated bowel compared with the control intestine may lead to shock or delayed healing of intestine.[273]

Fig. 32-40 Cross-section of the double lipid bilayer that forms the cell membrane of gram-negative bacteria. As is shown in this figure, lipopolysaccharide (LPS) is the principal component of the outer leaflet of the outer membrane. The *insert* shows a single LPS molecule with an O-polysaccharide chain, a two-part core oligosaccharide, and a hydrophobic lipid A phospholipid. R-mutant bacteria lack the O-chain ± varying amounts of the core oligosaccharide.



Similarly, the serosal mesothelium also heals rapidly after loss from abrasion, though it takes longer than the mucosa to heal with a functional cell boundary. The mesothelial cells come from multipotent stem cells in the serosal connective tissues. These migrate to the serosal surface and form an initial layer of cuboidal cells before transforming to the more characteristic flattened mesothelial cells. The healing time appears to be dependent on the amount of inflammation and subsequent production of fibrous tissue on the serosal surface.

Although healing is thought to be successful when clinical signs of colic, obstruction, or peritonitis are no longer observed, the latent effect of serosal fibrosis, residual mucosal inflammation, and ganglionitis with loss of neurons may increase the risk of future colic episodes. Horses that have had a colic episode or previous abdominal surgery are three to four times more likely to have a second colic episode than horses that have never had colic.[234] Whether chronic inflammation is responsible for recurrent colic has not been determined.

32.46 ENDOTOXEMIA

Robert J. Mackay

The heat-stable endotoxic activity of *Vibrio cholerae* identified by Pfeiffer more than 100 years ago resides in LPS, the principal component of the outer leaflet of the outer membrane of all gram-negative bacteria (Fig. 32-40).[274] Each LPS molecule has three structural domains: a polar polysaccharide O-region, which projects into the aqueous extracellular environment; a hydrophobic lipid A region, which is largely buried in the bacterial outer membrane; and a core acidic oligosaccharide region connecting the two. The O-region is highly variable, consisting of repeating units each of one to eight glycosyl residues, and contains antigens specific for each bacterial strain; the core glycolipid region is relatively constant among bacteria and mediates most of the toxic effects of endotoxin. On bacterial death or during bacterial proliferation, large (>10^6-dalton molecular mass) aggregates of LPS and membrane protein are released. It is these protein-lipid micelles that constitute native endotoxin and are to be found circulating in naturally acquired cases of endotoxemia. In recognition of the fact that most endotoxic activity resides in the LPS component, the terms *endotoxin* (the activity) and *lipopolysaccharide* (the molecule) are used interchangeably except when a specific or purified LPS is being referenced.[275]

711

712

Endotoxemia literally is the presence of endotoxin in the blood. When the term is used clinically, it implies only the presence of clinical signs typically caused by circulating endotoxin. A survey of diplomates of the American College of Veterinary Internal Medicine and the American College of Veterinary Surgeons found that neutropenia, leukopenia, hyperemic mucous membranes, tachycardia, and fever were the clinical and laboratory values most characteristic of horses with presumptive endotoxemia.[276,277] This term should not be confused with either *bacteremia*, which refers only to the presence of viable circulating bacteria, or *septicemia*, which is an older term referring to systemic disease caused by circulating microorganisms and/or their products.

The ability to respond to minute local concentrations of endotoxin by mounting vigorous inflammatory responses is well conserved across species.[278] Endotoxemia as a clinical syndrome in equine patients was first recognized more than 40 years ago.[279] The potential importance of endotoxemia was then shown by reports that intravenous infusion of LPS into horses reproduced many of the adverse clinical signs of diseases such as colitis, metritis, and strangulating intestinal obstruction.[280–288] Further evidence for the importance of endotoxemia was the detection of circulating endotoxin in some horses with experimentally induced laminitis[289] or intestinal strangulation obstruction[290,291] and in horses with naturally occurring gastrointestinal diseases or septicemia,[291–296] hemostatic disorders,[297] and exhaustion associated with endurance[298] or racing[299] events. Since the original case descriptions,

a large body of review literature has documented the efforts that have been made to understand and, more importantly, treat equine endotoxemia.[300–310]

Within the last decade, rapid advances have been made in deciphering the molecular pathologies of sepsis in human beings and experimental animals. Much existing dogma has been swept away by this new information, and the pivotal events of endotoxemia in horses with sepsis can now be discerned. Unfortunately, over the same period it has become distressingly clear that the frequent promise of "silver bullet" treatments thrown up by experimental models and preclinical studies has not been realized in large, controlled, multicentered clinical trials in human patients. Therefore it is conceivable that some of the cherished but largely unscrutinized mainstays of equine endotoxemia treatment are of questionable value (at least in the life-saving sense). This section explores the new information that identifies endotoxin as but one of many pathogen- or host-derived signals that elicit global and destructive host responses and focus on treatment strategies that have evidence-based support (at least in human medicine).

32.47 ENDOTOXEMIA AND SEPSIS

The extraordinary ferocity of the host response to endotoxin was nicely captured by Thomas[311]:

> *"The gram-negative bacteria … display lipopolysaccharide … in their walls and these macromolecules are read by our tissues as the very worst of bad news. When we sense lipopolysaccharides we are likely to turn on every defense at our disposal; we will bomb, defoliate, blockade, seal off, and destroy all tissues in the area …. Cells believe that it signifies the presence of gram-negative bacteria, and they will stop at nothing to avoid this threat."*

Although this picture still accurately describes modern concepts of the early responses to endotoxin, it has become clear that a variety of other pathogen-derived molecules set off similar or identical host responses. For example, toxic shock syndrome resulting from *Staphylococcus aureus* infection[312] and streptococcal toxic shock[313] are examples of hyperinflammatory septic syndromes in horses that resemble diseases characterized by endotoxemia. In severe sepsis (including putative endotoxemia in horses), it is likely that the clinical presentation is an aggregate of responses to multiple microbial signals and certain "danger" signals generated by the host itself.

32.48 DANGER SIGNALS AND INNATE IMMUNITY

Animals have the ability to recognize distinctive patterns on molecules that signal potential danger. As a group, these molecules that express danger motifs are aptly termed *damage-associated molecular patterns* (DAMPs).[314] Included among DAMPs are microbial signals like endotoxin, collectively termed *pathogen-associated molecular patterns* (PAMPs), and *alarmins*, endogenously produced molecules that originate from damaged or inflamed tissues (Table 32-2).[315] A limited number of germ-encoded receptor types, both soluble and cell-associated, are dispersed throughout the body to detect potential threats (both septic and nonseptic). These are pattern-recognition receptors (PRRs) and are exemplified by Toll-like receptors (TLRs) on (and in) cells and complement receptor proteins and Hageman factor in plasma.[316,317] A list of these and other PRRs is given in Table 32-3. The interaction between DAMPs and PRRs is the initial event in the innate immune responses that result in signs of endotoxemia or other forms of sepsis.

Table 32-2 Partial List of Damage-Associated Molecular Patterns[314,315,368]

PAMPs	Alarmins
LPS (endotoxin)	HMGB1
Lipoprotein	S-100 proteins*
Peptidoglycan	HSPs
Flagellin	Defensins
Lipoteichoic acid	Cathelicidins
Zymosan	
Viral double-stranded RNA	
N-acetyl glucosamine	

HMGB1, High-mobility group box 1 protein; *HSPs*, heat shock proteins; *LPS*, lipopolysaccharide; *PAMPs*, pathogen-associated molecular patterns.

* Proinflammatory proteins released by phagocytic cells during innate immune responses.

Table 32-3 Partial Listing of Pattern Recognition Receptors[316,317,368]

Cell-Associated	Soluble
TLR (1-11)	Hageman factor
RAGE	MBL
Nod1/Nod2	C3b, Bb
CD14	Ficolins

MBL, Mannan-binding lectin; *Nod*, nucleotide-binding oligomerization domain; *RAGE*, receptor for advanced glycation end products; *TLR*, toll-like receptor.

713

32.49 CLINICAL SEPSIS SYNDROMES

A scheme showing increasingly severe stages of sepsis, with definitions, from local infection to death is shown in Fig. 32-41. The lethality of each grade increases from the base to the apex of the figure. In humans, reported mortality rates for severe sepsis are 25% to 30%[318] and for septic shock are 40% to 70%.[319] Endotoxemia is shown as a subset of sepsis (at all stages) in acknowledgement of the common pathogenesis of all sepsis syndromes. Dysfunction of two or more organs is termed *multiple organ dysfunction syndrome* (MODS) and carries an additional increment of lethality in human beings.[320] Comparable data are not available for the horse. Definitions for SIRS, organ dysfunction, and laminitis are given in Table 32-4. Note that sepsis is defined as *suspected* infection plus SIRS; therefore a horse with a strangulating intestinal obstruction and SIRS but no definable infection is still classified as septic or endotoxemic. Horses with signs of mild endotoxemia—leukopenia and fever—fit the definition for sepsis. With the exception of laminitis, these definitions are not validated for the horse but are reasonable extrapolations from accepted human criteria.

The fundamental difference between serious sepsis in humans and the syndromes seen in equids is the propensity for the latter to be associated with laminitis. In the context of sepsis, laminitis is often life-threatening. Because an organ is defined here as "a dispersed or solid tissue that performs a specialized function," it is probably inappropriate to classify the hoof as an organ as part of an equine MODS definition. It is clear from recent data, however, that the same types of global inflammatory and coagulation disorders that lead to MODS in patients with sepsis also are involved in the pathogenesis of both carbohydrate- and black walnut—induced laminitis.[321–325] In light of their likely common pathogenesis, laminitis and MODS are presented together in Fig. 32-41 (as MODS/L).

Fig. 32-41 Scheme for sepsis classification. Definitions for systemic inflammatory response syndrome, organ dysfunction, and laminitis are given in Fig. 32-42.

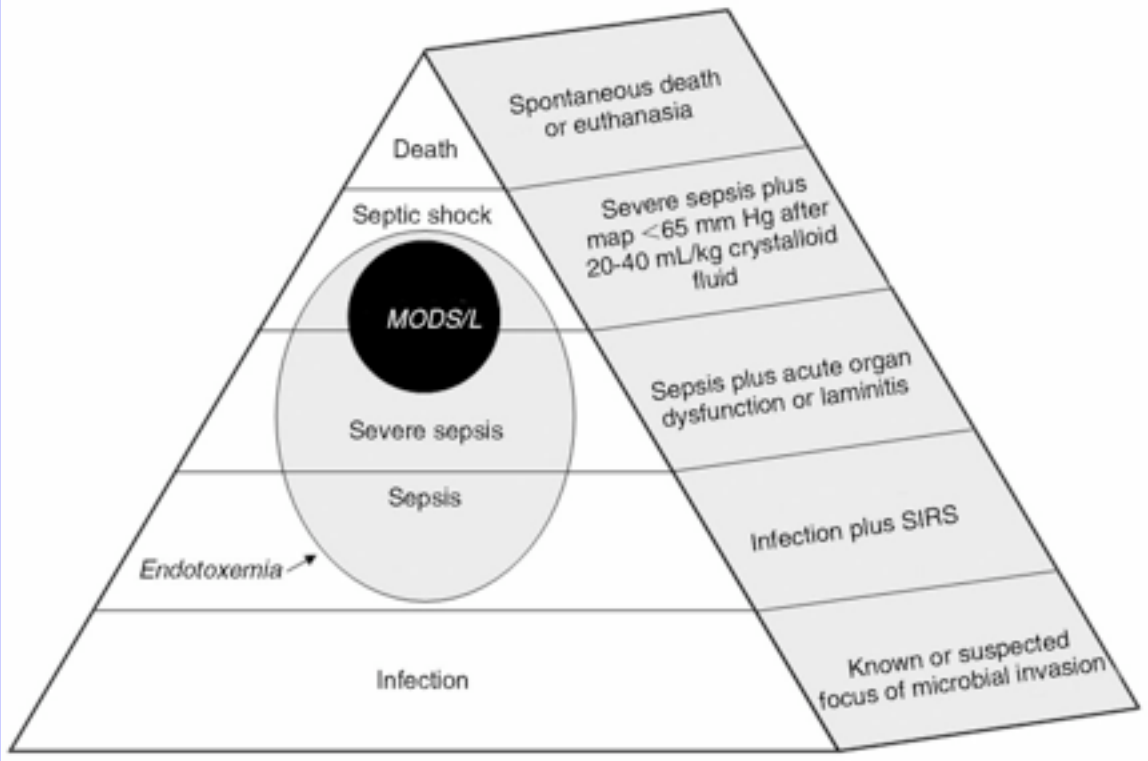

Table 32-4 Criteria for Systemic Inflammatory Response Syndrome, Organ Dysfunction, and Laminitis

SIRS CRITERIA (2 OR MORE OF THE FOLLOWING)	
Hypothermia	<98° F or hyperthermia >101.5° F
Leukopenia	<5000/μL or leukocytosis >14,500/μL
Tachycardia	50 beats/min
Tachypnea	25 breaths/min or $Paco_2$ <32 mm Hg
ORGAN DYSFUNCTION AND LAMINITIS CRITERIA	
Neurologic	Severe obtundation (stupor, semicoma, coma)
Renal	Creatinine >2 mg/dL after ≥20 mL/kg IV crystalloid fluids, or increase of ≥0.5 mm Hg since last measurement
Hemostatic	Platelet count <100,000/μL or aPTT >70 seconds
Respiratory	Pao_2 <65 mm Hg, or <75 mm Hg with oxygen supplementation or mechanical ventilation
Intestinal	Absent gut sounds, or absent motility on ultrasound examination
Hemodynamic	Mean arterial pressure <65 mm Hg after ≥20 mL/kg IV crystalloid fluids
Hepatic	Bilirubin concentration >6 mg/dL; GGT >60 U/L with no other explanation
Laminitis	Bounding digital pulses, sensitivity to digital pressure over the coronary band, sensitivity to hoof tester pressure over the sole, Obel grade >1

aPTT, Activated partial thromboplastin time; *GGT*, γ-glutamyltransferase; *IV*, intravenous; *SIRS*, systemic inflammatory response syndrome.

32.50 MOLECULAR BASIS FOR ENDOTOXEMIA AND SEPSIS

32.50.1 Endotoxin Enters the Circulation

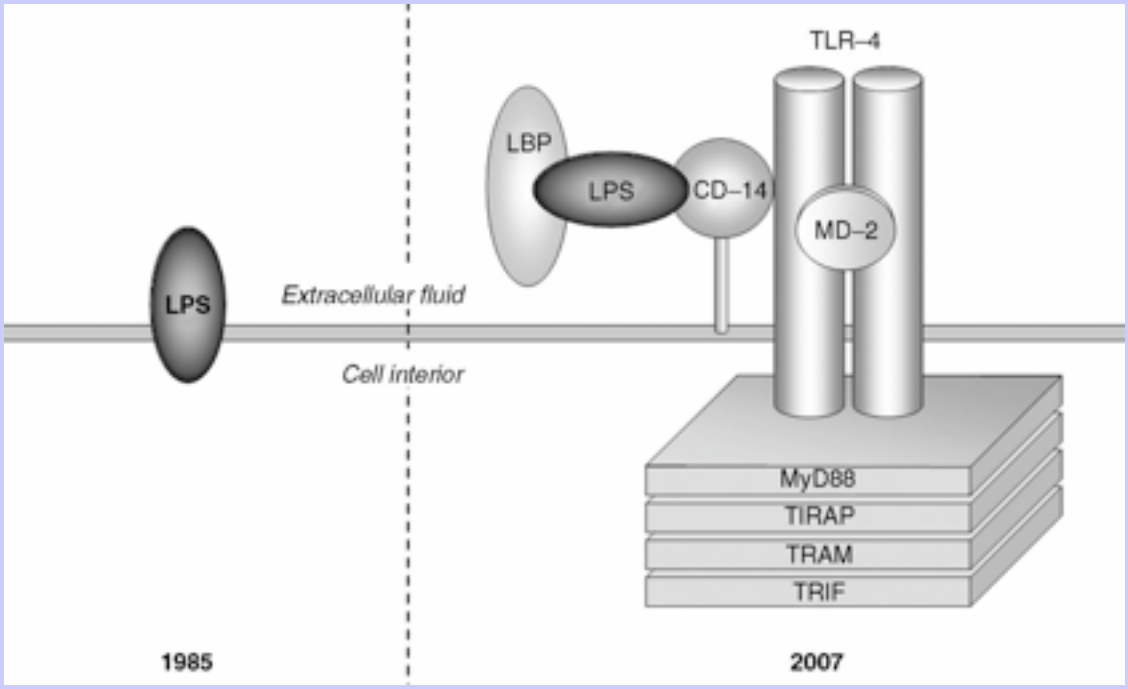
Although endotoxin is ubiquitous in the environment, both free and as a component of gram-negative bacteria, it normally is excluded from the body by the skin and mucous membranes. If the protective integument or mucosae are subjected to gram-negative bacterial infection or otherwise damaged, endotoxin may reach the blood in sufficient amount (<1 μg of purified LPS in experimental situations) to cause clinical signs. Gram-negative bacterial enterocolitis (e.g., salmonellosis), metritis, pleuropneumonia, wound infection, and neonatal septicemia are common examples. Because gram amounts of free endotoxin normally are safely sequestered within the intestine of the adult horse, damage to the gut wall as a result of local (e.g., intestinal volvulus, infarction, incarceration) or systemic (e.g., hypovolemic shock) causes of tissue hypoxia, inflammation (e.g., DPJ or

clostridial enteritis), mechanical trauma (e.g., rectal perforation, prolonged exercise), or intraluminal acidification (e.g., grain overload) is particularly likely to result in endotoxemia. In highly contaminated environments, potentially harmful amounts of endotoxin can be introduced into the lungs via inhalation.[326] Endotoxin may even be delivered directly into the blood via parenteral solutions (e.g., homemade intravenous fluids).

32.50.2 Endotoxin Interacts with Pattern Recognition Receptors

In 1985 almost nothing was known about the way in which LPS molecules interacted with cells of the immune system. In fact, endotoxin was widely believed to enter cells not via engagement of cell-surface receptors but by hydrophobic insertion into the membrane (Fig. 32-42). Since then, sequential discoveries of a plasma LPS-binding protein (LBP; 1989 for humans,[327] 2005 for horses[328]), CD14 (1990 for humans,[329] 2003 for horses[330]), and TLRs (1998 for humans,[331] 2005 for horses[332]) have elucidated the molecular processes of endotoxin binding and signaling (see Fig. 32-42). LPS first interacts with LBP, a normal plasma acute-phase protein; this interaction facilitates binding to the soluble or cell-associated co-receptor CD14. The LPS/LBP/CD14 complex recruits and activates TLR4 dimer and an accessory component MD-2 in preparation for LPS signaling. On ligation of the receptor, the conserved intracellular domain of TLR4 (Toll-IL-1 receptor [TIR]) initiates multiple downstream pathways that culminate in translocation to the nucleus of inducible transcription factors including nuclear factor (NF)–κB and activator protein 1 (AP-1).[333] NF-κB binds to consensus sequences on the promoter or enhancer regions of an array of genes whose products are involved in the inflammatory response.[333] It has recently been argued that the global activation of TLR4 typical of sepsis requires the actions of endogenous agonists (e.g., proteases).[335] Endotoxin also may activate NF-κB via TLR4-independent interactions with β_2-integrins, heat-shock proteins, and the intracellular Nod-1 receptor.[336] Although endotoxin binds predominantly to TLR4, a still-growing family of TLRs (12 in rodents, 11 in humans, unknown in horses) is available to bind to other DAMPs (Table 32-5).[336] During sepsis, this diversity of TLRs allows redundant signaling of inflammatory cells. For example, non-LPS components of gram-negative bacteria may bind other TLRs (e.g., lamellin binds to TLR5, lipoprotein and peptidoglycan to TLR2), whereas PAMPs from gram-positive bacteria or fungi bind different TLRs in the course of polymicrobial sepsis. Tissues subject to attack by mediators produced after the initial round of TLR binding can feed back and amplify the inflammatory response by releasing alarmins (e.g., high-mobility group box 1 [HMGB1][338]), which in turn can bind to TLR or other PRRs.

Fig. 32-42 Binding of lipopolysaccharide (LPS) to mammalian cell membranes. In 1985 it was widely believed that LPS initiated cellular signaling by hydrophobic interactions with the plasma membrane. By 2007 the components of the signaling complex were more fully understood. In addition to the extracellular receptor components (discussed in the text), the intracellular Toll-IL-1 receptor (TIR) domain is shown interacting with four adaptor molecules (MyD88, TIRAP, TRAM, TRIF) to initiate a molecular signaling cascade that ultimately leads to gene activation.



Simultaneous with cellular activation, endotoxin interacts with soluble PRRs normally present in plasma. Of particular importance, endotoxin binds to complement proteins to initiate the lectin-dependent and alternative pathways of complement activation and activates coagulation factor XII (Hageman factor) to set off the "contact" system of coagulation.

Table 32-5 Ligands for Human Toll-like Receptors[316,317]

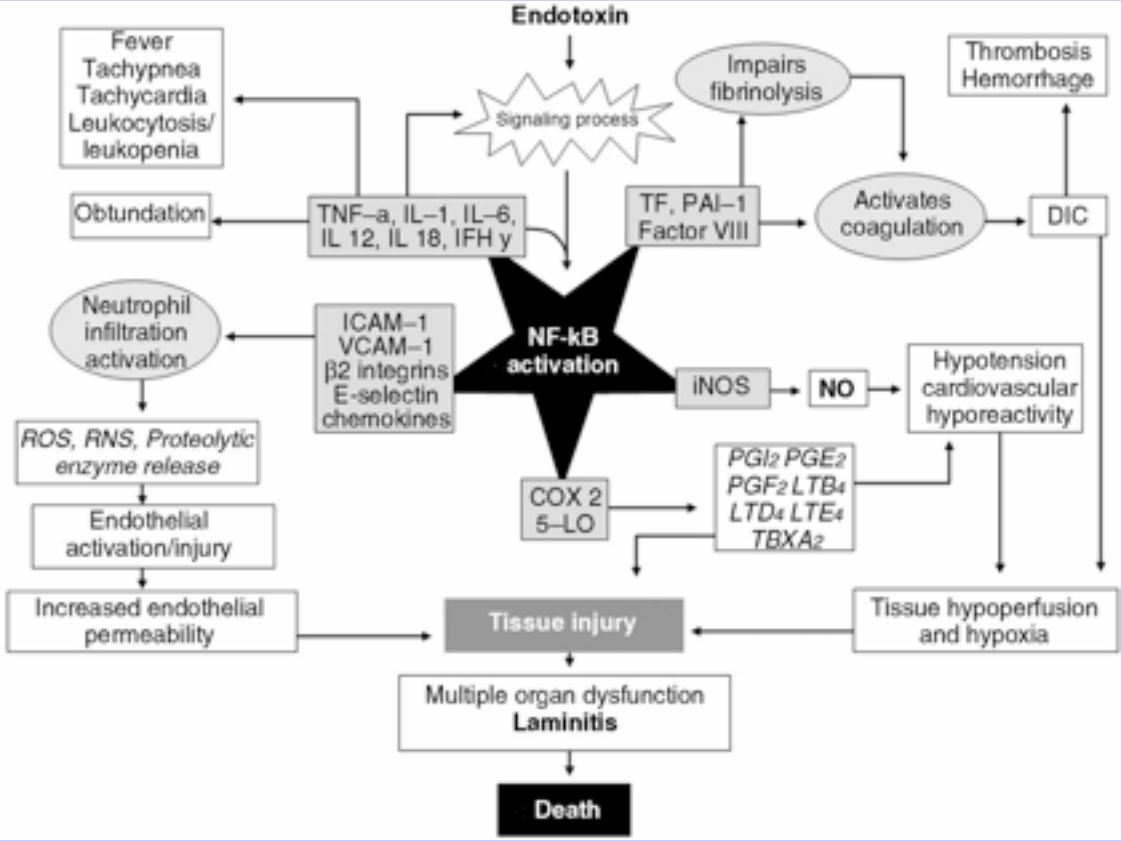
TLR1	Triacyl lipopeptides
TLR2	Lipoprotein
	Peptidoglycan (gram-positive bacteria)
	Lipoteichoic acid (gram-positive bacteria)
	Zymosan (yeast)
Lipoarabinomannan (mycobacteria)	
TLR3	Viral double-stranded RNA
TLR4	LPS
	Respiratory syncytial virus fusion protein
	HSP70
TLR5	Flagellin (*Salmonella* Typhimurium)
TLR6	Diacyl lipopeptides
	Zymosan
TLR7/8	Viral single-stranded RNA
TLR9	Unmyethylated CpG-containing DNA
	Herpes virus DNA
TLR10	Not determined
TR11	Uropathogenic bacteria

LPS, Lipopolysaccharide; *TLR*, Toll-like receptor.

32.50.3 Mediators are Released

As described earlier, endotoxin engages TLR4 on cells of the innate and adaptive immune systems, especially mononuclear phagocytes (monocytes and macrophages), neutrophils, endothelial cells, and dendritic cells. Pulmonary intravascular macrophages[339] and Kupffer cells likely are the most important mononuclear phagocytes in this regard. Endotoxin causes NF-κB activation in these and many other cell types via multiple signaling pathways resulting in the expression of more than 200 genes, many of which are involved in the pathogenesis of sepsis.[333] These include genes for proinflammatory cytokines (e.g., TNF, IL-1β, IL-6, IL-8, IL-12, IL-18), chemokines (e.g., IL-8, MIP), type 1 IFNs, procoagulants, adhesion molecules, immunoreceptors (e.g., TNF receptors), enzymes (e.g., elastase), and acute-phase proteins (e.g., fibrinogen).[341] NF-κB activity is further amplified by the paracrine actions of these proinflammatory cytokines, and by other DAMPs, cellular hypoxia, cellular necrosis, and chemical stress (including oxidant stress). Two of the cytokines secreted by macrophages, IL-12 and IL-18, stimulate IFN-γ synthesis and secretion from NK (natural killer) and other cells.[342] Because IFN-γ is a potent stimulator of both innate and acquired immune responses, it is considered to be a principal link between the two systems.

Fig. 32-43 Nuclear factor—κB signaling plays a central role in the pathophysiology of septic shock. *ICAM-1*, Intercellular adhesion molecule 1; *5-LO*, 5 lipoxygenase; *PAI-1*, plasminogen activator inhibitor 1; *TF*, tissue factor; *VCAM-1*, vascular cell adhesion molecule 1. Other abbreviations are explained in the text. Modified from Fig. 3 of reference333.



Endotoxin activates coagulation factor XII (Hageman factor) leading both to liberation of bradykinin and to initiation of intravascular coagulation. Even more important, complement is activated by alternative, lectin-mediated, and classical pathways to yield numerous active peptide products.

32.51 THE EARLY (HOT) PHASE OF SEPSIS

The early (hot) phase of sepsis is characterized by inflammation, coagulation, and necrosis. The principal NF-κB events during early sepsis are summarized in Fig. 32-43. This phase has been described as a "cytokine storm," during which there is flooding of inflammatory, procoagulant, and vasoactive mediators throughout the body. The net effects of these mediators are to promote microvascular injury and hypotension. The singular contributions of

many mediators to sepsis is demonstrated by experiments using sepsis models in which blocking or deleting a single mediator has had a positive effect on outcome.

32.52 THE LATE (COLD) PHASE OF SEPSIS

715

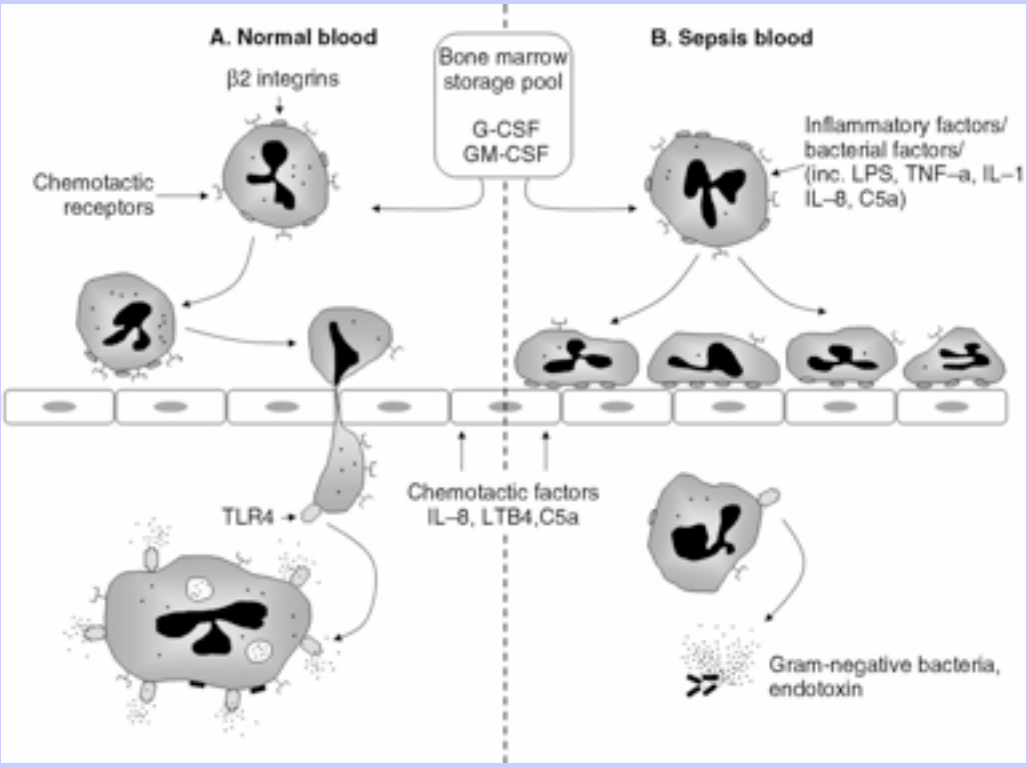
It recently has become apparent that many patients with sepsis are profoundly immunosuppressed as shown by lymphopenia, anergy, and susceptibility to opportunistic infections (e.g., pulmonary aspergillosis in horses with enteric salmonellosis).[343,344] This immunosuppression has been explained by the reactive production of antiinflammatory mediators in response to the cytokine storm and termed the *compensatory antiinflammatory response syndrome* (CARS).[345] Although many such mediators are produced and actually can have favorable antiinflammatory effects when used as therapy in models of sepsis, it is now clear that widespread apoptotic death of lymphocytes (particularly B-cells and CD4-positive T-helper cells) and dendritic cells secondary to activation of intracellular caspases is largely responsible for sepsis-associated immunosuppression.[346,347] During experimental endotoxemia in cats, there also is apoptosis of intestinal epithelial cells,[348] raising the possibility that apoptotic processes may affect intestinal permeability in endotoxemic horses. It is interesting to note that macrophages and neutrophils are spared premature apoptotic death; neutrophils actually are prevented from physiologic apoptosis during sepsis and remain viable in sequestered sites.[349] The relationship between the two "phases" of sepsis is not clear, and it cannot necessarily be inferred that hot and cold phases occur in the same patient.

716

32.53 THE EFFECTS OF ENDOTOXEMIA AND SEPSIS

During sepsis, large numbers of neutrophils accumulate on the endothelial surfaces of organs undergoing failure, and insult to one organ can trigger the widespread recruitment and sequestration of neutrophils in others. Such a scenario likely underlies the association of laminitis with severe intestinal disease.[350,351]

Fig. 32-44 Recruitment and activation of neutrophils to bacterial infection in healthy horses and septic or endotoxemic horses. In response to bacterial infection, cytokines are generated that induce the release of neutrophils from the bone marrow. In the normal state, large numbers of blood neutrophils enter sites of bacterial infection by first adhering to the activated endothelium of local postcapillary venules before migrating up a concentration gradient of chemotactic factors. Endotoxin is bound to TLR4, and bacteria are eliminated by phagocytosis. In patients with endotoxemia or sepsis, high levels of circulating inflammatory factors promote upregulation of surface integrins to promote firm endothelial adhesion to postcapillary venules. However, some of these factors also downregulate the expression of chemotactic receptors. Consequently, neutrophils are strongly bound but less responsive to underlying chemotactic factors. *G-CSF*, Granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony-stimulating factor. Modified from Fig. 2 in reference 349.



In response to PAMPs (including LPS), inflammatory cytokines produced by macrophages and other cells, and complement peptides, endothelial cells, and neutrophils express selectins.[349] Selectins on endothelial cells (E and P) and neutrophils (L) reciprocally engage glycoprotein ligands to "tether" the neutrophil to the endothelial surface. A series of these transient interactions between ligands and receptors allows neutrophils to roll along the endothelial surface (Fig. 32-44). Neutrophil capture is most efficient in areas of low shear force such as the walls of postcapillary venules and in pulmonary capillaries. During rolling, neutrophils are activated or "triggered" by selectins, chemokines, and PAF expressed on endothelial cells. The firm attachment or arrest step of the cascade is mediated by the avid interaction of neutrophil integrins with adhesion molecules of the immunoglobulin superfamily expressed on endothelial cells. During firm attachment the activated neutrophil spreads out and, in the healthy animal, squeezes between the intercellular junctions of adjacent endothelial cells and migrates into tissues up a gradient of chemotactic factors such as microbial chemotaxins, LTB_4, IL-8, or C5a. By contrast, when compared with normal neutrophils, those found in septic animals have defective chemotactic responses but bind with greater avidity to the endothelium and to other neutrophils. When cultured, macrophages and neutrophils from patients with gram-negative sepsis are hyporesponsive to LPS, suggesting a functional switch to LPS tolerance during the early stages of endotoxemia (see Fig. 32-44).[352] Sequestration of neutrophils on activated endothelium and in neutrophil aggregates accounts for the neutropenia found in most horses with endotoxemia. It is interesting to note that the lifespan of these sequestered neutrophils is prolonged during sepsis because normal apoptosis is prevented.[349]

716

717

Tightly adherent neutrophil-endothelial conjugates formed during sepsis seal off microscopic pockets between the juxtaposed cells into which cellular products can be concentrated. Of particular significance are the reactive oxygen species (ROS) produced as a result of the activation of NAD(P)H-oxidase in neutrophils (respiratory burst) and xanthine oxidase in endothelial cells.[354] Digital laminae of horses may be particularly vulnerable to the effects of ROSs because of low content of the endogenous oxidant scavenger superoxide dismutase.[355] In the presence of neutrophil granule myeloperoxidase and H_2O_2, highly toxic hypochlorous acid is formed on the endothelial surface.[356] Superoxide anion generated as part of the neutrophil respiratory burst reacts with nitric oxide (NO) from endothelial cells to yield reactive peroxynitrite radicals. Other potentially corrosive substances are contributed by neutrophil granules and include elastase, serine proteases, matrix metalloproteinases (MMPs), and defensins.[357] In addition to direct damage caused by membrane lipid peroxidation, ROSs indirectly stimulate the expression of multiple inflammatory, procoagulant, and vasoactive mediators via activation of NF-κB in both neutrophils and endothelial cells. Mediators such as bradykinin, PAF, C3a, C5a, and leukotriene B_4 (LTB_4) directly increase vascular permeability by promoting active retraction of endothelial cells via phosphorylation of the light chain of nonmuscle myosin.[358] Vascular leak facilitates the movement of potentially harmful substances into tissues.

In health the antithrombotic phenotype of endothelial cells is maintained by the presence of low amounts of prostacyclin (prostaglandin I_2 [PGI_2]) and NO, and surface expression of thrombomodulin, protein S, and protein C complex and TPA.[359] During endotoxemia, endothelium supports extrinsic pathway activation because of leukocyte-induced physical damage, expression of the procoagulant tissue factor,[360] downregulation of antithrombin-III and protein C, and inhibition of fibrinolysis through expression of plasminogen activator inhibitor 1 (PAI-1).[361,362] Additional procoagulant effect may be provided by deposition on the endothelial surface of all of the components of the intravascular coagulation system. Microvascular perfusion is further compromised by sepsis-associated increase in "stiffness" of both RBCs and WBCs.[363] Such cells are unable to deform and squeeze through narrow capillaries.

The effect of endotoxemia on vascular tone depends on the stage and severity of disease and the particular organ (vascular bed) considered. Neuroendocrine responses to sepsis lead to the upregulation of predominantly pressor mediators including arginine vasopressin, angiotensin II, serotonin, epinephrine, and norepinephrine. Inflammatory mediators are a mix of vasoconstrictors (thromboxane A_2 [TXA_2], endothelin, C3a, C4a, C5a) and vasodilators (PGE_2, PGI_2, adenosine, bradykinin, NO). In animals with serious sepsis, balances of constricting and dilating influences unique to each vascular bed, loss of vasoregulatory tone, and refractoriness of damaged endothelium to vasoactive substances causes maldistribution of blood flow among organs and systemic hypotension.

Because of poor perfusion pressure, direct microvascular injury, thrombosis, and loss of endothelial integrity (capillary leak), ischemia and hypoxia of organs and tissues occur.[364]

32.54 DEVELOPMENT OF GLOBAL TISSUE HYPOXIA

The fundamental event in serious sepsis is the development of global tissue hypoxia. During serious sepsis, widespread microvascular and mitochondrial injury[365] decrease oxygen delivery and consumption at the cell, tissue, and organ levels. Oxygen delivery to tissues is a product of cardiac output and oxygen content (which itself is a product of hemoglobin oxygen saturation and hemoglobin concentration). The product of systemic oxygen delivery and the percentage of oxygen extracted (normally ≤25%) by the tissues is the systemic oxygen consumption. The balance between systemic oxygen delivery and consumption is reflected by the mixed venous hemoglobin oxygen saturation (SVO_2). SVO_2 has been shown in other species to be a useful surrogate for cardiac index as a target for goal-directed therapy.[366] Central venous oxygen saturation ($ScVO_2$), obtained through a central venous line, is a reasonable substitute for SVO_2 (which must be measured via a Swan-Ganz catheter). Global tissue hypoxia results when systemic oxygen delivery fails to meet the oxygen requirements of tissues.

Global tissue hypoxia resulting from cardiovascular insufficiency is the sine qua non of serious sepsis. Various hemodynamic combinations may create a systemic imbalance between tissue oxygen supply and demand[367]:

- *Hypovolemia*. Because of decreased preload caused by hypovolemia, concomitant left ventricular dysfunction, and reflex systemic arterial vasoconstriction, early endotoxemia is often characterized by low cardiac output (i.e., hypodynamic circulatory insufficiency).
- *Compensated but maldistributed perfusion*. After fluid-electrolyte resuscitation, compensatory mechanisms and low afterload drive transition to a hyperdynamic state. Even with normal or increased cardiac output, perfusion abnormalities may persist owing to regional hypoperfusion associated with derangements in blood flow distribution and loss of vasoregulatory control to vascular beds. This state is often described as *distributive shock*.
- *Myocardial depression* secondary to effects of inflammatory mediators and apoptosis of cardiomyocytes is the primary cause of low cardiac output in 15% of human patients with serious sepsis or septic shock.[368]
- *Increased metabolic demands*. SIRS increases metabolic demands, as evidenced by increased splanchnic and total body oxygen consumption.
- *Impaired oxygen utilization*. The bioenergetics of cellular extraction and use or respiration may be abnormal at least partially because of mitochondrial dysfunction.[365,369]

These derangements may occur independently of measured hemodynamic parameters. The theoretic components of each of these hemodynamic states are shown in Table 32-6.

32.55 SIGNS OF ENDOTOXEMIA

32.55.1 Clinical Signs

The clinical signs of horses given intravenous endotoxin experimentally may range from fever without obvious malaise to multiple organ failure and death. Obviously, signs that are not due exclusively to endotoxin (e.g., severe pain caused by intestinal strangulation or diarrhea in horses with *Salmonella* colitis) may greatly influence the overall clinical presentation of horses with naturally acquired endotoxemia.

Typically in an adult horse given a moderate sublethal dose of endotoxin (e.g., 0.1 to 1 μg of LPS per kilogram of body weight), an early period of mild tachypnea peaks within 30 minutes and resolves within 2 hours. During this period, mucous membranes are pale. Beginning within 90 minutes of LPS injection, depression, restlessness, and inappetence are present and rectal temperature begins to rise. Auscultable intestinal sounds usually cease during this period and remain depressed for several hours. Intermittent signs of colic usually are seen, including recumbency (usually without rolling). Small amounts of loose feces usually are passed. Heart rate peaks during the stage of maximal abdominal discomfort (approximately 2 hours after administration of endotoxin), then temporarily declines. During this time, mucous membranes become congested, the capillary refill time is prolonged, and a dark “toxic” line may become apparent around the gingival margins of the teeth. Beginning at 4 to 6 hours after endotoxin administration, there is a secondary phase of tachycardia and tachypnea that likely is related to development of systemic hypotension and fever. This secondary phase persists for several hours. Horses presented clinically with mild to moderate endotoxemia usually resemble experimental animals during the period 2 to 6 hours after intravenous endotoxin administration.

Table 32-6 Effect of Hemodynamic State on Parameters of Cardiovascular Function

Pathologic State	MAP	CVP	$ScVo_2$	Lactate	CO	SVR
Hypovolemia	Variable	↓	↓	↑	↓	↑
Compensated but maldistributed	Normal to ↑	Normal	↑	Normal to ↑	↑	↓
Myocardial depression	Variable	↑	↓	↑	Normal to ↓	Normal to ↑
Increased metabolic demand	Variable	Normal	↓	Normal to ↑	Variable	Variable
Impaired O_2 usage	Variable	Normal	↑	↑	Variable	Variable

Adapted from Fig. 32-41 of reference 367.

CVP, Central venous pressure; *CO*, cardiac output; *MAP*, mean arterial pressure; *$ScVo_2$*, central venous oxygen saturation; *SVR*, systemic vascular resistance.

At higher LPS doses (e.g., 100 µg/kg) in experimental animals or in patients with severe endotoxemia, signs of circulatory failure and disordered hemostasis dominate the clinical picture. Usually these horses are stuporous and totally anorectic. Signs of dehydration such as reduced skin turgor, dry mucous membranes, and sunken eyes are obvious. As systemic blood flow becomes more compromised, rectal temperature may drop into or below the normal range. Urine output is reduced or nonexistent. There are dark, congested mucous membranes, rapid and weak peripheral pulses, cold extremities, and sweating, and the horse may have muscle tremors and become recumbent.

Vascular damage may be seen as petechial and ecchymotic hemorrhages on mucous membranes. A poor prognostic sign is the development of a hypercoagulation syndrome, during which routine venipuncture or catheter placement initiates thrombosis along the entire visible length of the jugular veins (or other superficial veins). If both jugular veins are thus occluded, there usually is massive swelling of the soft tissues of the head, and associated laryngeal edema may cause signs of upper respiratory tract obstruction. In some horses, thrombosed superficial vessels can easily be palpated through the skin of the legs and abdomen. Infarction of bowel segments or lungs may cause severe clinical signs that are unresponsive to treatment. A rare syndrome of thrombosis of major limb arteries found in young foals is likely a result of sepsis syndrome.[370,371] At the time that hypercoagulation syndrome is recognized clinically, there is often evidence of a secondary bleeding tendency (a consequence of platelet and clotting factor depletion and uncontrolled activation of fibrinolysis), seen as prolonged hemorrhage from venipuncture sites and widespread mucosal petechiation. In cases with a severe pulmonary component, there may be hemorrhage into the respiratory tract with progressive tachypnea and dyspnea.

If moderately to severely affected animals survive for more than 24 hours, there usually is visible edema of the ventral abdomen and limbs. Signs of laminitis may first become apparent at this stage and may progress in severity even while the other systemic signs of endotoxemia improve.

32.55.2 Clinicopathologic Signs

Although the measured concentration of endotoxin in blood does not correlate well with severity of clinical signs, demonstration of circulating endotoxin obviously is definitive proof of endotoxemia. In one study, 12% of horses with acute gastrointestinal disease had detectable plasma endotoxin.[372] Reported concentrations in these horses were 0 to 30,400 pg/mL with a mean of 218 pg/mL. Experimentally, plasma endotoxin usually is assayed by some variant of the *Limulus* amebocyte lysate assay. A simple horse-side test for endotoxin that was marketed for use in clinical practice is no longer commercially available.

There is early and profound leukopenia principally caused by neutropenia (usually accompanied by left shift and a toxic appearance of stained cells). Lymphopenia (<1000/μL) is found in the most severe cases and likely reflects sepsis-induced apoptosis and immunosuppression. Adult horses often are hyperglycemic at presentation, whereas neonates with sepsis are usually hypoglycemic. Other abnormalities are nonspecific and reflect altered tissue perfusion and organ dysfunction (see Table 32-4).

In moderate and severe cases of endotoxemia, there also may be evidence of disordered hemostasis; values affected in blood may include any to all of the following: reduction in the circulating platelet count (<100,000/μL), reduction in plasma fibrinogen concentration, prolongation of the activated partial thromboplastin, prothrombin, or thrombin time, increased activity of PAI-1, and increased concentration of fibrin degradation products. In horses with acute gastrointestinal diseases, there also is increased activity in peritoneal fluid of many of the elements of the fibrinolytic system, including TPA. Depletion of key clotting factors can most simply be detected as prolongation of plasma recalcification time.[373]

32.56 NO “SILVER BULLET”

There is no “silver bullet” for treatment of endotoxemia. It has to be admitted that, almost without exception, potentially novel treatments for gram-negative sepsis that have been promising at the experimental level have failed when applied in clinical settings in human beings (and to a limited extent horses). A short list of such trials includes anti-TNF-α,[374] IL-1-receptor antagonist,[375] ibuprofen,[376] PAF antagonist,[377] elastase inhibitor,[378] nitric oxide synthase (NOS) inhibitor,[379] antithrombin III (AT-III),[380] and tissue factor pathway inhibitor.[381] It is clear that most experimental sepsis models do not replicate naturally occurring sepsis, at least as it occurs in humans. Several of many likely explanations for the disparity between the results of experimental models and large clinical studies are (1) heterogeneity of presentations among enrollees in clinical studies; (2) diversity in genetic susceptibility to sepsis among outbred populations; (3) differences between experimental and clinical study species; (4) differences in timing of potential treatments relative to the onset of sepsis between the two study populations; (5) preponderance of cold sepsis and immunosuppression states in naturally occurring sepsis compared with the “cytokine storm” usually recreated in experimental models.

718

719

Even among sepsis models, results for the same candidate treatment are often inconsistent. For example, neutralization and inhibition of inflammatory cytokines usually have salutary effects in LPS-infusion experiments; however, equivalent studies involving the cecal ligation-puncture model in mice (widely considered to be one of the best sepsis models) usually have shown either neutral or negative effects on mortality.[382]

It is sobering to review the most pertinent available data for the three antiendotoxic drugs that are most commonly used to treat horses with suspected endotoxemia—namely, flunixin meglumine, polymyxin B, and pentoxifylline. Although various NSAIDs have been shown to effectively prevent the signs of LPS infusion in horses,[383–392] there is no convincing study that shows NSAIDs actually save lives in patients with naturally occurring sepsis. In contrast, a large multicentered, controlled, masked, prospective study of ibuprofen in humans with sepsis syndrome showed no effect of this drug on the development of shock or the acute respiratory distress syndrome and did not improve survival.[393] Polymyxin B and the nontoxic polymyxin B-dextran 70 conjugate PMX622 also safely prevented signs of endotoxemia when given before LPS to otherwise healthy horses[394–399]; however, the drug has not advanced beyond Phase 1 trials in human patients because experimental studies showed that it did not protect mice if given after intraperitoneal endotoxin.[400] Finally, intravenous pentoxifylline significantly, albeit only partially, reduced adverse signs in horses given LPS.[401] The usefulness of this finding is called into question by the observation that the lethality-sparing effect of pentoxifylline in endotoxemic mice was removed if the drug was given in combination with indomethacin, a potent NSAID.[402,403] It was concluded that upregulation of prostacyclin production by pentoxifylline, which was prevented by concurrent indomethacin, reduced mortality in subject mice by preventing endotoxin-induced leukopenia. It is interesting to note that pentoxifylline alone increased WBC counts in horses. This effect was prevented by flunixin[401,405]; thus, a potential beneficial effect of pentoxifylline in endotoxemic horses may be neutralized by concurrent NSAID administration.

Evidence-based medicine so far acknowledges only one agent, drotrecogin alfa (activated protein C),[406] as able to reduce mortality in patients with sepsis, although there has been some recent controversy regarding the side effects of the drug and the analyses performed in the original study.[407,408] Despite theoretic potential in some patients with endotoxemia, drotrecogin is much too expensive to be considered for equine use.

Fortunately, there is powerful evidence to support the value of early aggressive cardiovascular resuscitation. Use of oxygen, fluids, pressors, inotropes, and packed RBCs during the first 6 hours after admission to achieve a sequence of physiologic goals reduced in-hospital mortality of human patients with serious sepsis from 46.5% in the group that received standard therapy to 30.5% in patients given early goal-directed therapy (EGDT).[409] Similar protocols now are widely used in emergency rooms throughout the United States.[367] Many of the underlying principles of EGDT can be applied to resuscitation of septic horses, especially neonates (see later). It is reasonable to conclude that improvements in cardiovascular support of horses with sepsis will continue to be of much more value than any single “magic bullet” currently available or even on the horizon.

32.57 ASSESSMENT OF THE STAGE OF ENDOTOXEMIA OR SEPSIS

Horses with endotoxemia should be staged according to the criteria found in Fig. 32-41 andTable 32-4. It is especially important to recognize that horses with serious sepsis need aggressive intervention in order to survive.

32.58 TREATMENT OF ENDOTOXEMIA AND SEPSIS

A prioritized strategy for management of horses with endotoxemia is as follows: (1) cardiovascular resuscitation; (2) laminitis prevention; (3) removal of the cause(s) of endotoxemia; (4) neutralization of circulating endotoxin; and (5) inhibition of endotoxin-induced inflammation. These approaches are most applicable to horses with serious endotoxemia or sepsis.

32.58.1

Cardiovascular Resuscitation

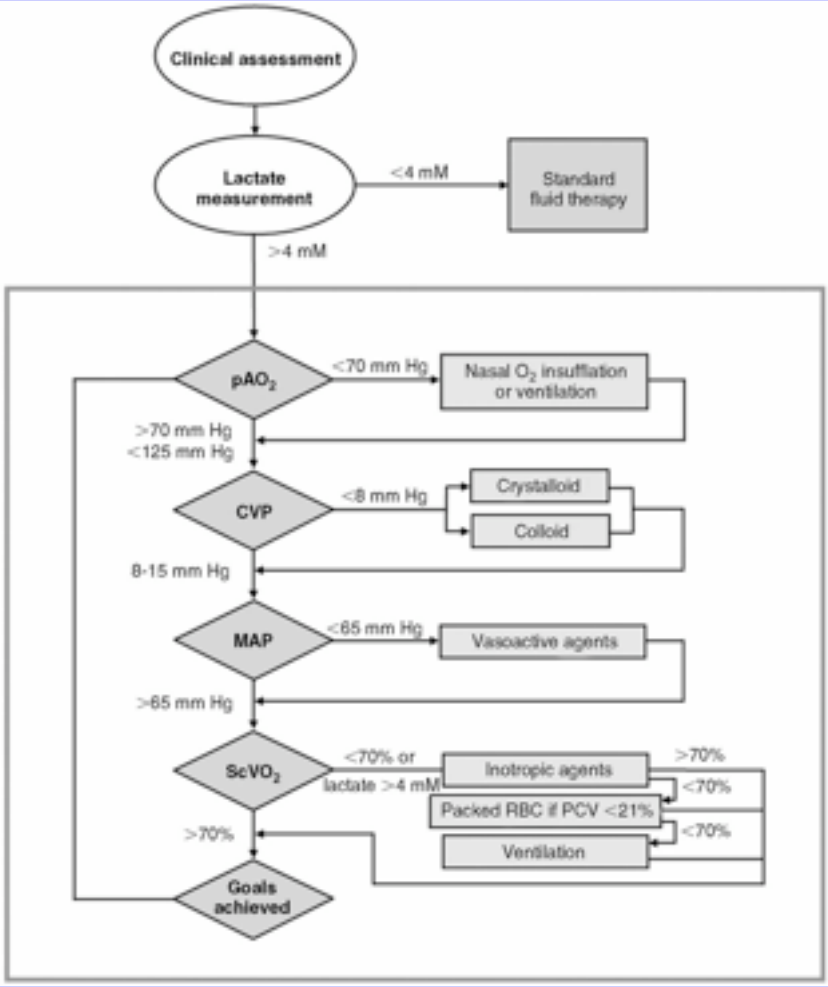
Expansion of blood volume remains the cornerstone of treatment for horses with serious sepsis or endotoxemia. Most cases (e.g., adults with blood lactate of 2 to 4 mmoles/L) can be treated successfully with intravenous balanced polyionic solution according to guidelines for estimating water deficits provided in the fluid therapy section of this chapter. Urination should begin during the rapid replacement of estimated losses. Ideally the fine control of fluid replacement should be based on serial measurements of packed cell volume (PCV) or plasma protein concentration and further guided by following blood lactate concentration. Some clinicians prefer the early use of compatible plasma (5 L for a 450-kg horse, 1 to 2 L for a neonate) or other colloid solutions such as 6% hydroxyethyl starch solution (6% hetastarch in 0.9% saline; Abbott Laboratories, North Chicago, IL) to replace the extravasated colloid lost as a result of capillary leak. Plasma has the advantage of providing immunoglobulin, acute-phase proteins, and anticoagulants (see Laminitis Prevention).

In horses with the most life-threatening forms of endotoxemia and sepsis (lactate >4 mmoles/L [>5 mmoles/L in neonates <24 hours old], MODS/L, septic shock), aggressive hemodynamic monitoring and EGDT are indicated. Because such treatment still carries at best a guarded prognosis for survival, financial commitment often in the range or $5000 to $20,000, and transfer to a referral center, a decision to continue treatment requires that a very clear and realistic discussion of these issues take place with the horse's owner. Early intervention is essential in sepsis therapy, in critical care parlance, terms such as the “golden 6 hours” and the “silver 24 hours” exemplify this concept.[410]

Relatively simple equipment and supplies but time-intensive monitoring and treatment are needed for effective EGDT. A central venous catheter (e.g., for 50-kg neonates, two-lumen indwelling catheter, 7 Fr × 30 cm [ES-14702], Arrow International, Reading, PA; 500-kg adults, two-lumen Hickman 9 Fr × 90 cm, Bard Access Systems, Salt Lake City, UT), a blood gas and lactate analyzer, an indirect arterial blood pressure monitor, and a central venous blood pressure monitor (transducer and data display and recorder or water monometer) are required for the full EGDT bundle; however, much can be achieved with a jugular catheter, water manometer, and lactate analyzer. The details of an intensive approach to EGDT for the first 6 hours after admission are shown in Fig. 32-45. $ScVO_2$ has been shown to correlate well in this context with cardiac index. Unfortunately, although measurements obtained via a typical jugular intravenous catheter can be used to approximate arterial lactate concentration and CVP in humans[412,413] (although not in dogs and cats[414]), jugular blood SO_2 did not correlate with central measurements in endotoxemic pigs[415] and probably should not be used for that purpose. Although labor-intensive, none of monitoring techniques is technically difficult. One advantage of being able to measure both lactate and $ScVO_2$ is that inferences can be made as to the particular hemodynamic derangement responsible for signs of global tissue hypoxia (see Table 32-6).

719 720

Fig. 32-45 Protocol for early goal-directed therapy. An initial 20 mL/kg bolus of isotonic crystalloid (or equivalent colloid) is given, followed by boluses of 10 mL/kg every 30 minutes until CVP reaches 8 to 15 mm Hg. If the heart-base adjusted MAP is still less than 65 mm Hg, vasopressors are given to effect. Norepinephrine, dopamine, or vasopressin can be used according to the clinician's preference. If the $ScVO_2$ is still less than 70%, dobutamine continuous rate infusion can be increased in increments up to 15 µg/mL. If the PCV is less than 21% after the preceding steps and $ScVO_2$ is less than 70%, packed cells should be given to increase oxygen-carrying capacity. *CVP*, Central venous pressure; *MAP*, mean arterial pressure; *PCV*, packed cell volume.



When the goals of EGDT are met, fluid management should continue according to standard protocols (see Fluid Therapy section) but with adjustments made according to the results of continued monitoring (Pa_{O_2}, Cv_{O_2}, lactate, CVP, mean arterial pressure [MAP]). If the blood bicarbonate concentration is <16 mmol/L after EGDT goals are met (or plasma total CO_2 concentration is <17 mmol/L), sodium bicarbonate should be given IV to replace calculated deficits. During correction of acidemia, intravenous fluids should be supplemented with potassium (10 to 20 mmol/L) to prevent correction-induced hypokalemia. A maintenance-rate infusion of glucose should be given to neonates with sepsis (4 mL of 5% dextrose—containing fluids per kilogram per hour) and hypoglycemic adults (2 mL of 5% or 0.2 mL of 50% dextrose per kilogram per hour). Glucose concentration should be regularly monitored, and the use of concurrent insulin infusion should be considered, especially if blood glucose is normal or high (see Laminitis Prevention section).

720

721

32.58.1.1

Box 32-3 Laminitis Prevention Bundle

Fluid resuscitation

Cryotherapy[479]

Flunixin (0.25 mg/kg every 8 hours)

Pentoxifylline (10 mg/kg PO bid)

Plasma (10 mL/kg)/heparin (4 U/mL plasma)

Insulin (0.01-0.05 U/kg/h)/glucose (0.2 mL 50% dextrose per kilogram per hour) with 2- to 4-hourly measurement of blood glucose concentration

32.58.2

Laminitis Prevention

Adult horses with serious sepsis are at high risk for the development of laminitis. Among the clinical risk factors likely operative in the setting of sepsis are body condition score ≥ 5, being a pony, ≥24 hours since onset of signs of endotoxemia or sepsis, rectal temperature >101.5° F, CRT >2 seconds, or cold extremities. The digital laminae are injured early in the period of hot sepsis, perhaps irreversibly, by processes associated with cytokine storm and global tissue hypoxia. Insulin resistance, hyperglycemia, microvascular injury and thrombosis, and protease activation all may be involved in sepsis-associated laminitis. The laminitis prevention bundle provided in Box 32-3 provides a reasonable preventative strategy, but it must be implemented very early (preferably before increased digital pulses are detected). Global tissue hypoxia is addressed with standard or EGDT fluid resuscitation, small vessel plugging with flunixin (reduced TXA_2), pentoxifylline (vasodilation with PGI_2, suppression of inflammatory cytokines, increased RBC deformability), and plasma and heparin (increased active AT-III), and hyperglycemia and insulin resistance with continuous-rate infusions of regular insulin and glucose (prevention of the damaging effects of hyperglycemia; possible salutary, glucose-independent effects of insulin). If laminitis is already present, or if it develops during the course of treatment, it should be treated as described in Chapter 38.

32.58.3 Removal of the Cause(s) of Endotoxemia and Sepsis

Removal of the cause of endotoxemia usually involves both removal of the source of endotoxin and correction of the abnormality that allows access of endotoxin to blood. In some cases a source of endotoxin can be mechanically removed; for example, gram-negative bacteria and associated inflammatory effusion can be drained from pleural or peritoneal cavities or carefully siphoned from the postpartum uterus. Antimicrobial therapy for gram-negative infection also is essential. In general, broad-spectrum bactericidal drugs should be selected because endotoxemic horses may be immunosuppressed. In horses in which endotoxemia is associated with diarrhea or other signs of colitis or typhlitis, the use of antimicrobial drugs is controversial because of their causal association with severe colitis. They probably should be given only in the following situations: (1) the horse is <3 months old; (2) there is suspicion of clostridial or antimicrobial-associated enteritis (metronidazole or vancomycin); (3) there is degenerative left shift or total neutrophil or lymphocyte count of <1000 μg/mL; or (4) there is clinical evidence of dyshemostasis (e.g., jugular thrombosis or abnormal coagulogram). It should be noted that effective antimicrobial therapy could temporarily worsen clinical signs by causing the release of endotoxin from killed bacteria. This possibility should be anticipated and minimized by the timely use of NSAID or other antiendotoxic therapy (see following paragraphs).

When intestinal strangulation is the cause of endotoxemia, surgical correction obviously is of paramount importance. For the purposes of perioperative management, however, it should be noted that resumption of intestinal blood flow could worsen endotoxemia: sequestered endotoxin may be flushed into the circulation through compromised intestinal walls. At least in the case of small intestinal ischemia, the mucosal barrier to endotoxin may be further compromised by ischemia-reperfusion injury when full blood flow is restored by luminal decompression or other manipulation. Again, prophylactic use of NSAIDs and/or ROS scavengers may be warranted.

32.58.4 Neutralization of Circulating Endotoxin

32.58.4.1 HYPERIMMUNE PLASMA AND SERUM

An antiserum (Endoserum; Immvac Inc., Columbia, MO) and several hyperimmune plasmas (e.g., Polymune J; Veterinary Dynamics, Templeton, CA) produced by immunization of horses against R-mutant endotoxins are used in horses with suspected endotoxemia (in some cases, this is an off-label use). As is the case with studies in human beings and small experimental animals, use of cross-reactive endotoxin antibodies in horses with either experimentally or naturally acquired endotoxemia has yielded conflicting results. In several studies there was impressive reduction of mortality rate or improvement in clinical signs when antiendotoxin serum or plasma was given to horses[416–418]; however, in other studies no improvement was demonstrated.[419,420] Pretreatment of foals with antiserum was associated in one report with significant worsening of clinical response to IV administered endotoxin compared with foals that received no pretreatment.[421] These disparate results probably reflect, at least in part, variation in the quality of antisera and experimental conditions; therefore no blanket recommendation can be made as to the clinical use of such products. As evidence of the potential general value of hyperimmune plasmas, it is worth noting the reduction in mortality achieved when antiendotoxin plasma raised against the *E. coli* mutant J5 was given to bacteremic humans (39% for controls versus 22% for those give antiendotoxin plasma) in a masked, well-controlled study at a single hospital.[422] In contrast, subsequent large multicenter studies of two different antiendotoxin monoclonals failed to show beneficial effects.[423,424] Hyperimmune plasmas (raised against any antigen[s]) also contain colloid,

anticoagulant, and increased amounts of substances such as acute-phase proteins, which might have nonspecific beneficial effect in the setting of endotoxemia and sepsis. Therefore the use of 10 to 40 mL of hyperimmune plasma (of any specificity) per kilogram can be justified in treatment of serious endotoxemia or sepsis.

32.58.4.2 POLYMYXIN B

Polymyxin B is a broad-spectrum cyclic peptide antibiotic with potent endotoxin-binding activity. Potentially lethal side effects of respiratory paralysis and nephrotoxicity have precluded use of this agent as a systemic antimicrobial drug; however, polymyxin B retains endotoxin-neutralizing capacity at nontoxic dosages. Pretreatment of foals with polymyxin B at a dosage rate of 6000 U (1 mg)/kg significantly suppressed clinical and cytokine responses to intravenous endotoxin without causing toxic side effects.[425] Repeated administration to ponies of 15,000 U/kg also produced no sign of toxicity.[426] At dose of 5000 U/kg, polymyxin B protected even when given 30 minutes after the start of LPS infusion.[427] The results of a pharmacokinetic and pharmacodynamic study of polymyxin B in horses suggested that the drug could safely be given at 6000 U/kg every 8 hours to maintain continuous endotoxin neutralization.[428] Horses given polymyxin B at 5 mg/kg as a polymyxin B–dextran 70 conjugate (also known as *PMX622*) were fully protected from the effects of endotoxin but had a transient hypertensive response to treatment infusion.[429] This side effect was prevented by the use of an NSAID. In horses with moderate or severe endotoxemia, consideration should be given to the cautious use of polymyxin B (Polymyxin B sulfate; Bedford Laboratories, Bedford OH) given IV two or three times daily at a dosage rate of 6000 U/kg. Each treatment should be given over at least 15 minutes.

721

722

32.58.5 Inhibition of Endotoxin-Induced Inflammation

32.58.5.1 NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Through inhibition of cyclooxygenase (COX), NSAIDs reduce the formation of prostanoid metabolites (e.g., thromboxanes and prostaglandins) from arachidonic acid and thereby attenuate much of the adverse effect of endotoxin. As stated earlier, it has not yet been established whether or not NSAIDs actually reduce mortality in patients with sepsis. Flunixin meglumine, phenylbutazone, ketoprofen, eltenac, and aspirin are examples of this class of drugs used in horses. When flunixin is administered at 0.25 mg/kg every 6 to 8 hours, endotoxin-induced prostanoid production is prevented, and maximal antiendotoxic effects are produced in experimental situations without obscuring the signs of colic or risking toxic side effects of the drug.[430] It should be noted that flunixin does not reduce endotoxin-induced leukopenia. Because there is evidence that aspirin does not prevent endotoxin-induced aggregation of platelets,[431] there appears to be no rationale for the common practice of adding aspirin to the NSAID regimen. Most NSAIDs inhibit constitutive COX-1 activity (in addition to endotoxin-induced COX-2 activity), so there is some morbidity associated with their use. There may be gastric ulceration, right dorsal colitis, renal papillary necrosis, and possibly impairment of intestinal motility.[432,433] In light of this toxic potential of equine NSAID use, it has been suggested that use of COX-2 selective drugs may minimize side effects while maintaining efficacy. Two NSAIDs with documented analgesic effect in horses, carprofen and meloxicam, have been shown to be COX-2-selective.[434] Etodolac, a COX-2–specific drug in dogs and humans, is not COX-2 selective in horses when used at analgesic doses (23 mg/kg PO once or twice daily).[435] Also, COX-2 activity does have potentially beneficial effects in horses with

sepsis: COX-2 products (e.g., PGE_2, PGI_2) mediate epithelial restitution in damaged equine colon[436] and are thought to be important in maintaining the antithrombotic phenotype of normal endothelium. NSAIDs in the coxib class, which are potently COX-2 specific in humans, have been shown to increase the risk of atherosclerotic cardiovascular disease in humans.[437]

32.58.5.2 METHYL XANTHINE DERIVATIVES

Inflammatory cytokine production by macrophages is suppressed in dose-dependent fashion by methyl xanthine derivatives. This effect appears to be caused by phosphodiesterase inhibition and consequent elevation of intracellular cAMP. Pentoxifylline, a drug that is in widespread use in human beings as a hemorheologic agent, has also been shown to increase RBC deformability in horses.[438] Pentoxifylline also inhibits TNF production in horse blood and in cultured equine macrophages while increasing secretion of prostacyclin.[405,439] Studies in other species suggest that pentoxifylline stimulates production of the antiinflammatory cytokine IL-10, suppresses neutrophil activation, and inhibits activation of NF-κB.[441] A pharmacokinetic study in horses has indicated that administration at 10 mg/kg PO two times daily provides serum concentrations equivalent to those used therapeutically in humans.[442] The potential for flunixin to antagonize the potential beneficial effects of pentoxifylline was discussed earlier in this section. In light of the strong conceptual arguments for its use, pentoxifylline therapy (10 mg/kg PO bid) in endotoxemia is reasonable.

32.58.5.3 CORTICOSTEROIDS

The corticosteroid class of drugs theoretically has many useful actions in combating the effects of endotoxemia. These include reduced production of cytokines, inhibition of TNF production by macrophages, stabilization of cell membranes, and prevention of neutrophil activation. It is surprising, however, that neutral or negative effects of steroid use were found in large, multicenter studies of humans with gram-negative sepsis.[443] Corticosteroids also are widely believed to increase susceptibility to laminitis in endotoxemic horses, perhaps by increasing the sensitivity of digital vessels to the constrictive actions of circulating catecholamines or by inducing insulin resistance and hyperglycemia.[444,445] Use of high-dose corticosteroids is contraindicated in the treatment of endotoxemia in adult horses.

Some human patients with sepsis appear to respond to “physiologic” doses of hydrocortisone.[446] Most of these patients had high baseline cortisol concentrations but were thought to be in a state of adrenal insufficiency. In one study, low-dose hydrocortisone was associated with reduced vasopressor use and lower mortality rates.[446] This concept is not universally accepted, and the use of low-dose hydrocortisone therapy has not yet been reported in equine patients.[448]

32.58.5.4 HEPARIN

The use of heparin in horses with endotoxemia is somewhat controversial. It prevents microvascular thrombosis principally by promoting the anticoagulant activity of AT-III. Unfortunately, heparin cannot reverse existing thrombosis, and because AT-III is consumed during severe coagulopathy, it may not prevent additional intravascular coagulation in such cases. Fresh and fresh-frozen plasma are good sources of AT-III but also provide clotting factors that could potentiate intravascular coagulation. When given at the recommended intravenous or subcutaneous dose of 40 U/kg tid or 150 U/kg bid, respectively, unfractionated

heparin causes intravascular agglutination of equine RBCs.[449] Therefore it could be argued that the use of heparin might actually exacerbate intravascular cellular plugging. This side effect can be avoided by using *low—molecular weight* heparin, which is nonagglutinating but retains anticoagulant activity, principally via inhibition of factor Xa.[450] The use of heparin should be considered in horses that are at high risk for laminitis (e.g., DPJ or grain overload) or hypercoagulation syndrome (early evidence of dyshemostasis such as abnormal coagulogram or spontaneous venous thrombosis). In the latter setting, heparin should be given with plasma (10 to 40 mL/kg) at a dose of either 200 to 300 IU/kg/day for unfractionated heparin (either divided bid SC or as a continuous intravenous infusion) or 50 anti-Xa IU/kg for low—molecular-weight heparin (SC sid).

32.58.5.5 SCAVENGERS OF REACTIVE OXYGEN SPECIES

ROSs are thought to cause corrosive tissue damage during endotoxemia and potentiate the production of inflammatory cytokines via activation of NF-κB. Surgical deflation of distended small intestine is thought to lead to ischemia-reperfusion injury, a process that generates ROSs from epithelial xanthine oxidase. The life-saving process of fluid resuscitation in horses with hypovolemic shock may even lead to whole body ischemia-reperfusion. Despite these presumed associations between oxidant stress and the signs of endotoxemia, little effort has been made to intervene therapeutically at this level. There is some evidence that allopurinol, a hydroxyl radical scavenger and inhibitor of xanthine oxidase activity, has positive clinical effect during sublethal endotoxin infusion.[451] A recommended dose for allopurinol is 5 mg/kg IV. Because dimethyl sulfoxide (DMSO) has been shown to be a potent scavenger of hydroxyl radicals with efficacy in rodent sepsis models,[452] it seems reasonable to use this agent in the treatment of equine endotoxemia. Like allopurinol, DMSO may reduce intestinal mucosal injury after ischemia-reperfusion; to date, evidence for efficacy in this setting has been mixed. DMSO can be given by rapid intravenous infusion (or by nasogastric tube) as a 10% to 20% solution in saline at dose of 0.02 to 1 g/kg every 6 to 12 hours.

722

723

Other antioxidants that are used in equine medicine, including vitamin C, vitamin E, and *N*-acetylcysteine, have shown benefit in rodent sepsis models but have not been evaluated in equine endotoxemia.

Ethyl pyruvate, a stable analog of pyruvate, has been shown to have remarkable protective efficacy in a variety of models of septic and nonseptic shock in rodents and other species.[453] Because this agent is inexpensive and can be given in intravenous crystalloid fluids, it would appear to have potential for the treatment of endotoxemia and sepsis. The beneficial actions of this agent have been ascribed to its antioxidant actions.

32.58.6 Miscellaneous Treatments

Naloxone, a narcotic antagonist, at a dose of 0.2 mg/kg, blunted some of the cardiovascular effects of high-dose endotoxin in one study,[455] but a dose of 1 mg/kg had no effect in another.[456] Of importance, 0.75 mg/kg naloxone caused signs of colic in conscious horses,[457] probably by blocking the actions of endogenous β-endorphins at the high affinity μ-receptor. The detergent tyloxapol was remarkably effective in preventing the effects of endotoxin in anesthetized horses.[458] The mechanism of antiendotoxic action of tyloxapol is unknown, but the detergent has been shown to have wide-ranging effects on cells and proteins, some of which may preclude its use in clinical cases. For example, the detergent has been shown to inhibit cellular phagocytosis, an important event in innate immunity. Also, this agent induces marked hyperlipidemia (up to 100-fold higher than controls) in horses because of interference with lipoprotein metabolism. Similarly, a phospholipid emulsion effectively prevented adverse effects of subsequent endotoxemia; however, the treatment induced hemolysis

sufficient to preclude its use in clinical cases.[459] A published report[460] on the use of the sulfonyl analog of the alpha-phenyl-*N*-tert-butyl-nitrone spin trap molecule suggests that this agent was effective in reducing clinical signs in horses given endotoxin. A cautionary note was the observation that some rodents given the same agent at high doses actually suffered enhanced endotoxin-induced mortality.

PAF inhibitors have been effective antiendotoxic agents in some species but have not yet shown much positive clinical effect in horses or humans.[461] In dogs and other experimental animals, inhibitors of NO production such as N^G-monomethyl arginine reverse endotoxin— or TNF-induced hypotension[462]; however, NOS inhibitors generally have no protective effect in sepsis models. Furthermore, NO production may not be increased in horses with endotoxemia.[463]

A promising method of treatment may be the use of ketamine CRI. Ketamine has been shown in vitro to suppress the production of inflammatory mediators by LPS-stimulated equine peritoneal macrophages.[464] Constant-rate infusion of ketamine at 1.5 mg/kg/h for 320 minutes achieves blood concentrations compatible with this inflammatory effect and has been shown to be safe and nonsedating.[465] The antiinflammatory actions of ketamine appear to be mediated by the actions of adenosine on the adenosine A2A receptor.[466] The equine adenosine A2A receptor was recently cloned and characterized pharmacologically and is itself a potential direct target for antiinflammatory drugs.[467] Because ketamine inhibits inducible macrophage-type nitric oxide synthase and thus potentially causes vasoconstriction,[468] this approach should be used with caution.

32.58.7 Future Treatment Considerations

Current research in horses and other experimental animals suggests that magic bullets will be very hard to find. Most antiinflammatory approaches, even if they are aimed at the "root and trunk" of the inflammatory cascade (e.g., NF-κB activation) do not work consistently in severe sepsis models (e.g., cecal-ligation puncture) or in phase III clinical trials of human patients. It is becoming increasingly clear that much of the morbidity and mortality associated with sepsis results from "cold" sepsis, the state characterized by profound immunosuppression rather than cytokine storm. Affected patients are likely to be injured further by antiinflammatory therapy. There is some indication that IFN-γ, a cytokine that is pivotal in both innate and acquired immunity, can improve survival in immunosuppressed septic mice by preventing apoptosis of lymphocytes.[469] The issue of cold versus hot sepsis raises the issue of the need for accurate recognition of the stages of sepsis. Plasma procalcitonin concentration apparently is able to discriminate levels of sepsis and septic versus nonseptic SIRS.[470,471] Similarly, HMGB1 levels have been used to define sepsis categories in humans and to provide prognostic information.[472] These or equivalent markers need to be introduced into equine sepsis diagnosis.

There remains enthusiasm for strategies aimed at effective means to suppress or scavenge ROSs. In this regard, the remarkable effects of ethyl pyruvate in multiple models of inflammation, which likely mediates via its antioxidant effects, offer considerable promise.[453]

On the horizon are some different approaches that have the potential to be both effective and affordable. One of the most exciting possibilities is that gene therapy might be used to transfect host cells transiently in a targeted way with genes encoding antiinflammatory mediators (e.g., IL-10, TGF-β) or antisense RNA or ribozymes directed against mRNA of proinflammatory or even antiinflammatory or apoptotic mediators.

32.59 MEDICAL DISORDERS OF THE SMALL INTESTINE

Jennifer L. Davis

32.60 ULCERATIVE DUODENITIS

32.60.1 Pathophysiology

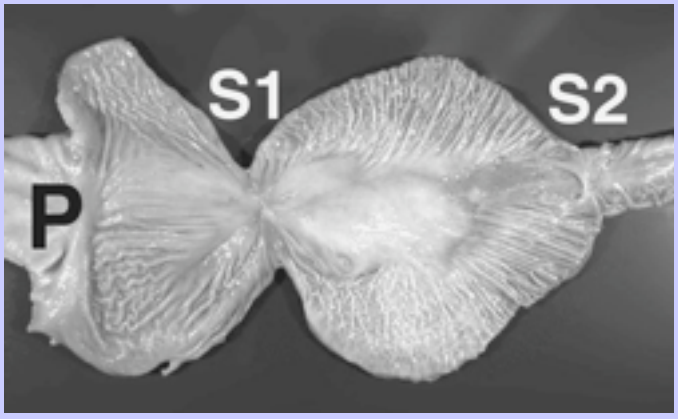
Ulcerative duodenitis most often affects foals and, to a lesser degree, yearling horses. Older horses are rarely affected. Lesions occur primarily in the proximal duodenum and may include erosions, focal ulceration, and diffuse inflammation with or without ulceration. The terms *duodenal ulceration* and *ulcerative duodenitis* may refer to differing clinical manifestations of the same problem, and the terms are used interchangeably in this section.

The pathophysiology of duodenal ulcer disease in foals is less well understood than gastric ulcer disease. The disorder is classically considered to be a peptic disease, one in which damage to the duodenal mucosa results from excessive exposure to hydrochloric acid and pepsin. This concept may require revision. Equine duodenal ulcer disease has been presumed to be similar to the disorder in humans, but most cases of duodenal ulcer disease in people are associated with *H. pylori* infection.[480] *H. pylori* bacteria have not been reported in equine gastrointestinal tissues; however, *H. pylori* colonize only gastric (glandular) mucosa, and infection of the duodenum must be preceded by metaplasia of areas of duodenal mucosa to gastric mucosa. This is thought to occur from chronic peptic injury. In humans the incidence of duodenal ulcer disease increases with age,[481] which contrasts with horses, in which duodenal ulcer occurs primarily in animals less than 1 year old.[482]

723

724

Fig. 32-46 Proximal duodenum of a 10-month-old horse with a history of chronic poor appetite and condition. The pylorus is at the left. There are two strictures in the duodenum: S1 is orad from the major duodenal papilla, and S2 is aborad from the duodenal papilla. The segment of the duodenum between the strictures is dilated. Courtesy Dr. M.J. Murray.



We have recognized occurrences of duodenal ulceration and inflammation in which cases were clustered geographically (same farm) and temporally. These foals all had moderate to severe gastric ulceration, and they had extensive inflammation with varying degrees of erosion or ulceration in the proximal duodenum (see Plates 10, 11). A similar temporal and geographic association was reported in two cases of ulcerative duodenitis in yearlings.[483] These findings seem inconsistent with a purely peptic insult as the cause for the ulcerative duodenitis. In one report of seven foals with ulcerative duodenitis,[484] lesions typically extended into a large area of the proximal duodenum, were characterized by mucosal necrosis, and often had a sharp line of demarcation between affected and more normal-appearing mucosa. In the foals of that report, no common microbial organism other than *E. coli* was identified, and a cause for the ulcerative duodenitis was not determined. In most foals with duodenal disease the lesions were not focal ulcers but rather appeared as more generalized inflammation. An infectious cause seems likely but has not been identified. In the 1980s rotavirus infection was thought to be associated with gastroduodenal ulcer disease in foals, but most foals with duodenal ulcer disease do not have rotavirus infection.

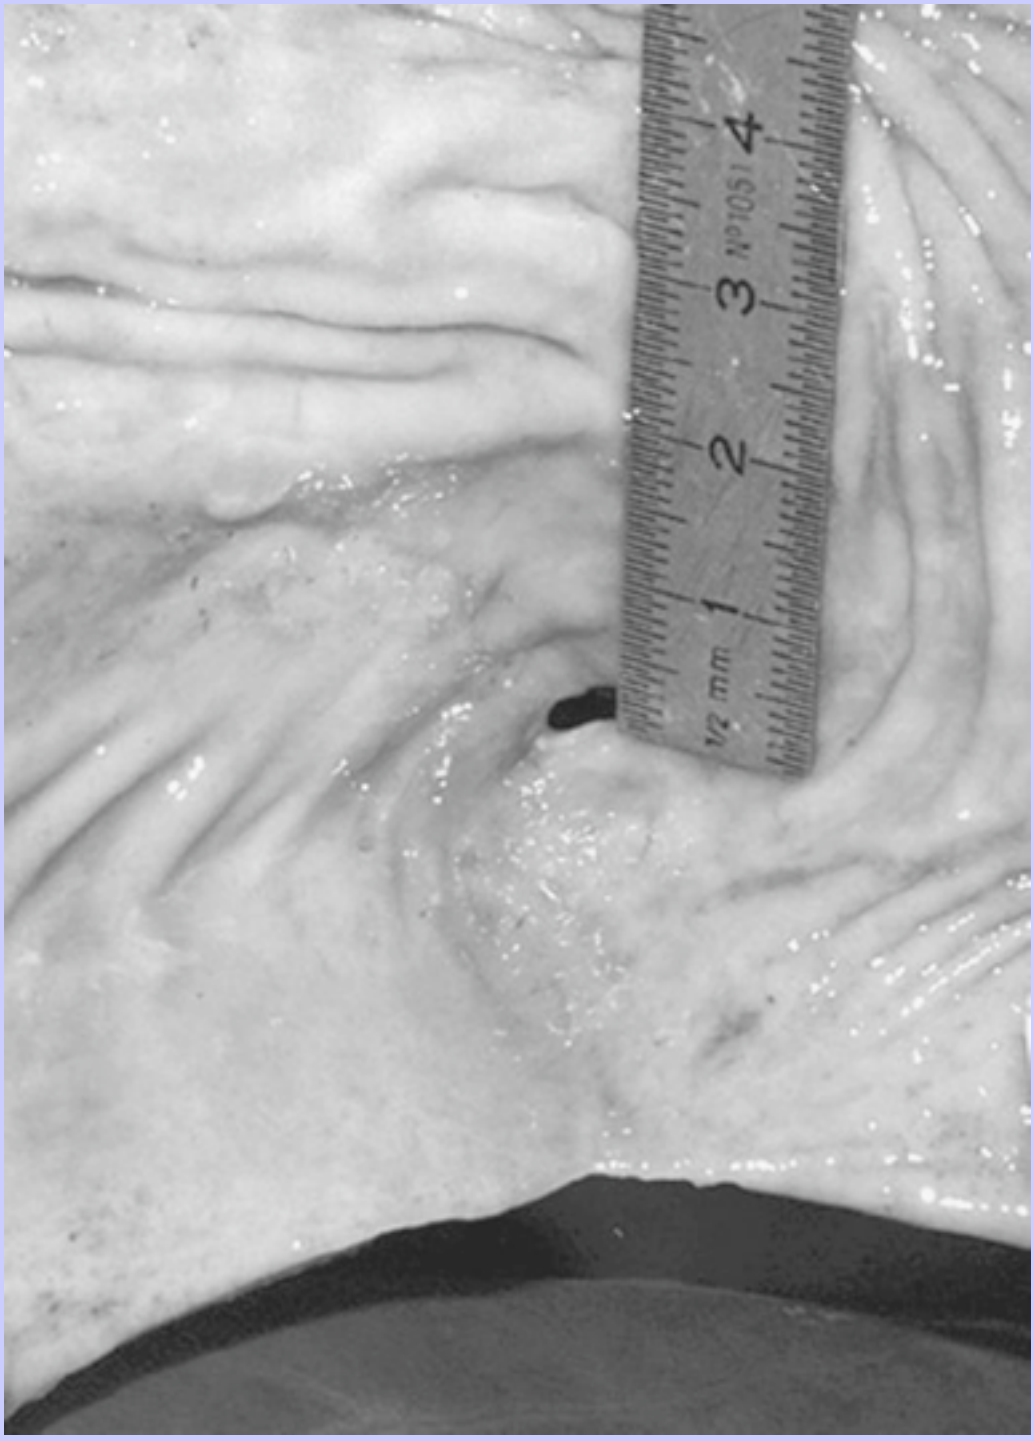
Duodenal ulcer disease in foals may have a component of peptic injury. The duodenal mucosa possesses some intrinsic properties that are protective against peptic injury, although these are not as elaborate as in the gastric glandular mucosa. The most important factor that protects the duodenal mucosa from acidic gastric secretions may be the sodium- and bicarbonate-rich secretions that probably originate from the pancreas and that will neutralize acid entering the duodenum from the stomach.[485]

32.60.2 Clinical Signs

The signs of duodenal ulceration or ulcerative duodenitis have been classically described as being the severe forms of gastric ulcer signs,[486] and in many cases duodenal and gastric ulcers occur simultaneously. However, many foals with ulcerative duodenitis will not have signs similar to those of gastric ulceration until severe gastric ulceration has occurred. Thus the primary signs of duodenitis can be nonspecific; they include fever, mild to moderate abdominal discomfort, mild obtundation, and diarrhea. A CBC will often reveal peripheral blood leukocytosis and hyperfibrinogenemia.

Gastric ulceration frequently occurs along with duodenal ulceration and may be secondary to physiologic or anatomic obstruction to gastric emptying. The gastric ulceration tends to be severe (see Plate 12), often leading to gastroesophageal reflux and esophagitis. Foals with esophagitis often exhibit ptyalism. In general the sequelae of duodenal ulceration are more severe than those of primary gastric ulceration. Complications of duodenal ulceration include duodenal perforation with peritonitis or adhesions, duodenal stricture with complete or partial obstruction (Figs. 32-46 and 32-47), ascending cholangitis and hepatitis, and ascending pancreatitis.

Fig. 32-47 Duodenal stricture *(S1)* of the horse in Fig. 32-46. The diameter of the duodenal lumen at the stricture is only 3 mm. Courtesy Dr. M.J. Murray.



32.60.3 Diagnosis

Duodenoscopy is the most specific means of diagnosis. It requires an endoscope with at least a 200-cm working length in foals up to 6 months of age, and a longer endoscope is required in older foals to examine the duodenal mucosa. Because of the size of the stomach and the anatomic configuration of the duodenum in foals, it is usually not possible to advance the endoscope past the duodenal ampulla. Occasionally the endoscope can be advanced into the descending duodenum.

A diagnosis is most readily made in cases in which lesions are diffuse or located within the ampulla. Excessive enterogastric reflux of bile through the pylorus is consistent with duodenal dysfunction. Ulceration at the pylorus or pyloric antrum may accompany duodenal ulceration and thus provide an indication of potential duodenal involvement. Severe gastric ulceration in foals should alert the endoscopist to the potential for duodenal involvement. In such cases, oral H_2 receptor antagonist therapy may be less effective in resolving gastric lesions than in cases of primary gastric ulceration, because of delayed gastric emptying secondary to duodenal ulceration. Therefore if a foal has received such treatment before endoscopy and if gastric ulceration is severe, suspicion of duodenal ulceration should increase.

Other diagnostic procedures that may be helpful include evaluation of peritoneal fluid; serum liver enzymes, particularly biliary-associated enzymes (γ-glutamyltransferase [GGT], ALP); serum bile acids; and radiography. With severe duodenal ulceration, survey radiographs of the cranial abdomen may reveal accumulation of fluid within the stomach and gas ascending the biliary ducts.[487] If barium contrast medium is placed into the stomach, complete emptying is usually delayed (>2 hours) and an irregular mucosal border may be noted in the descending duodenum. It should be recognized that in most cases radiography would not contribute to a diagnosis of duodenal ulcer per se, although duodenal stricture may be noted. If the descending duodenum is to be imaged, the volume of contrast medium placed in the stomach should not exceed 0.5 to 1 L in a foal and 1 to 2 L in a weanling or yearling, or the proximal descending duodenum will be obscured by contrast medium within the stomach.

32.60.4 Treatment

The effectiveness of treatment of duodenal ulceration or ulcerative duodenitis depends on the extent and severity of ulceration and the absence of complications, particularly perforation and stricture of the duodenum. Treatment objectives are to decrease duodenal inflammation, treat secondary gastric and esophageal ulceration, promote gastric emptying, and treat related problems such as peritonitis. If duodenal ulceration is confirmed or even suspected on the basis of clinical signs, treatment should be aggressive.

In acute cases of ulcerative duodenitis there usually is a pronounced lymphocytic infiltration of the mucosa. In more chronic cases there is a mixture of neutrophils, macrophages, fibroblasts, and fibrinonecrotic exudate. Definitive antiinflammatory therapy has not been described for these cases, and the use of corticosteroids or nonsteroidal antiinflammatory medications is controversial because they may worsen gastric ulcer disease through inhibition of protective prostaglandin synthesis.

Suppression of gastric acid secretion is still an important objective in the treatment of ulcerative duodenitis in foals, because most affected foals have gastric ulcers. Initially, acid suppression should be accomplished via parenteral administration of H_2 antagonist (cimetidine, 7 mg/kg IV q6h, or ranitidine, 1.5 mg/kg IV q8h). Oral medications are unlikely to be adequately delivered to and absorbed from the small intestine in the first days of

treatment. Gastric emptying can be enhanced with bethanechol (0.02 mg/kg SC q6–8h or 0.35 mg/kg PO q8h when the foal can consume orally). In foals that have severe duodenal disease or that have required surgery, bethanechol has been given for up to 3 months. Once the foal can accept oral medication, it should be treated with the proton pump inhibitor omeprazole at a dose of 4 mg/kg once daily for the paste formulation. It should be noted that in the 24 hours after the first dose, acid suppression is incomplete, and maximal suppression of acid secretion is achieved between days 1 and 5.[488] Therefore a common practice is to administer an H_2 antagonist IV for the initial 2 days of treatment with omeprazole in foals with duodenitis.

Misoprostol is a synthetic prostaglandin E_1 analogue that has been successfully used in treating duodenal ulcerations in humans. Doses of 2 to 5 µg/kg q8-12h can be used in horses, although side effects may include abdominal pain and diarrhea. Sucralfate promotes duodenal mucosal healing in humans.[489] The dose of sucralfate that is effective in humans with duodenal ulceration ranges from 1 to 2 g two to four times daily. Foals treated for duodenal ulceration that do not have impaired gastric emptying should be administered 2 to 4 g of sucralfate three times daily. *Sucralfate should not be used as the sole therapeutic agent for duodenal ulceration.*

Foals with duodenitis must usually be prevented from nursing or eating for 1 to 3 days. During this time, parenteral feeding should be considered. Depending on the age of the foal, administration of parenteral nutrition should provide 40 to 60 kcal/kg/day.

If medical therapy is ineffective or if sequelae of duodenal ulceration cause complications, surgical intervention may be required. Gastroenterostomy has been reported to be effective in some cases through bypassing the affected portion of duodenum and allowing for an alternative route for gastric emptying.[487] However, short-term survival and long-term quality of life and use are often unsatisfactory. Patients that have a successful surgical outcome require long-term aftercare and usually require long-term maintenance acid suppression and treatment with a prokinetic drug until gastric emptying is normalized. Therefore an owner should be prepared to make a significant time and financial commitment before surgery is considered.

32.61 DUODENITIS–PROXIMAL JEJUNITIS

DPJ, also known as *anterior enteritis* or *proximal enteritis*, describes a clinical syndrome that is characterized by inflammation and edema of the duodenum and proximal jejunum, excessive fluid and electrolyte secretion into the small intestine, and, consequently, large volumes of enterogastric reflux. The syndrome of DPJ was first described in 1982[490] and was more fully characterized in 1987.[491] A subsequent report[492] described clinical and clinicopathologic parameters in horses with DPJ that differed somewhat from cases in the 1982 report, suggesting that either the cases were of similar etiopathogenesis but of different severity or that the cases were of different etiopathogenesis with the only similarity being the segment of bowel affected. A diagnosis of DPJ is often applied to cases in which there is abdominal discomfort, small intestinal distention, and excessive enterogastric reflux without obstruction, yet it is unclear whether all of these cases lie along a spectrum of severity of DPJ or whether there are several disease entities that affect the proximal small intestine and that share clinical features. The latter seems more likely.

32.61.1 Pathophysiology

In horses with DPJ, lesions are consistently found in the duodenum, but the severity and frequency of lesions in the jejunum are variable. Serositis is a consistent finding, characterized by bright red to dark red petechial and ecchymotic hemorrhages on the serosal surface.[491] Histologic lesions include hyperemia and edema of the

mucosa and submucosa, villous epithelial degeneration, epithelial cell sloughing, neutrophilic pleocytosis, hemorrhages in the muscular layers, and fibrinopurulent exudation on the serosa.

With DPJ there is an increased volume of duodenogastric reflux, typically 50 to 100 mL/min. This reflux has been considered to result from increased intestinal fluid secretion and decreased motility. Mechanisms of intestinal fluid secretion include passive transmucosal exudation, secondary to mucosal and submucosal inflammation and characterized by a protein-rich fluid secretion, and active fluid secretion, caused by increased cyclic nucleotides and characterized by fluid with a high electrolyte and low protein content. The components of fluid in the intestines of horses with DPJ have not been characterized, but it is likely to result from a combination of passive and active secretion. In some horses the hemorrhagic nature of the gastric reflux implies increased capillary permeability of the duodenal mucosa, whereas in other horses the watery nature of the reflux, the presence of serum electrolyte disturbances,[493] and the absence of peripheral hypoproteinemia are most consistent with an active secretory process.

Another potential source of the large volume of fluid secreted into the proximal small intestine and refluxed into the stomach is the pancreas. Normally there is periodic orad movement of duodenal contents into the stomach, which has been observed endoscopically and has been documented by collecting gastric contents with and without pyloric obstruction.[485] The duodenal contents have a large component of water, sodium, and bicarbonate, as well as bile salts from the liver. These secretions are presumed to originate from the pancreas, as well as the liver, and pathology of either of those organs may contribute to the pathophysiology in cases of DPJ.

Suppurative cholangiohepatits has been reported in cases of small intestinal inflammation secondary to DPJ.[494,495] The pathophysiology behind this observation may be related to an increased luminal pressure in horses with DPJ, increasing the likelihood of intestinal content regurgitation into the bile ducts. It is also possible that horses with DPJ absorb inflammatory mediators or bacterial products from the small intestine via the portal blood flow or systemic circulation.

Although the exact cause of DPJ is not known, several bacteria and toxins have been implicated. *C. difficile* has been frequently implicated in causing the disease. One prospective study cultured toxigenic species of *C. difficile* from the reflux of 10 out of 10 horses diagnosed with DPJ, and only 1 of 16 horses diagnosed with other causes of nasogastric reflux. Of the strains cultured from these horses, 8 of 10 produced both A and B toxins, whereas the remaining two produced only toxin B.[496] This is significant in that toxin B as been shown to cause inhibitory electromechanical disturbances to smooth muscle in the small intestine, which may be a possible cause of ileus in these horses.[497] Toxin A has also been shown to promote inflammatory cell infiltration into the smooth muscle layers.[498] Influx of neutrophils and release of inflammatory mediators in the intestinal wall have been shown to activate nitric oxide pathways, which results in inhibition of the enteric nervous system, increases in sympathetic tone, and a subsequent reduction of contractile activity in the gut.[499] *C. perfringens* and *Salmonella* species have also infrequently been associated with DPJ, but the significance of these pathogens remains unknown.

Fusarium moniliforme has been cultured from the feed of horses with naturally occurring DPJ. Under experimental conditions, *F. moniliforme* producing fumonosin B1 mycotoxins caused lesions consistent with DPJ.[500] Neurologic lesions were also present in the horses with DPJ in that study, however, and both of those horses died with lesions consistent with equine leukoencephalomalacia. Cantharidin toxins can also cause reddening of the mucosa in the small intestine, as well as excessive gastric reflux[501] and may be a cause in some cases. It is possible that this one syndrome has multiple initiating causes and that no one causative agent will ever be definitively identified.

32.61.2 Clinical Signs and Differential Diagnosis

The major differential diagnoses for DPJ include simple or strangulating small intestinal obstructions. Differentiation can be extremely difficult in some cases and may delay surgical intervention in cases of small intestinal obstruction, to the detriment of the patient. The criteria used to discriminate between DPJ and obstructive lesions include degree of pain, presence of fever, and changes in hematologic parameters and abdominal fluid.

Horses with DPJ have a history of an acute onset of moderate to severe abdominal pain that often is followed by varying degrees of depression. Nasogastric intubation yields a large volume of enterogastric reflux, which is frequently orange-brown in color, with a fetid odor. Palpation per rectum reveals multiple loops of mild to moderately distended small intestine. The initial volume of reflux may range from as little as 4 to 5 L to up to 32 L. The duration of the reflux may be as short as 24 to 48 hours, but it usually lasts 3 to 7 days. Horses are often febrile (rectal temperature greater than 38° C [101° F]) and dehydrated and have injected mucous membranes, prolonged capillary refill time, diminished intestinal sounds, tachycardia (>60 beats/min), and tachypnea.[490–493,502,503] Although abdominal pain usually abates after gastric decompression, most horses remain depressed, which perhaps is the most consistent and characteristic clinical sign of the disease. If the fluid that accumulates in the proximal intestinal tract is not removed periodically, signs of abdominal pain recur.

Assessment of the degree of small intestinal distention and the thickness of the intestinal wall can be useful indicators. Often, horses with DPJ have generalized distention of small intestine, but when palpated per rectum the intestine does not feel taut. In many cases of small intestinal obstruction the bowel will feel tightly distended, but this is not universally true. Ultrasonography can be used, both transrectal and transabdominal, to determine the diameter of the small intestine, evaluate contractions, and measure the thickness of the wall of the intestine. With acute obstruction one can see several segments of small intestine that are 6 to 10 cm in diameter, have no contraction, and have a wall diameter of 3 to 5 mm. With DPJ small intestinal diameter may be less, and the thickness of the intestinal wall may exceed 6 mm.

Culture of the reflux for *Clostridium* and *Salmonella* species can be attempted. This can be difficult, however, given the special conditions required for anaerobic cultures, as well as the intermittent shedding of *Salmonella* species into the gastrointestinal tract of normal horses. Also, the large volume of reflux in these cases may dilute the bacterial population to the point where isolating low numbers of bacteria is difficult.

32.61.3 Clinicopathologic Findings

Clinical laboratory findings include increased PCV and total plasma proteins (hemoconcentration) and a metabolic acidosis in longstanding or severe cases. Abdominocentesis often reveals an elevated peritoneal fluid total protein concentration and a mild to moderate increase in the peritoneal WBC count (>5000 cells/μL).[502] The peritoneal fluid is usually yellow and turbid, but in severe cases diapedesis occurs, resulting in a serosanguineous color. An abdominal fluid total protein concentration ≥3.5 g/dL is associated with a poorer prognosis.[502] The WBC count in the peripheral blood may be normal or increased.[491,492] In addition, hypocalcemia, hyponatremia, hypochloremia, hypokalemia, and acid-base alterations have been reported in horses with DPJ.[493] An elevated anion gap may be present, secondary to decreased calcium and magnesium or increased lactate or albumin concentrations.[502] Increases in the anion gap to ≥15 mEq/L have also been associated with a poor prognosis.

Elevations in liver enzymes, particularly GGT, may be seen in horses with DPJ and may be a useful way to help differentiate between DPJ and strangulating lesions of the small intestine.[494,495] A study examining a large series of DPJ cases retrospectively to determine the prevalence of hepatic damage in horses with small intestinal inflammation showed that horses with DPJ had significantly higher hepatic enzyme activities than the control group of horses with small intestinal strangulating obstruction (SISO).[495] Over 50% of horses with PE had biochemical evidence of hepatic disease (high GGT, aspartate aminotransferase [AST], or ALP activity). Horses with DPJ had a 12.1-fold higher risk of having a high GGT activity and a 1.8-fold risk of having a high AST activity than horses with SISO. AST activity in horses with PE ranged from 133 to 2994 IU/L (reference range 215.8 to 365 IU/L), GGT ranged from 7 to 117 IU/L (reference range 6.2 to 19.1 IU/L), and ALP ranged from 86 to 1103 IU/L (reference range 69.4 to 293.7 IU/L). Bile acid concentrations were rarely abnormal, indicating that hepatic failure was uncommon. Histopathologic evidence of liver pathology was a common feature in the horses with PE that had either biopsies or necropsies performed. Centrilobular necrosis and inflammation were noted in some cases.

32.61.4 Treatment

Because the causative agent(s) of DPJ are unknown, treatment remains empiric and consists of aggressive supportive therapy. The continuous production of enterogastric reflux requires gastric decompression every 1 to 2 hours to relieve pain and to prevent gastric rupture. Approximately 4 to 8 L of malodorous gastric fluid can be collected during decompression. The stomach should be decompressed frequently, regardless of whether or not the horse is showing signs of abdominal pain, as these signs may be masked by severe depression or the administration of analgesic or antiinflammatory medications. Horses should receive nothing by mouth until small intestinal function has returned, recognized clinically by cessation or reduction of the nasogastric reflux to 1 to 2 L over a 4-hour period and increased frequency of borborygmi. The time necessary for gastric decompression varies with each individual patient. Repeated rectal examinations after the first day of therapy will inconsistently reveal distended loops of small intestine, depending on the frequency of removal of the reflux and the severity of the initial lesion. Ultrasonography may reveal fluid-filled small intestine when such bowel is not discernible by rectal palpation. Loops of small intestine are most frequently visualized in the ventral flank area, near the udder or prepuce; therefore this area should be examined in all cases of suspected small intestinal distention.

Intravenous administration of a balanced electrolyte solution is necessary to maintain intravascular fluid volume and cardiovascular performance. In some horses even rapid administration of fluid fails to adequately restore and maintain intravascular volume because of enteric fluid losses that can be as great as 8 L hour. In addition, the very large volume of isotonic crystalloid fluid that must be given IV to keep pace with enteric fluid losses with DPJ may accelerate the flux of fluid from the vasculature into the intestinal lumen because of reduced intravascular oncotic pressure, increased capillary perfusion pressure, and increased capillary permeability in the inflamed intestine. Consequently the balance between adequate hydration and the volume of enterogastric reflux obtained requires careful and frequent monitoring.

Administration of colloid solutions may be of benefit in preserving intravascular volume without promoting enterogastric reflux. The most frequently used colloids in the horse include hyperimmune plasma, and hydroxyethyl starch solutions. Plasma products require a large volume of administration to exert a colloidal effect, which is cost prohibitive in many cases. Smaller doses, however, may have a beneficial effect in horses with DPJ, particularly in animals showing signs of sepsis or endotoxemia. Hydroxyethyl starch solutions have been shown to significantly increase plasma oncotic pressure in ponies administered 10 mL/kg[504] and represent a reasonably priced alternative to plasma. These solutions have been associated with changes in the hemostatic

profile in normal ponies at higher doses of 20 mL/kg[505] and should be used only with caution in horses already at risk for coagulopathies.

During the initial hours of therapy, even aggressive intravenous fluid administration may result in only moderate clinical improvement. A positive clinical response, as evidenced by improved hydration status, decreased heart rate, decreased enterogastric reflux, improved attitude, and improvement in parameters reflecting kidney function (decreased blood urea nitrogen [BUN] and serum creatinine), correlates with resolving intestinal inflammation.

NSAIDs should be used judiciously to avoid masking the clinical signs of a potential surgical lesion. Flunixin meglumine can be used at a dose of 0.25 to 0.5 mg/kg every 6 hours to reduce the untoward effects of arachidonic acid metabolites.

Antimicrobial agents are typically administered to horses with DPJ, although the necessity for antimicrobial treatment in horses with DPJ is uncertain. Given the association of DPJ with *C. difficile*, administration of intravenous penicillin (22,000 to 44,000 IU/kg q6h) is warranted. Metronidazole also has excellent activity against *C. difficile*; however, administration is difficult because nothing can be administered per os. Rectal administration of metronidazole has been studied[506] and can be used in these cases. The dose and frequency of administration should be increased because bioavailability after rectal administration is much less than after oral administration (30% vs. 74%, respectively). Broad-spectrum antimicrobial treatment may be indicated in horses with low WBC counts, but care must be taken in selecting an antimicrobial to avoid potential adverse effects, particularly nephrotoxicosis with aminoglycosides in a dehydrated patient with compromised renal function.

Horses with DPJ may have to be kept from eating for several days and are often in a hypermetabolic state; therefore they rapidly develop a negative energy and nitrogen balance. In these horses parenteral nutritional support should be considered. Parenterally administered solutions containing glucose, balanced amino acid solutions, lipid emulsions, balanced electrolyte and trace minerals, and vitamins have been administered to adult horses with a variety of intestinal disorders, including DPJ. Providing for part of the horse's nutritional requirements (8000 to 12,000 kcal/day) is possible with glucose—amino acid solutions that are of moderate cost. The rationale for this treatment is that through provision of nutritional support to an anorectic, severely ill horse, the healing process will be facilitated, complications will be reduced, and the duration of hospitalization may be shortened. Thus the overall cost of providing nutritional supplementation, enteral or parenteral, to horses with DPJ may well be offset by quicker recoveries and diminished requirements for other costly treatments.

727

728

Prokinetic agents may also be useful in cases of DPJ. Of the available prokinetics, lidocaine is used most frequently.[507] A loading dose of 1.3 mg/kg slow intravenous bolus followed by a continuous infusion of 0.05 mg/kg/hr has been shown to shorten the time of reflux and decrease the hospital stay in horses with DPJ.[508] It may do this by decreasing sympathetic tone, acting as an analgesic agent, or decreasing granulocyte infiltration in the intestinal wall. Its use should be reserved for horses in which a surgical lesion has been ruled out, as it can very effectively mask intestinal pain. Horses should be refluxed frequently during the infusion and checked for other signs of complications, such as laminitis, routinely. Metoclopramide, erythromycin lactobionate, and cisapride are also used in cases of DPJ.[507] The efficacy of prokinetics in this disease is debated, mainly because they require a healthy intestine in order to exert an effect. A more in-depth discussion of prokinetic agents can be found in the section on gastrointestinal ileus in this chapter.

Medical therapy is sufficient in most cases of DPJ. In patients with prolonged nasogastric reflux (>7 days), excessive fluid losses that cannot be corrected with conventional fluid therapy, or clinical and laboratory findings strongly suggestive of an intestinal obstruction, surgery should be considered. Animals with severe cases of DPJ may develop infarction of a segment of the small intestine that requires surgical removal. Surgery is used to

make the diagnosis and potentially to alleviate enterogastric reflux by providing an alternative route for fluid that accumulates in the small intestine. On entrance into the abdominal cavity, dilated small intestine is immediately apparent. After the extent of the diseased intestine is determined, a segment of normal distal jejunum is laid side to side to the proximal diseased intestine in an isoperistaltic fashion, as far proximal on the affected bowel as possible without extending to bowel that cannot be removed from the abdominal cavity. A small 1- to 1.5-cm hand-sewn anastomosis can then be made between the two segments of intestine.[509] This provides an adequate stoma for direct intestinal decompression while minimally compromising the digestive and absorptive capacity of the small intestine. Potential complications of this procedure include development of an intestinal incarceration through the loop that is formed and the development of small intestinal adhesions.

32.61.5 Complications

Complications of DPJ include septic peritonitis, myocardial and renal infarction, aspiration pneumonia, adhesions of the proximal small intestine, and laminitis. The prognosis for surviving the initial intestinal insult is good in cases of DPJ. The death and function losses from this disease are more commonly related to the secondary complications such as laminitis and intraabdominal adhesions. In one report, laminitis occurred in 28% of horses with DPJ, and associated factors were high body weight and hemorrhagic gastric reflux.[510] Laminitis prophylaxis is routinely incorporated into the medical therapy and can consist of a variety of treatments, none of which is proven to be effective. These include NSAIDs, topical glyceryl trinitrate, and DMSO (200 mg/kg given as a 10% solution in normal saline). Horses that received heparin as a prophylactic treatment for laminitis were less likely to develop clinical laminitis than horses that did not receive heparin in one study.[510]

32.62 PROLIFERATIVE ENTEROPATHY

PE is an infrequently diagnosed disorder of the small intestine of weanling foals or yearlings caused by *Lawsonia intracellularis*, an obligate intracellular pathogen. Alternative names for this condition include *proliferative enteritis, proliferative ileitis*, and *intestinal adenomatosis*. The hallmarks of PE are chronic wasting with severe hypoproteinemia accompanied by grossly thickened small intestine with mucosal ulceration. The disease can occur in individual animals or as a herd outbreak among young animals.[511–515]

32.62.1 Pathophysiology

The mechanism of enteritis after infection with *L. intracellularis* involves invasion of the proliferating crypt cells in the ileum, causing excessive mitotic division and severe hyperplasia.[516] The hyperplastic mucosa becomes grossly thickened and develops a corrugated appearance. As would be expected, this thickening of the mucosa, along with the proliferation of immature crypt cells rather than mature villous cells, leads to a limited brush border development and a decreased absorptive capacity, which results in the weight loss and hypoproteinemia present in these cases. The organism can divide within the infected cells and migrate up to the mucosal layers as the cells proliferate and advance. The main differential diagnosis in these cases is *R. equi* enteritis, which can also cause ulceration in the areas of Peyer's patches throughout the small intestine, cecum, and colon.

A genetic predisposition to *L. intracellularis* infection has been proposed. A recent study showed that polymorphisms in several important immune response genes in foals were related to the fecal shedding of *L. intracellularis* organisms.[517] None of these foals had clinical disease consistent with PE, however, and the significance of these gene polymorphisms is still unknown.

32.62.2 Clinical and Laboratory Findings

PE is a chronic, progressive disorder, and therefore affected animals are typically not presented until the disease is advanced. Horses with PE have a variety of clinical problems, most notably chronic weight loss, intermittent abdominal discomfort, or diarrhea. Some affected animals are erroneously treated for primary gastric ulceration, and indeed there may appear to be temporary improvement in attitude and appetite. This may reflect successful treatment of gastric ulcers that develop as a secondary problem. Many affected animals are diminished in stature, reflecting retarded growth resulting from a chronic intestinal disorder that probably affects absorption of nutrients. Affected animals typically appear lethargic with a rough haircoat and may have concurrent respiratory infection, dermatitis, and intestinal parasitism.

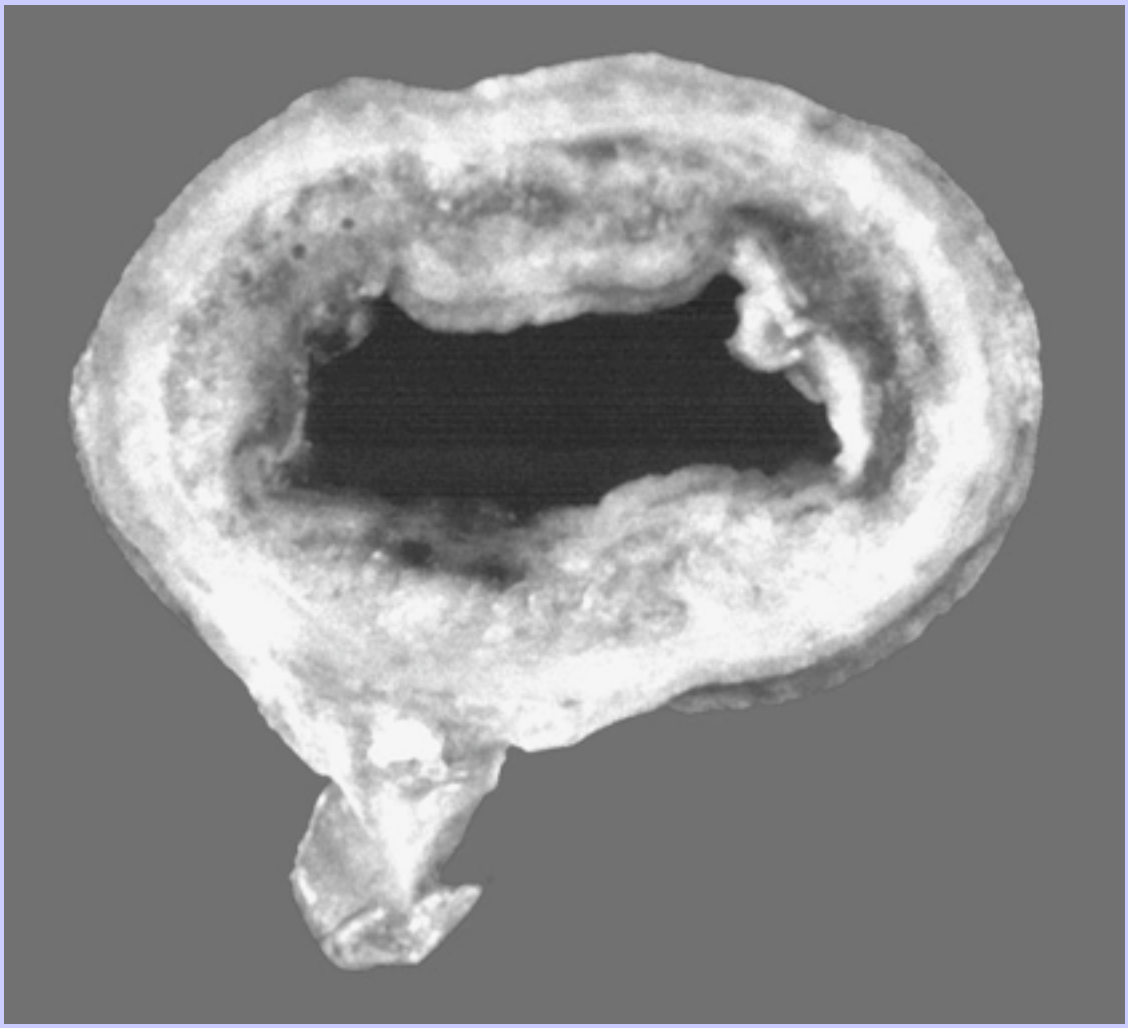
Ventral edema often is present as a result of hypoproteinemia. Some animals have tachycardia and tachypnea. Fever is an inconsistent finding. Abdominal ultrasonography is often useful to identify thickened small intestine. The entire ventral abdomen should be examined, but the affected intestine is most often in the distal jejunum and ileum, which can be most commonly seen along the midline caudally. If transrectal ultrasonography is possible, better detail of the intestinal wall will be appreciated. In affected animals the intestinal wall diameter will be 6 to 12 mm. More normal surrounding small intestine may be seen, and in contrast the affected segment of bowel will appear rigid with a corrugated appearance to the mucosa, and the diameter of the lumen will be decreased in size because of mucosal proliferation (Fig. 32-48).

CBC findings in horses with PE vary. Leukocytosis is a frequent finding, and this may be characterized by a lymphocytosis. Profound hypoproteinemia (serum protein <3 g/dL, albumin <1.5 g/dL) is a consistent finding. A foal in one report had mildly decreased total serum protein with markedly low albumin (0.6 g/dL) and polyclonal gammopathy (4.6 g/dL). Hyperfibrinogenemia occurs in some cases. Other clinicopathologic findings are variable and depend on the chronicity and whether there are excessive fluid and electrolyte losses through diarrhea.

728

729

Fig. 32-48 Cross-section of ileum from a 6-month-old horse with proliferative enteropathy. Courtesy of Dr. M.J. Murray.



For definitive diagnosis of PE caused by *L. intracellularis*, isolation of the organism is considered the gold standard. However, culture of this organism is difficult and requires specialized culture media; therefore the sensitivity of this test is questionable. Specific tests for *L. intracellularis* infections in foals have been developed. A PCR can be performed on tissues or feces of PE-suspect foals. Use of this test in tissues is sensitive and specific; however, fecal PCR has a higher incidence of false-negative results.[515] A more useful antemortem test is the indirect fluorescent antibody (IFA) test that detects antibodies against *L. intracellularis* in serum.[515] Titers ≥1:30 were found to be diagnostic of infection in foals.

32.62.3 Pathologic Findings

Lesions are most frequently found in the distal jejunum and ileum, although diffuse thickening of the small intestine may occur. Classically there is pronounced mucosal thickening with varying severity of ulceration and transmural edema. The affected bowel appears to be stiff, and the mucosal surface has a corrugated appearance. Mucosal pleocytosis is a common feature, but in different cases the predominating inflammatory cell type will differ. A lymphocytic or plasmacytic cellular infiltration may be present. There is crypt proliferation, accompanied by crypt elongation and epithelial hyperplasia. The villi are blunted and may become fused. Silver staining with Warthin-Starry stain reveals elongated, curved bacilli in the apical zone of the crypt epithelial cells.[514]

32.62.4 Treatment

Treatment objectives are to eliminate the infection, reduce intestinal inflammation, and maintain hydration and plasma colloid oncotic pressure. Several antibiotics have been reported to be useful for the treatment of *L. intracellularis* infection. Lipophilic drugs with high intracellular penetration are most effective because the bacterium resides within the cells. Ampicillin has good activity against the bacterium in vitro, but because it does not penetrate intracellularly, it is unlikely to be effective in vivo. The most common antibiotic used in PE is erythromycin with or without rifampin for approximately 6 weeks.[515] Other drugs in this class, including azithromycin, may be useful for treatment of this disease owing to their high intracellular concentrations.[518] Chloramphenicol has also been reported to be effective and is a good alternative in foals that develop a worsening of the diarrhea while on erythromycin. The tetracyclines, particularly oral doxycycline, are a cheap and effective alternative to other antibiotics. A recent report looked at 11 cases of PE in foals treated with tetracycline therapy.[519] In this report, 9 of the 11 survived to discharge. The average time to resolution of the diarrhea was 3.5 days after initiation of therapy, and the average treatment time was 3 weeks. The most common administration schedule used was oxytetracycline 6.6 mg/kg IV q12h for 3 to 7 days followed by oral doxycycline 10 mg/kg PO q12h for up to 17 days.[517]

Supportive therapy with crystalloid fluids to correct dehydration, electrolyte imbalances, and azotemia secondary to fluid losses from profuse diarrhea is warranted. Colloidal support with plasma or hydroxyethyl starch solutions can help correct the edema and decreased colloid oncotic pressure. NSAIDs should be used with caution in foals showing signs of dehydration.

Prognosis in these cases is generally good with early and correct diagnosis of the problem. Therapy can be prolonged and should be continued until the diarrhea and hypoproteinemia have resolved and there is no longer evidence of thickened small intestine on ultrasound.

32.63 RHODOCOCCUS EQUI ENTERITIS

R. equi bacteria most frequently cause a severe pyogranulomatous pneumonia in foals 2 to 3 months of age. Extrapulmonary disorders have been associated with *R. equi* infection in foals, however, and include several intestinal manifestations. Enterocolitis and typhlitis were reported in 10 of 61 foals in one study.[520] Diarrhea (13 of 61) and abdominal lymphadenitis (17 of 61) were also reported in the same study.

32.63.1 Pathophysiology

Intestinal infection with *R. equi* can occur through either fecal-oral transmission or swallowing of infected sputum. The organism invades and reproduces within the macrophages, causing a pyogranulomatous disease. In a survey of normal foals on two different farms, *R. equi* was shed in the feces of 16 of 17 and 19 of 26 foals, respectively.[521] Only two foals developed clinical signs of intestinal disease, and the shedding of bacteria in the feces increased threefold to fourfold during those times. Such foals, as well as adults, are likely the source of repeated contamination on endemic farms. Whether or not the organism causes disease is based on the presence of virulence factors, particularly VapA, which has been most commonly associated with disease in pneumonic foals.

32.63.2 Clinical and Laboratory Findings

Foals diagnosed with *R. equi* enteritis typically manifest the signs of pneumonia first, although foals in which the enteric form is the major pathology have been reported.[522] With the enteric form of the disease, diarrhea, weight loss, and colic are present. Foals are often febrile, anorectic, and depressed. Typical clinicopathologic findings include leukocytosis with neutrophilia and severe hyperfibrinogenemia. Ultrasound of the abdomen may reveal pyogranulomatous abscesses in the lymph nodes.

A diagnosis of *R. equi* enteritis can be presumed in pneumonic foals showing signs of gastrointestinal disease 729
that culture positive for *R. equi* in transtracheal wash fluid. *R. equi* can also be cultured from the feces, small 730
intestinal luminal contents, or occasionally the peritoneal fluid of affected animals. A PCR based on the *vapA* gene has been developed and can be used as an adjunct diagnostic in these cases.[523]

32.63.3 Pathologic Findings

The most common small intestinal lesion is multifocal ulcerative enteritis in the area of the Peyer's patches of the ileum. Other parts of the small intestine may be affected, with lesions present throughout the entire small intestine.[523] These lesions frequently extend into the cecum and colon as well. A suppurative exudate is also present, along with pyogranulomatous inflammation of the mesenteric lymph nodes.

32.63.4 Treatment

Treatment of *R. equi* enteritis is similar to treatment of *R. equi* pneumonia. Erythromycin estolate (25 mg/kg PO q6-8h) or erythromycin phosphate (37.5 mg/kg PO q12h) combined with rifampin (5 to 7.5 mg/kg PO q12h) has been the traditional treatment for these foals, and it is still effective but requires a long duration of treatment and is difficult for owners to administer because of the frequency of the treatments. Alternative treatments include azithromycin (10 mg/kg PO q24h for 5 days, followed by q48h) and clarithromycin (7.5 mg/kg PO q12h). It is very important to continue treatment until the hematologic abnormalities and radiographic examinations have returned to normal, in order to prevent relapses.

32.63.5 Complications

Complications associated with *R. equi* enteritis include septic peritonitis and the development of intestinal adhesions. These may lead to death of the animal, or chronic abdominal problems in those that survive. Therapy

is often prolonged in these cases, and owners should be warned that foals with extrapulmonary disorders associated with *R. equi* pneumonia have a more guarded prognosis.

32.64 ENTERIC PYTHIOSIS

Pythium species are protistal organisms that belong to a group of phycomycotic organisms that also includes *Conidiobolus* and *Basidiobolus* species. They are a frequent cause of severely pruritic cutaneous granulomas in horses along the Gulf Coast and southern United States. Much less frequently, the disease can cause granulomatous lesions in the small intestine.

32.64.1 Pathophysiology

Pythium species are presumed to be transmitted via contact with contaminated water. Once ingested the organisms are thought to penetrate the intestinal mucosa through an existing lesion, because necrotic tissue is considered chemotactic.[524] *Pythium* species may be able to penetrate healthy tissue, however, because some cases in dogs have been reported to have mesenteric lymph node involvement without any mucosal lesions.[525]

32.64.2 Clinical and Laboratory Findings

Four reports of enteric pythiosis can be found in the literature.[526–529] In all cases, masses occurred in the mid to distal jejunum. One horse died suddenly, one was euthanized during surgery, and two were successfully treated with a jejunal resection. Organic iodide therapy was instituted in one horse postoperatively for 30 days. In three cases clinical signs of intestinal disease had been present for several months before diagnosis. Chronic colic, weight loss, inappetence, and ill thrift have all been reported and could be related to the intestinal lesion. None of the reported animals had skin lesions. Hematologic evaluation was nondiagnostic in the three cases in which it was performed.

Grossly, lesions are caseous with discrete yellow foci (“kunkers”), and the intestinal wall is thickened because of a pyogranulomatous inflammation. Microscopically, a diffuse, mixed inflammatory infiltrate, along with granulation tissue, is found in the submucosa, tunica muscularis, and mesenteric attachments. Culture of the organism is difficult in these lesions; however, an indirect immunoperoxidase technique to stain for *Pythium*-positive hyphae is available in some laboratories.[528]

32.64.3 Treatment

Treatment of phycomycetes is often difficult. They are not true fungi; therefore they are resistant to many antifungal drugs. Systemic amphotericin B is only rarely effective in treating the cutaneous disorder. Organic iodides are inexpensive and safe when administered orally, but the mechanism of action as an antimicrobial drug is not understood, and the efficacy of this compound has not been proven when treating this disease. A vaccine can be formulated against the organism, and this has been shown to shrink the lesions in horses with cutaneous disease. Whether or not it would work in enteric disease is unknown at this time. In addition, premortem or presurgical diagnosis of the disease is extremely difficult, making surgical resection and biopsy the most effective treatment.

32.65 INFLAMMATORY BOWEL DISEASE

Several intestinal disorders characterized by inflammatory cell infiltration have been placed under the umbrella of inflammatory bowel disease (IBD), including granulomatous enteritis, multisystemic eosinophilic epitheliotropic enterocolitis, eosinophilic enterocolitis, lymphocytic-plasmacytic enteritis, and basophilic enterocolitis.[530–536] IBD in humans is typically characterized by a neutrophilic inflammation, but neutrophils are just the effector cell in a highly complex disease process.[537] The syndromes described for equine inflammatory intestinal disorders therefore appear to differ from human IBD; given the different types of cellular infiltrates found in affected horses, these disorders presumably reflect different pathophysiologic mechanisms. Thus use of the term *inflammatory bowel disease* is not intended to imply either a similarity to the condition described in human beings or similarity among the various syndromes described in horses.

32.65.1 Clinical and Laboratory Findings

Horses with IBD typically have progressive weight loss despite a good appetite and have intermittent abdominal discomfort. If the disease predominates in the small intestine, diarrhea will not be a feature. In some cases there will be associated dermatitis.[538] Horses often present with peripheral edema secondary to hypoproteinemia from enteric protein losses. Ultrasonography may reveal thickened small intestine (>5 mm wall diameter).

Clinicopathologic abnormalities may include anemia, hypoalbuminemia, hypoproteinemia, and malabsorption of glucose and D-xylose. Hypoalbuminemia in the absence of proteinuria or severe liver dysfunction is consistent with protein-losing enteropathy. Some horses may have a relative gammopathy. Serum electrolyte concentrations and total CO_2 are usually normal. Subclinical disseminated intravascular coagulation with thrombocytopenia and increased fibrinogen degradation products have been identified in horses with chronic enteritis.[533,539]

730

731

In many horses inflammatory cells infiltrate throughout the intestinal tract. Therefore rectal mucosal biopsy may be useful to identify cases of IBD in horses.[540] A definitive diagnosis often requires biopsy of the small and/or large intestine. With appropriate instruments this can be done by laparoscopy, although an exploration via a ventral midline approach permits a more thorough evaluation of the abdomen. In most horses cellular infiltration can be found to varying degrees throughout the intestinal tract.

Histopathologic evaluation of biopsy specimens can be used to differentiate among the various IBDs reported in horses, based on the following criteria.[534] A diagnosis of granulomatous enteritis is made when aggregates of macrophages and epithelioid cells are found in the mucosa and/or submucosa, along with villous atrophy. In lymphocytic-plasmacytic enterocolitis, lymphocytes and plasmacytes are present in the lamina propria, and villous atrophy usually occurs. For multisystemic eosinophilic epitheliotropic disease, eosinophils, lymphocytes, and macrophages are found in the mucosa and submucosa. Rarely basophils have also been reported.

A new syndrome has recently been discovered involving focal areas of eosinophilic inflammatory infiltrates within the small intestine, termed *idiopathic focal eosinophilic enteritis* (IFEE).[536,541–544] Affected horses typically are presented not because of chronic weight loss or diarrhea, but rather as acute colic cases. Hypoproteinemia and malabsorption are not present. The lesions are intramural masses or circumferential mural bands. Eosinophils with or without lymphocytes are seen infiltrating all layers of the intestine, with varying degrees of fibrosis.[534] No underlying cause of the disease has been found, although food allergy, parasitism, and

Pythium species have all been suggested.[544] The incidence, or at least the diagnosis, of this disease appears to be increasing.

32.65.2 Treatment and Prognosis

Because the specific diseases included under the general category of IBD are quite different, a generalized treatment recommendation cannot be made. Most reported cases of IBD in horses have been fatal, even with aggressive treatment with corticosteroids. Classically reported cases of eosinophilic, lymphocytic, and basophilic enteritis have failed to respond to treatment. If treatment is attempted, immunosuppressive doses of dexamethasone, up to 0.2 mg/kg, once daily are recommended. Successful remission of granulomatous enteritis was reported in one patient that was treated with dexamethasone[545]; however, in the vast majority of cases treatment is unsuccessful. Cases of IFEE should be differentiated from other causes of IBD with regard to treatment and prognosis. These cases frequently respond to surgical decompression without resection if circumferential mural bands are the only lesion present.[544] In cases of intramural masses, surgical resection of the lesions usually resolves the problem.[543]

32.66 NEOPLASIA

Primary and secondary neoplasia involving the alimentary tract of horses is relatively uncommon, although several cases have been reported.[546] Typical signs associated with, but not diagnostic for, small intestinal neoplasia include colic and weight loss. In most horses with focal intestinal neoplasia the problem becomes apparent when only lumen obstruction develops. Lymphosarcoma can be disseminated throughout a large portion of intestine, eventually resulting in a malabsorption and weight loss syndrome. Lymphosarcoma affects horses of all ages and can be manifested as an enteric disorder, as well as affecting other systems.[547] The diagnosis of enteric lymphosarcoma can occasionally be made on the basis of cytologic examination of fluid obtained by abdominocentesis. In other cases intestinal biopsy is required to diagnose the neoplastic disorder. The prognosis is best if the tumor is discrete and can be removed surgically. A combination chemotherapy protocol of cytarabine (170 mg/m^2 IM), cyclophosphamide (142 mg/m^2 IV), and prednisolone (86 mg/m^2 PO) has been reported to be effective in the treatment of mixed-cell thoracic lymphoma.[548] In other cases, corticosteroid therapy may induce clinical remission for several months, although it is not curative.

Other neoplasms affecting the small intestine are unusual, typically arising from the wall of the bowel, and include adenocarcinoma,[549] leiomyosarcoma,[550] and neurofibroma.[551] These tumors often result in intestinal obstruction and signs of abdominal discomfort. Discrete tumors may be surgically removed.

Paraneoplastic syndromes may the first indication of neoplastic processes in the horse. Pemphigus, hypoglycemia, hypercalcemia, erythrocytosis, and neuropathies have all been associated with tumors in horses.[552] Paraneoplastic processes may also lead to intestinal tract dysfunction in horses with extraintestinal tumors. Amyloid deposition secondary to multiple myeloma in a horse has been described.[553]

32.67 SMALL INTESTINAL FIBROSIS

Small intestinal fibrosis is a rare syndrome that causes weight loss, chronic colic, and progressive debility in horses and ponies. Clusters of affected animals are reported in Colorado[554,555]; however newer reports have been published in horses from Missouri.[556] The pathophysiology behind the fibrosis is not known, although ingestion of

toxins (*Convolvulus arvensis* or common bindweed), inhibitors of 11β-hydroxysteroid dehydrogenase, or compounds with mineralocorticoid activity has been suggested.

Palpation per rectum typically reveals thickening of the small intestinal wall, which may be confirmed by ultrasound.[555] Grossly, the overall length of the intestine may be shortened by as much as 50%.[554,555] The histologic lesions include arteriosclerosis, capillary endothelial hypertrophy, extensive fibrosis of the submucosa, and hypertrophy of the muscularis mucosae and tunica muscularis.[554] The prognosis for the disease is determined by the length of the intestine that is involved. Surgical resection may be attempted.

32.68 LYMPHANGIECTASIA AND CHYLOABDOMEN

There are few reports of lymphangiectasia and chyloabdomen in the literature. Lymphangiectasia is dilation of the lymphatics of the small or large intestine (Fig. 32-49), usually caused by an abscess[557] or neoplasia. There are reports of chyloabdomen resulting from congenital lymphatic defects in a neonatal foal, intraabdominal abscesses in a foal, and abdominal adhesions in a miniature horse.[557–559] Typically, thickening of the intestinal wall and leakage of chyle into the peritoneal cavity results from obstruction or rupture of the lymphatics. Animals can have signs that include abdominal discomfort, diarrhea, and chronic weight loss. Diagnosis is made on the basis of abdominal fluid analysis and ultrasonography. Chylous abdominal fluid appears milky and may contain a high percentage of lymphocytes. Ultrasonography may reveal segments of thickened small intestine. Diagnosis is confirmed at surgery or postmortem examination, and treatment, if possible, is usually surgical, although in my experience medical resolution of the effusion has been achieved.

731

32.69 SURGICAL DISORDERS OF THE SMALL INTESTINE

Anthony T. Blikslager

32.70 SIMPLE OBSTRUCTION

Simple intestinal obstruction is a physical obstruction of the lumen without obstruction of vascular flow. The most common causes are intraluminal masses composed of feed material (e.g., ileal impaction) or accumulation of parasites (e.g., ascarid impactions). There are other instances in which the bowel is obstructed without associated compromise of blood supply, most commonly by extraluminal compression by a mass or band of tissue in horses with intraabdominal adhesions. Because a large volume of fluid enters the small intestinal lumen on a daily basis, [560,561] the obstructed intestine becomes distended. The volume of fluid on a daily basis in a hindgut fermenter such as the horse is approximately one extracellular fluid volume, or approximately one third of the horse's body weight. [560] Therefore, although the blood supply is not directly involved in simple obstructions, progressive and marked distention can result in decreased mural blood flow[562] and eventual necrosis of tissues.[563]

32.70.1 Ascarid Impactions

Impactions caused by *Parascaris equorum* typically occur in weanling foals (median age, 5 months; range, 4 to 24 months) that have been on a poor deworming program and that are administered an anthelmintic when they have a heavy parasite burden.[564] Products that cause sudden ascarid paralysis or death, including piperazine, organophosphates, and pyrantel pamoate, have been incriminated.[565] However, it is likely that any effective broad-spectrum anthelmintic, such as the avermectins, will have the same effect. Clinical signs include variable onset of colic after administration of an anthelmintic (usually within 1 to 5 days) and signs compatible with small intestinal obstruction, including nasogastric reflux.[564] The onset of the disease varies according to the degree of obstruction.[565] Diagnosis may be tentatively based on the history in a foal that appears unthrifty, has been recently dewormed, and has signs referable to small intestinal obstruction. The presence of dead ascarids in nasogastric reflux would raise the index of suspicion of this particular form of obstruction.[564] Abdominal radiographs or ultrasound will likely indicate the presence of multiple loops of distended small intestine but are not needed if clinical signs indicate the need for immediate surgery. Surgical treatment typically involves an enterotomy made over the intraluminal impaction and removal of ascarids.

Although simple intestinal obstruction tends to carry a favorable prognosis for survival, ascarid impaction is a notable exception. The mortality rate in these cases is high (up to 92% in one study) as a result of severe intestinal compromise, peritonitis, and development of adhesions. The severe intestinal compromise is almost entirely attributable to the duration of impaction, which for unknown reasons is not as readily recognized in foals as it is in adults. Reasons for this could include failure of the owner or farm manager to recognize colic in foals, or failure on the part of the owner or veterinarian to recognize the implications of colic in foals. Although foals readily display signs of colic, other medical causes of colic such as gastric ulcer disease or enteritis might be higher on the list of differential diagnoses than for adults. Second, the size of a foal may make episodes of colic appear more manageable than in adults, in which colic-induced trauma, especially to the head, may force the issue of referral and surgery at an earlier stage. This is speculative, but early intervention in foals with ascarid impaction would likely result in dramatic reductions in the reported mortality rate.[564]

32.70.2 Ileal Impaction

Ileal impactions occur most commonly in adult horses in the southeastern United States. Although feeding of coastal Bermuda hay has been implicated in the regional distribution of this disease, it has been difficult to separate geographic location from regional hay sources as risk factors.[566] However, a recent study from the Southeastern United States showed that feeding coastal Bermuda hay and failing to deworm with an anthelmintic with efficacy against tapeworms are significant risk factors for ileal impaction.[567] Furthermore, in a study performed in the United Kingdom, horses with evidence of tapeworm infection were at risk for developing ileal impaction.[568] Signs are typical for an adult horse with small intestinal obstruction, including onset of moderate to severe colic and palpable loops of distended small intestine per rectum as the condition progresses. Because the ileum is the distalmost aspect of the small intestinal tract, nasogastric reflux may take a considerable time to develop and is found in only approximately 50% of horses requiring surgical correction of ileal impaction.[569,570] The diagnosis is usually made at surgery, although an impacted ileum may be palpated per rectum.[571] However, multiple loops of distended small intestine frequently make the impaction difficult to palpate. Nonetheless, clinicians working in the southeastern United States who evaluate horses with cases of mild or moderate colic that have a history of eating coastal Bermuda hay, and in which distended loops of small intestine can be detected adjacent to the cecum, should have ileal impaction high on the list of differential diagnoses. Ileal impactions may resolve with medical treatment. In particular, horses that have clinical signs compatible with obstruction of the small intestine but also have normal abdominal fluid should be treated medically unless pain is unmanageable or subsequent abdominal fluid samples indicate intestinal compromise. In those cases in which surgery becomes necessary, fluids (2 to 3 L) can be directly infused into the mass, allowing the surgeon to breakdown the impaction. However, extensive small intestinal distention and intraoperative manipulation of the ileum frequently leads to POI.[572] Therefore some surgeons now elect to perform an enterotomy and to flush the contents from the intestinal lumen with minimal manipulation. Although early studies indicated a guarded prognosis,[570] more recent studies indicate that the prognosis is good.[569,571]

732
733

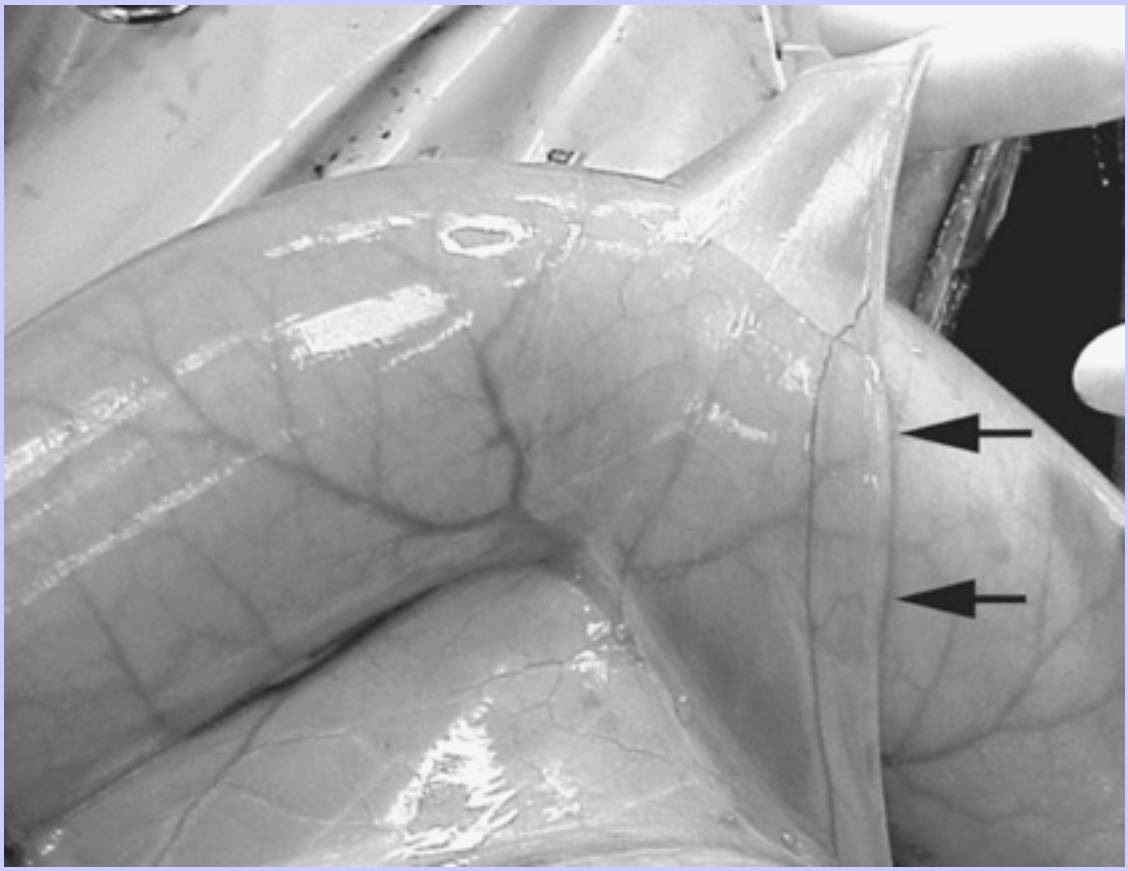
32.70.3 Ileal Hypertrophy

Ileal hypertrophy is a disorder in which the muscular layers (both circular and longitudinal) of the ileum hypertrophy for unknown reasons. Parasitism has been implicated, particularly for those parasites that tend to localize to the ileum (such as tapeworms), but this has never been proven. In some cases the jejunum may also be hypertrophied, either alone or in combination with the ileum.[573] It is clear from these findings that initial functional obstruction initiates this syndrome, causing the musculature of the intestine to hypertrophy in order to push intestinal contents aborally, but there is no evidence as to the mechanisms of this disease. Clinical signs include chronic intermittent colic as the ileum hypertrophies and gradually occludes the lumen. In one study partial anorexia and chronic weight loss (1 to 6 months) were documented in 45% of the horses.[573] The diagnosis is usually made at surgery, although in some cases the hypertrophied ileum may be palpated per rectum or seen on ultrasonographic evaluation of the abdomen. For treatment, an ileocecal or jejunocecal anastomosis to bypass the hypertrophied ileum is performed. Without surgical bypass, intermittent colic persists, and the thickened ileum may ultimately rupture. According to one recent report of 11 horses with hypertrophy of the ileum, only one horse survived, indicating a poor prognosis. The most common reason for euthanasia was spontaneous ileal rupture.[573]

32.70.4 Meckel's Diverticulum

Meckel's diverticulum is an embryonic remnant that may become impacted. The diverticulum arises from the vitelloumbilical duct, which fails to completely atrophy, and becomes a blind pouch projecting from the antimesenteric border of the ileum.[574,575] Occasionally an associated mesodiverticular band may extend from the diverticulum to the umbilical remnant and serve as a point around which small intestine may become strangulated. Mesodiverticular bands may also originate from the embryonic ventral mesentery and attach to the antimesenteric surface of the bowel, thereby forming a potential space within which intestine may become entrapped (Fig. 32-50).[576] Clinical signs range from chronic colic for an impacted Meckel's diverticulum to acute severe colic if a mesodiverticular band strangulates intestine. The diagnosis is made at surgery, and treatment requires resection of the diverticulum and any associated bands.

Fig. 32-50 Jejunal mesodiverticular band. This anomaly was discovered in this horse as an incidental finding during exploration of the abdomen. Intestine may become entrapped within the mesenteric pocket formed by the attachment of the ventral to the dorsal mesentery *(arrows)*.



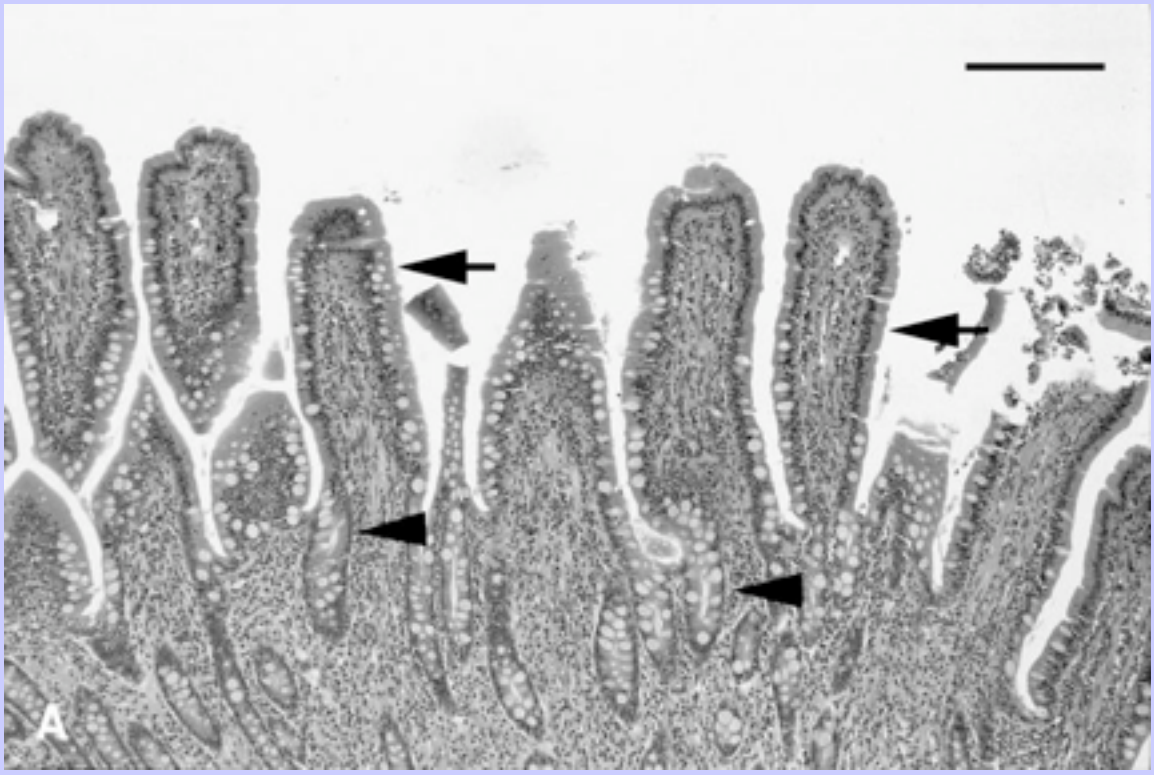
32.71 STRANGULATING OBSTRUCTION

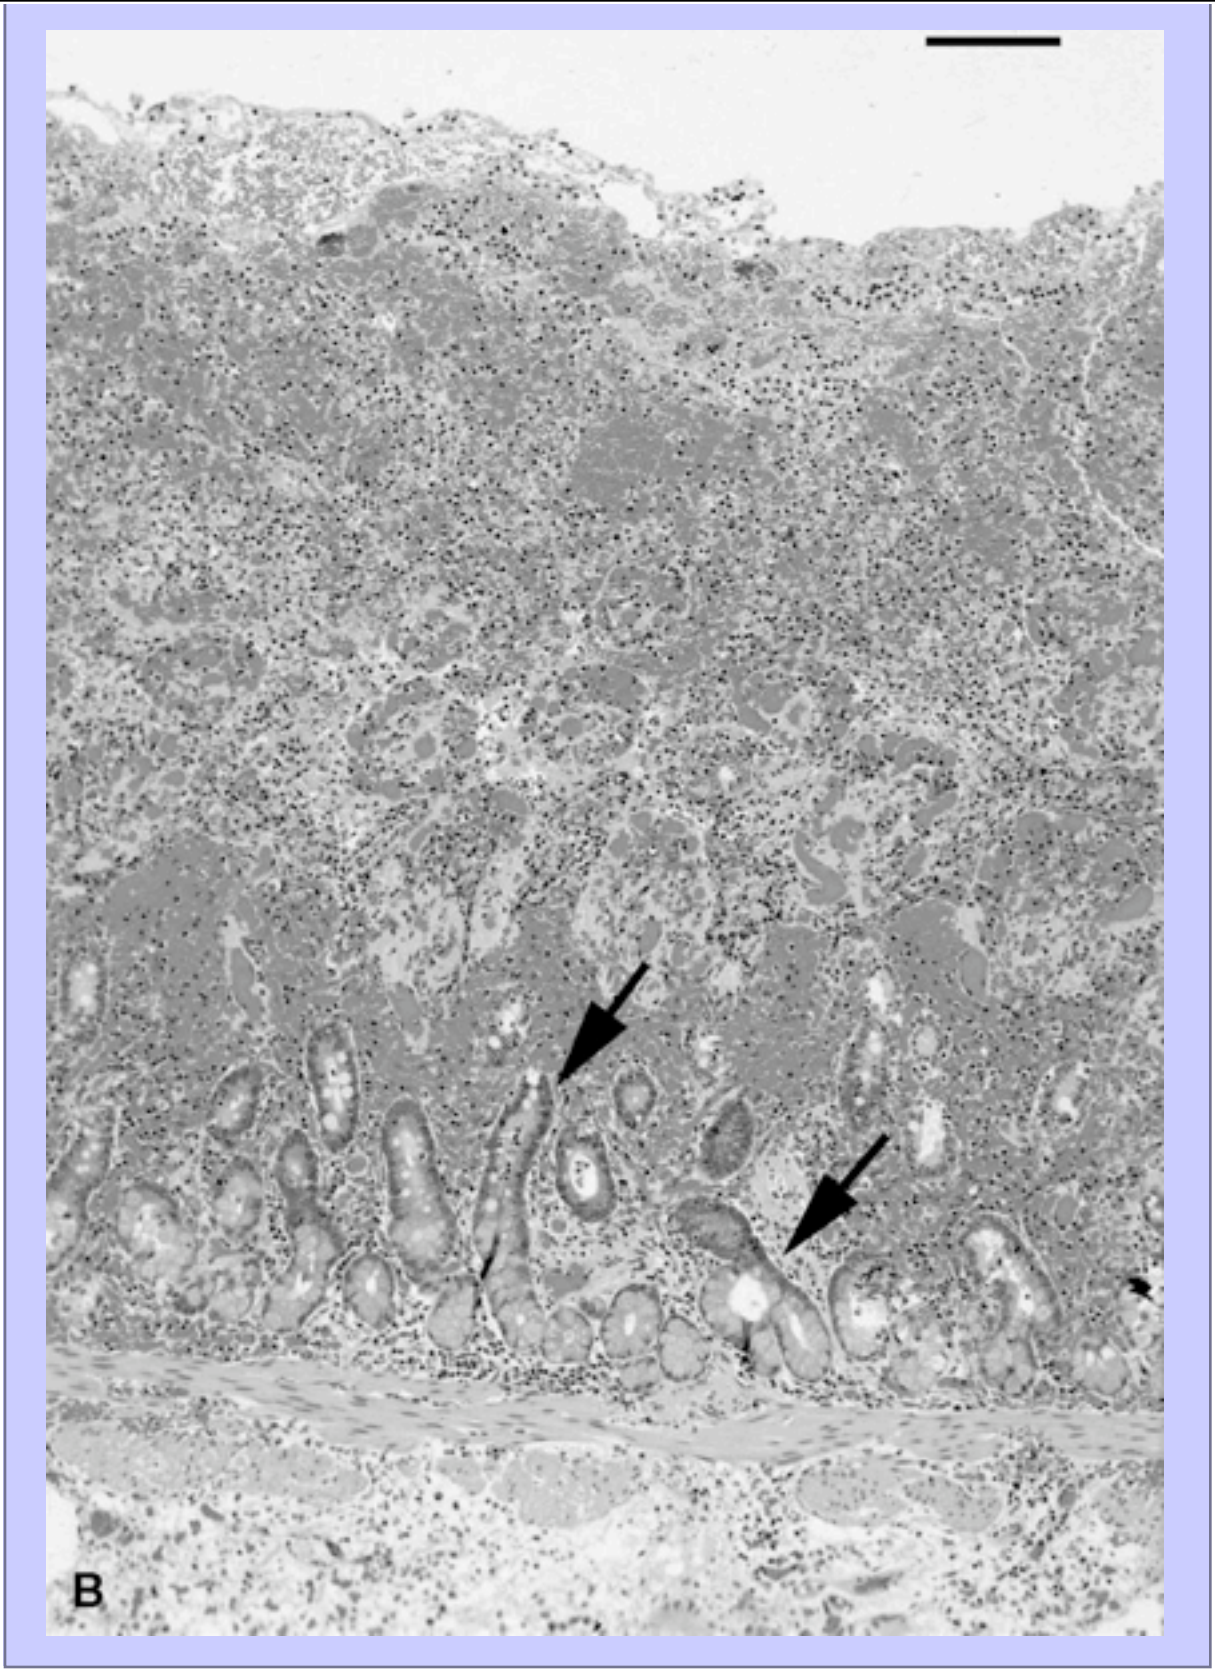
Strangulation obstruction of the intestine is characterized by simultaneous occlusion of the intestinal lumen and its blood supply. Although strangulation of the intestinal lumen results in clinical signs similar to those of simple obstruction, occlusion of the blood supply results in a more rapid deterioration of the intestinal mucosa and subsequent onset of sepsis. Therefore clinical signs (including pain, heart rate, mucous membrane color, and capillary refill time) are typically more severe, and the prognosis is less favorable.

A great deal of work has been done to characterize mucosal injury that occurs during strangulation[577,578] and, more recently, during reperfusion.[579] In general, the lesion that develops during strangulation is severe, leaving little viable bowel for further injury during reperfusion.[580] The severity of the ischemic lesion is partly attributable to the fact that in most cases initial occlusion of veins and partial occlusion of arterial blood supply during strangulation induces a hemorrhagic lesion. This results in extensive congestion and mucosal degeneration (Fig. 32-51).[577] Bowel peripheral to the strangulating lesion may also become injured as a result of distention.[581] In addition, distended small intestine that remains viable after surgical correction of strangulation may be subject to reperfusion injury after surgical correction of the lesion.[582] Unfortunately, attempts at reducing mucosal injury in the horse with antioxidants, which would be expected to inhibit injury attributable to reperfusion injury and associated reactive oxygen metabolites, have been unsuccessful.[583]

The prognosis for survival in horses with small intestinal strangulating lesions is generally lower than with most types of colic. In a large multicenter study, SISO had a fatality rate of 67% compared with that of small intestinal simple obstruction, which had a fatality rate of 48%.[584] Although recent studies indicate higher survival rates in general, the relative fatality of strangulating obstruction compared with simple obstruction is probably similar. One study indicated that in excess of 70% of horses were discharged from the hospital after surgical correction of SISO.[585] These figures should be interpreted cautiously because they are based on the number of horses that are recovered from surgery rather than the number of horses initially presented for evaluation of severe colic. In addition, owners should be warned that the long-term survival rate is reduced by long-term complications.[586] The principal reason for reduced long-term survival in patients that have had small intestinal surgery is intraabdominal adhesions (Fig. 32-52). For example, in one study 22% of horses that had small intestinal surgery required further surgery or were euthanized because of adhesions, and only 25% of horses that had a clinical problem with adhesions survived.[587]

Fig. 32-51 Histologic appearance of normal and strangulated jejunal mucosa. **A**, Normal equine jejunal mucosa, with extensive villi *(arrows)* and mucosal crypts *(arrowheads)*. **B**, Hemorrhagic strangulating lesion of the jejunum, with complete loss of villi and extensive hemorrhage. Note the presence of crypts *(arrows)*, which remain relatively undamaged. 1 cm = 100 µm.





B

32.71.1 Epiploic Foramen Entrapment

The epiploic foramen is a potential opening (because the walls of the foramen are usually in contact) to the omental bursa located within the right cranial quadrant of the abdomen. It is bounded dorsally by the caudate process of the liver and caudal vena cava and ventrally by the pancreas, the hepatoduodenal ligament, and the portal vein.[588,589] Clinical signs include acute onset of severe colic with examination findings compatible with small intestinal obstruction. Although the condition was reportedly more prevalent in older horses, recent studies have not detected an age predilection.[590] However, studies have detected a seasonal pattern for this disease. Specifically, more horses appear to suffer from epiploic foramen entrapment during the fall and winter months.[591] An additional factor associated with epiploic foramen entrapment is crib-biting. One potential reason for this association is the development of negative intrathoracic pressure during cribbing, which might then result in cranial movement of intestine into the vicinity of the epiploic foramen. The association between crib-biting and epiploic foramen entrapment has now been shown in separate studies performed in the United Kingdom and the United States.[592]

734
735

Fig. 32-52 Intraabdominal adhesion in a foal. Note the presence of a mature fibrous adhesion between two segments of jejunum *(arrows)* that resulted in kinking and partial obstruction of affected intestine.

The diagnosis is definitively made at surgery, although ultrasonographic findings of distended loops of edematous small intestine adjacent to the right middle body wall are suggestive of epiploic foramen entrapment.[588] Entrapped small intestine may enter the foramen from the visceral surface of the liver toward the right body wall or in the opposite direction. Reports differ as to which is the more common form. Entrapped small intestine may be limited to a portion of the intestinal wall (parietal hernia).[593] In addition, the large colon may become entrapped within the epiploic foramen.[594] In treating epiploic foramen entrapment, the epiploic foramen must not be enlarged either by blunt force or with a sharp instrument, because rupture of the vena cava or portal vein and fatal hemorrhage may occur. In addition, excessive force used to extract entrapped bowel during surgery may also result in rupture of a mesenteric branch of the cranial mesenteric artery. The finding of intraabdominal hemorrhage in some cases of epiploic foramen entrapment before surgery may result from compromise of the mesenteric blood supply rather than the major blood vessels that border the epiploic foramen. Prognosis has substantially improved over the last decade, with current short-term survival rates (discharge from the hospital) ranging from 74% to 79%.[588,595]

32.71.2 Strangulation by Mesenteric Pedunculated Lipoma

Lipomas form between the leaves of the mesentery as horses age, and mesenteric stalks develop as the weight of the lipoma tugs on the mesentery. The stalk of the lipoma and a loop of small intestine or small colon may become intertwined, causing strangulation (Fig. 32-53). Strangulating lipomas should be suspected in mature horses (>10 years old) with acute colic referable to the small intestinal tract.[596] In addition, geldings and ponies appear to be at risk for developing strangulating lipomas,[597] possibly because of differences in fat metabolism. One recent study documented a case of strangulating lipoma in a much younger patient, indicating that although the aging process is associated with development of lipomas, this disease cannot be ruled out preoperatively purely on the basis of age.[598,599] The diagnosis is usually made at surgery, although on rare occasions a lipoma can be palpated per rectum.[600]

Fig. 32-53 Strangulating lipoma of the ileum. A lipoma, together with its mesenteric stalk *(arrows)*, has become intertwined with a loop of the ileum, resulting in a hemorrhagic strangulating obstruction.

Treatment involves surgical resection of the lipoma and strangulated bowel, although strangulated intestine is on occasion viable. Studies indicate that approximately 50% to 78% of horses are discharged from the hospital after surgical treatment.[585]

32.71.3 Small Intestinal Volvulus

A volvulus is a twist along the axis of the mesentery, whereas torsion is a twist along the longitudinal axis of the intestine. Small intestinal volvulus is theoretically initiated by a change in local peristalsis, but the mechanisms of this disease are unclear.[601] It is reportedly one of the most commonly diagnosed causes of small intestinal obstruction in foals.[602,603] It has been theorized that young foals may be at risk for small intestinal volvulus because of changing feed habits as they adapt to a forage-based adult diet. Onset of acute, severe colic, a distended abdomen, and radiographic or ultrasonographic evidence of multiple loops of distended small intestine in a young foal would be suggestive of small intestinal volvulus. However, volvulus is not possible to differentiate from other causes of small intestinal obstruction preoperatively.

In adult horses, volvulus frequently occurs in association with another disease process, during which small intestinal obstruction results in distention and subsequent rotation of the small intestinal around the root of the mesentery (e.g., in horses that have strangulation caused initially by a pedunculated lipoma). Although any segment of the small intestine may be involved, the distal jejunum and ileum are most frequently affected, most likely because the mesentery is longer in the more distal bowel. The diagnosis is made by palpating a twist at the origin of the cranial mesenteric artery during surgical exploration. Treatment includes resection of devitalized bowel, which may not be an option because of the extent of small intestinal involvement. For example, if complete volvulus of the small intestinal tract occurs, the only option would be to untwist the intestine and hope that the bowel was sufficiently viable to survive the disease process. This would in turn depend on the duration of disease and the extent of intestinal ischemia (i.e., how tightly the intestine twisted as the volvulus developed). Prognosis is based on the extent of small intestine involved and its appearance after surgical correction of the lesion.[604] For example, the degree of sepsis may relate to the surface area of devitalized tissue. In addition, the length of the time it takes to complete the surgery can become problematic, particularly in patients with sepsis, in which it is difficult to maintain adequate arterial blood pressure. Nonetheless, survival in patients with extensive small intestinal resection may not relate to the absolute length of intestine resected.[605] A recent study indicated that the prognosis for survival is good (80% of horses recovered from surgery and were discharged).[606]

32.71.4 Inguinal Hernia

Inguinal hernias are more common in standardbred and Tennessee Walking horses, which tend to have congenitally large inguinal canals. Inguinal hernias may also occur in neonatal foals, but they differ from hernias in mature horses in that they are typically nonstrangulating. Typical historical findings in mature horses with inguinal hernias include acute onset of colic in a stallion that has recently been used for breeding. A cardinal sign of inguinal herniation is a cool, enlarged testicle on one side of the scrotum.[607,608] This is attributable to occlusion of the testicular blood supply in most cases rather than strangulated intestine within the scrotum itself. Inguinal hernias can also be detected on rectal palpation, and ultrasound of the testicle is very helpful in determining the diagnosis, particularly considering the differential diagnosis of testicular torsion. The nature of the hernia (direct versus indirect) is determined by the integrity of the parietal vaginal tunic. In horses in which the bowel remains within the parietal vaginal tunic, the hernia is said to be indirect, because strictly speaking the bowel remains within the peritoneal cavity. Direct hernias are those in which bowel ruptures through the parietal

vaginal tunic and occupies a subcutaneous location, followed by strangulation. Direct hernias most commonly occur in foals and should be suspected when a congenital inguinal hernia is associated with colic, swelling that extends from the inguinal region of the prepuce, and intestine that may be palpated subcutaneously.[609,610] Although most congenital indirect inguinal hernias resolve with repeated manual reduction and/or application of a diaper, surgical intervention is recommended in foals with congenital direct hernias in order to reduce the hernia as well as repair the parietal vaginal tunic.

In stallions with indirect inguinal hernias, manipulation of herniated bowel per rectum can be used to reduce a hernia but is not generally recommended because of the risk of a rectal tear. In addition, the inability to visually assess the integrity of the bowel may well be problematic. However, in many cases taken to surgery, the short segment of herniated intestine will markedly improve in appearance once it has been surgically reduced, and in some cases the affected intestine can be left unresected. The affected testicle will be congested because of vascular compromise within the spermatic cord, and although it may remain viable, it is recommended that it be resected. Furthermore, the inguinal canal should be partially closed at surgery to prevent recurrence, and the risk that this procedure will reduce spermatic cord vasculature is a further problem. The prognosis in adult horses is good, with up to 75% of horses surviving to 6 months of age.[608] Horses that have been treated for inguinal hernias may be used for breeding. In these horses, the remaining testicle will have increased sperm production, although an increased number of sperm abnormalities will be noticed after surgery because of edema and increased temperature of the scrotum.

32.71.5 Strangulating Umbilical Hernias

Although umbilical hernias are common in foals, strangulation of herniated bowel is rare. In one study, 6 of 147 horses with umbilical hernias (4%) had incarcerated intestine.[611] Clinical signs include a warm, swollen, firm, and painful hernia sac associated with signs of colic. The affected segment of bowel is usually small intestine, but herniation of cecum or large colon has also been reported.[612] In rare cases a hernia that involves only part of the intestinal wall may be found and is referred to as *Richter's hernia*. In foals that have Richter's hernia, an enterocutaneous fistula may develop. In one study, 13 of 13 foals with strangulating umbilical hernias survived to discharge, although at least three horses died because of long-term complications.[612]

32.71.6 Diaphragmatic Hernias

Herniation of intestine through a rent in the diaphragm is uncommon in the horse, accounting for 0.3% of all cases of colic in a large multicenter study.[584] Any segment of bowel may be involved, although small intestine is most frequently herniated.[613] Diaphragmatic rents may be congenital or acquired, but acquired hernias are more common. Congenital rents may result from incomplete fusion of any of the four embryonic components of the diaphragm: pleuroperitoneal membranes, transverse septum, and esophageal mesentery. In addition, abdominal compression of the foal at parturition may result in a congenital hernia. Acquired hernias are presumed to result from trauma to the chest or a sudden increase in intraabdominal pressure such as might occur during parturition, distention of the abdomen, a sudden fall, or strenuous exercise.[614] In one study, 19 of 40 horses diagnosed with diaphragmatic hernia (48%) had a history of recent trauma.[615] Hernias have been located in a number of different locations, although large congenital hernias are typically present at the most ventral aspect of the diaphragm and most acquired hernias are located at the junction of the muscular and tendinous portions of the diaphragm. In addition, a peritoneal-pericardial hernia has been documented in at least one horse.[616]

The clinical signs are usually associated with intestinal obstruction rather than respiratory embarrassment. However, careful auscultation may reveal an area of decreased lung sounds associated with obstructed intestine and increased fluid within the chest cavity. Such signs may prompt thoracic radiography or ultrasound, both of which can be used to make a diagnosis. In one review, 7 of 40 horses reported in the literature with diaphragmatic hernia (18%) had dyspnea.[615] Auscultation may also reveal thoracic intestinal sounds, but it is typically not possible to differentiate these from sounds referred from the abdomen. In one report, two of three horses diagnosed with small intestinal strangulation by diaphragmatic hernia had respiratory acidemia, attributable to decreased ventilation.[617]

32.71.7 Intussusceptions

An intussusception involves a segment of bowel (intussusceptum) that invaginates into an adjacent aboral segment of bowel (intussuscipiens). The reason for such invagination is not clear, but it may involve a lesion at the leading edge of the intussusception, including small masses, foreign bodies, or parasites. In particular, tapeworms *(Anoplocephala perfoliata)* have been implicated.[618] Ileocecal intussusceptions are the most common intestinal intussusceptions in the horse and typically affect young animals. For example, in one study evaluating 26 cases of ileocecal intussusception, the median age of the horses was 1 year old.[619] Acute ileocecal intussusceptions are those in which the horse has a duration of colic of less than 24 hours and involve variable lengths of intestine that ranged in one study from 6 cm to 457 cm long. In acute cases the involved segment of ileum typically has a compromised blood supply. Chronic ileocecal intussusceptions typically involve short segments of ileum (up to 10 cm long), and the ileal blood supply is frequently intact. Abdominocentesis results are variable because strangulated bowel is contained within the adjacent bowel. There is often evidence of obstruction of the small intestine, including nasogastric reflux and multiple distended loops of small intestine on rectal palpation. Horses with chronic ileocecal intussusceptions have mild, intermittent colic, often without evidence of small intestinal obstruction. A mass may be palpated in the region of the cecal base in approximately 50% of cases. Transabdominal ultrasound may be helpful in discerning the nature of the mass. The intussusception has a characteristic target appearance on cross-section.[620]

736

737

Other segments of the small intestine may also be intussuscepted, including the jejunum. In one study on 11 jejunojejunal intussusceptions, the length of bowel involved ranged from 0.4 to 9.1 m.[621] Attempts at reducing intussusceptions at surgery are usually futile because of intramural swelling of affected bowel. Jejunojejunal intussusceptions should be resected. For acute ileocecal intussusceptions the small intestine should be transected as far distally as possible, and a jejunocecal anastomosis performed. In cases with particularly long intussusceptions (length up to 10 m has been reported), an intracecal resection may be attempted. For horses with chronic ileocecal intussusceptions, a jejunocecal by-pass without small intestinal transection should be performed.

In one study that evaluated the survival of horses with ileocecal intussusceptions, seven of seven horses with chronic intussusceptions survived long term (>4 months), whereas only 5 of 12 horses with acute intussusceptions (42%) survived long term.[619] In a separate study that evaluated survival in horses with jejunojejunal intussusceptions, 6 of 11 horses (54%) were discharged from the hospital after surgery, and 4 of 11 horses (36%) survived long term (>16 months).[621]

32.71.8 Other Small Intestinal Strangulations

Entrapment of the small intestine may occur through rents in the mesentery, internal ligaments such as the gastrosplenic ligament,[622] the broad ligament, and the proximal aspect of the cecocolic ligament.[623] Entrapments may also occur through trauma-induced body wall hernias. For all of these conditions it is often necessary to enlarge the rent or hernia to allow reduction of entrapped small intestine. In the case of body wall hernias, the defect should be closed with suture, or patched using mesh. Entrapment of small intestine within mesenteric rents appears to be particularly problematic because they are difficult to reduce and have an unfavorable prognosis. The latter may be a result of the fact that large lengths of intestine may become strangulated, and because the mesenteric vasculature is frequently compromised to the extent that intraabdominal hemorrhage has been noted in some cases.[624]

32.72 NONSTRANGULATING INFARCTION

Nonstrangulating infarction occurs secondary to cranial mesenteric arteritis caused by migration of *S. vulgaris*[625] and has become a rare surgical disorder since the advent of broad-spectrum anthelmintics. Although thromboemboli have been implicated in the pathogenesis of this disease, careful dissection of naturally occurring lesions has not revealed the presence of thrombi at the site of intestinal infarctions in most cases. These findings suggest that vasospasm plays an important role in this disease.[625] Clinical signs are highly variable, depending on the extent to which arterial flow is reduced and the segment of intestine affected. Any segment of intestine supplied by the cranial mesenteric artery or one of its major branches may be affected, but the distal small intestine and large colon are more commonly involved. There are no clinical variables that can be used to reliably predict or differentiate this disease from strangulating obstruction. In some cases massive infarction results in acute, severe colic. Other cases may have intermittent colic as smaller emboli are released into the colonic blood supply. Occasionally an abnormal mass and fremitus may be detected on palpation of the root of the cranial mesenteric artery per rectum. This disease should be considered a differential diagnosis in horses with a history of inadequate anthelmintic treatment and the presence of intermittent colic that is difficult to localize. Although fecal parasite egg counts should be performed, they are neither indicative of the degree nor specific for the type of parasitic infestation.

In addition to routine treatment of colic, dehydration, and endotoxemia, medical treatment may include aspirin (20 mg/kg q24h) to decrease thrombosis. Definitive diagnosis requires surgical exploration. Surgical treatment depends on the distribution of infarction. Unfortunately, these cases are difficult to treat because of the patchy distribution of the lesions and the possibility of lesions extending beyond the limits of surgical resection. In addition, further infarction may occur after surgery. The prognosis is fair for horses with intermittent mild episodes of colic that may be amenable to medical therapy, but horses that require surgical intervention have a poor prognosis.[625]

32.73 GASTROINTESTINAL ILEUS

Guy D. Lester

A number of factors are responsible for movement of feed through the gastrointestinal tract, and disturbance to any of these could result in ineffective transit and signs of abdominal pain. Gastrointestinal motility involves an extremely complex interaction among the enteric nervous system, the wall of the intestine, and the luminal contents. Other factors that influence the transit of digesta include gravity, the volume and viscosity of the contents,

and pressure gradients created by simultaneous contraction and relaxation of adjacent segments of bowel. Several equine diseases likely involve altered gastrointestinal motility including POI, cecal emptying defect, gastroduodenal ulcer disease, intraluminal obstruction, bowel distention, strangulating obstructions, peritonitis, and primary IBDs, such as DPJ or colitis. Ineffective intestinal motility is also a feature of several neonatal diseases including prematurity, systemic sepsis, and perinatal asphyxia. Certain parasitic infections, electrolyte derangements, and endotoxemia can modify digesta transit in horses of all ages. Intestinal motility is also disturbed during general anesthesia and when specific sedatives, such as xylazine, romifidine, or detomidine, are administered.

32.74 POSTOPERATIVE ILEUS

The inhibition of propulsive bowel activity is usually referred to as *ileus*. Ileus is most frequently ascribed to the condition that occurs after laparotomy and is termed *simple* or *uncomplicated postoperative ileus*. When intestinal motility is disturbed for longer periods after surgery, typically for more than 72 hours, the term *complicated* or *paralytic ileus* is used.[626] POI in horses is most commonly associated with surgery of the small intestine, particularly after resection and anastomosis. The true incidence of POI in horses undergoing laparotomy for gastrointestinal disease is difficult to determine because of variation in definition, surgical skill, and anesthetic technique. POI was reported as a complication in only 10% of horses that underwent laparotomy for a small intestinal lesion at a referral practice.[627] However in a multicenter study 47 of 251 horses undergoing laparotomy for acute colic including small and large intestinal disease developed POI.[628]

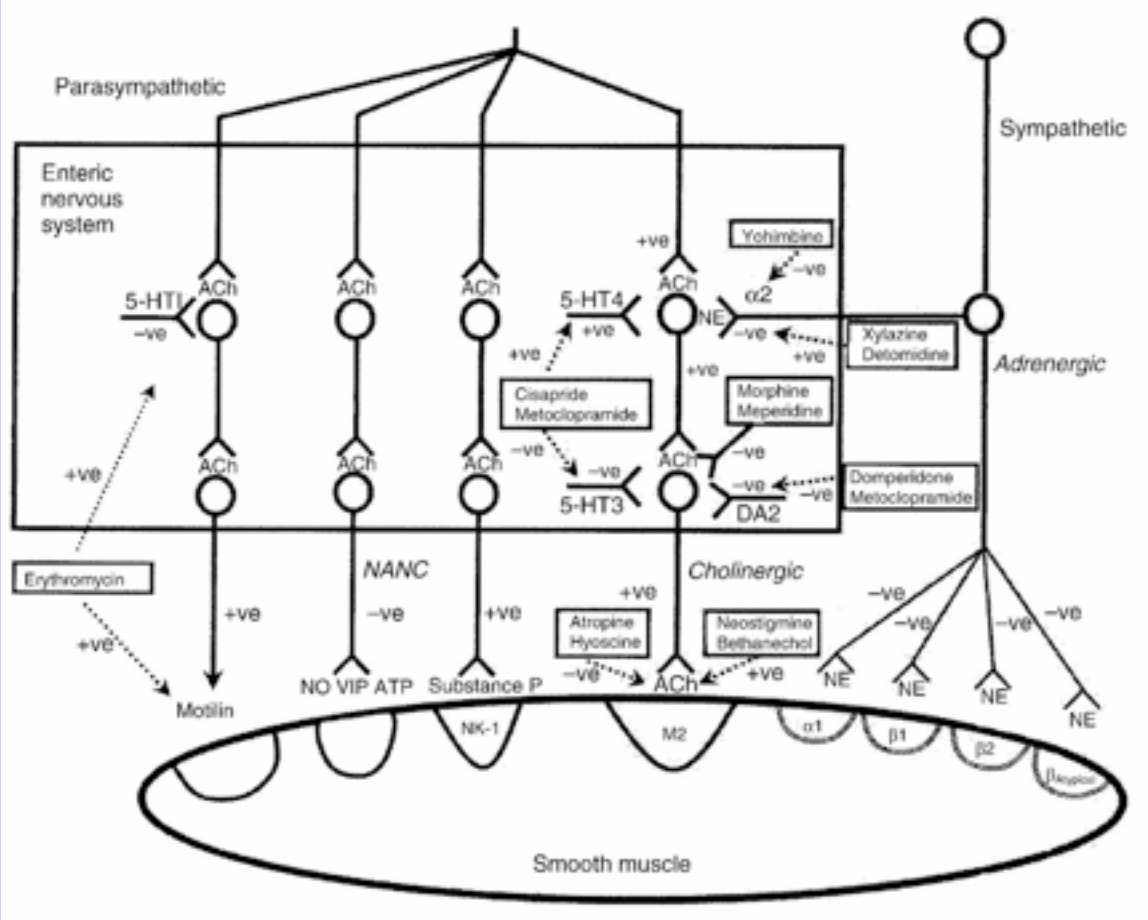
POI can have a significant negative impact on short-term postoperative survival.[629,630] Motility dysfunction is likely present in all horses after laparotomy, but most cases are subclinical and require minimal intervention. In symptomatic animals clinical signs are typically observed within 24 hours of recovery and include colic, tachycardia, dehydration, decreased borborygmi and fecal output, and sequestration of fluid within the stomach. Rectal examination and ultrasound may reveal small intestinal distention with rare or absent wall movement. The severity and duration of intestinal stasis is variable, lasting from minutes to days.

737 738

32.75 CECAL EMPTYING DEFECT

An important and specific motility problem involving the cecum occurs sporadically in horses.[631–634] There are limited epidemiologic data about the condition, and key aspects of the pathophysiology are not known. Cecal emptying defect occurs most commonly after general anesthesia and extraabdominal surgery, particularly orthopedic and upper airway procedures, and is therefore often categorized as a form of POI. Young male performance animals appear to be at greatest risk, especially if the procedure is performed with the animal in full work. Other cases occur spontaneously, often in animals with painful primary conditions such as uveitis, orchitis, or septic tenosynovitis. Clinical signs are often subtle unless perforation has occurred. In horses with a cecal emptying defect after anesthesia, clinical signs are usually apparent by 3 to 5 days after the procedure. The earliest detectable signs include depression and a reduction in appetite and fecal output. Ineffective emptying results in overfilling of the cecum with moist contents, which is manifest by signs of mild to moderate colic. If the condition is recognized late or untreated, the cecum may rupture, resulting in fatal peritonitis.

Fig. 32-54 Schematic representation of some neural and hormonal influences on intestinal motility. *ACh*, Acetylcholine; *ATP*, adenosine triphosphate; *DA2*, dopamine type 2 receptors; *+5-HT1*, 5-hydroxytryptamine type 1 receptors; *M2*, muscarinic type 2 receptors; *NANC*, noncholinergic, nonadrenergic pathway; *NE*, norepinephrine; *NK-1*, neurokinin-1 receptors, *NO*, nitric oxide; *+ve*, excitatory; *+ve*, inhibitory; *VIP*, vasoactive intestinal peptide.



32.75.1 Physiology

The control of intestinal motility is complex and involves a combination of central innervation, autonomic innervation, and the enteric nervous system (Fig. 32-54). Intestinal contractions are primarily controlled by the enteric nervous system and do not require extrinsic neural input. The inherent rhythmicity of electrical activity in the intestine is controlled by the interstitial cells of Cajal (ICCs). These are highly specialized cells that are electrically coupled to the smooth muscle syncytium via gap junctions.[635] ICCs are responsible not only for

generation of slow waves (cyclical electrical activity), but also for coordination of pacemaker activity and propagation of slow waves along the intestine. ICCs appear to be critically involved in a range of motility disorders in humans, including gastroparesis, pseudoobstruction, and chronic constipation.[636] In horses a reduction in ICC density was demonstrated with equine dysautonomia (grass sickness) and in horses with large intestinal disease.[637,638]

The inherent "excitability" of smooth muscle cells in response to stimuli varies among regions of the gastrointestinal tract and among species. This variability in cell excitability is dependent on the magnitude of the membrane potential, which in turn is regulated by the number and subtype of potassium channels.[635]

The enteric nervous system plays an important role in control and coordination of intestinal contraction. Contractile events are influenced by central and autonomic innervation, but external neural input is not required for contraction. The parasympathetic supply to the gastrointestinal tract is via the vagus and pelvic nerves, and the sympathetic supply is through postganglionic fibers of the cranial and caudal mesenteric plexuses. A complex network of interneurones within each plexus integrates and amplifies neural input, and the intensity and frequency of resultant smooth muscle contractions are proportional to sympathetic and parasympathetic input. Additional binding sites for a number of other endogenous chemicals, including dopamine, motilin, and serotonin, can be found within the enteric nervous system and on smooth muscle cells.[639] It is important to appreciate that mechanisms to slow progressive intestinal motility are also critical in order to retain feed for adequate digestion and absorption of nutrients. The terms *jejunal* and *ileal brake* have been used to describe the slowing of transit caused by mediators such as peptide YY, noradrenergic nerves, and opioid, serotonergic, and chemosensitive afferent neurons.[640]

738

739

Acetylcholine (ACh) is the dominant excitatory neurotransmitter in the gastrointestinal tract and exerts its action through muscarinic type 2 (M_2) and M_3 receptors. Sympathetic fibers innervating the gastrointestinal trace are adrenergic, postganglionic fibers with cell bodies located in the prevertebral ganglia. Activation of α_2-adrenergic receptors on cholinergic neurons within enteric ganglia inhibits the release of ACh and therefore reduces intestinal contraction. The β_1-, β_2- and β-atypical receptors are directly inhibitory to the intestinal smooth muscle.[641] Inhibitory nonadrenergic, noncholinergic (NANC) neurotransmiters include ATP, vasoactive intestinal peptide (VIP), and nitric oxide (NO).[642,643] These neurotransmitters are critical for mediating descending inhibition during peristalsis and receptive relaxation. Substance P is a NANC neurotransmitter that may be involved in contraction of the small intestine and large colon.[644–646] The rate and force of intestinal contractions along the small intestine and large colon of the horse are key determinants of intestinal motility. Of even greater importance to the net propulsion of digesta are the cyclical patterns of contractile activity. These patterns are known as the *small intestinal* and *colonic migrating motility complexes (MMC)*.[647] The colonic complex usually originates in the right ventral colon and variably traverses the ascending and descending colons. Many of these complexes are temporally related to a specialized motility event of the ileum known as the *migrating action potential complex*.

32.76 MEDIATORS OF GASTROINTESTINAL ILEUS

Inflammation within the intestinal muscularis and inhibitory neural events are important initiators of intestinal ileus.[648,649] Intestinal inflammation is not only important in primary intestinal diseases in horses, such as DPJ and colitis, but is induced after simple intestinal handling during laparotomy. Experimental data from other species suggests that handling of the small or large intestine at the time of surgery induces an intense inflammatory response within the muscularis and a reduction in the intensity of smooth muscle contraction. Furthermore, the

inflamed intestine fails to contract normally in response to putative prokinetic agents. Additional studies have identified that this inflammatory response was not restricted to segments that were manipulated at the time of surgery but also involved other regions throughout the gastrointestinal tract.[649] Intestinal handling in experimental animals causes local overproduction of NO because of the upregulation of iNOS by resident macrophages.[650] NO is a key inhibitory neurotransmitter of the NANC system.[643] Consequently NOS inhibition could be an important target for prevention of ileus.

The inhibition of motility associated with peritoneal inflammation may also be mediated through neural reflexes. The afferent segment is partly composed of capsaicin-sensitive visceral afferent C-fibers that terminate in the dorsal horn of the spinal cord, where they can activate inhibitory sympathetic fibers or, alternatively, synapse directly on the sympathetic ganglia. Consequently the efferent limb of the reflex expresses increased sympathetic outflow, primarily mediated through stimulation of α2-adrenoreceptors, with subsequent inhibition of ACh release. This provides the rationale for alpha-2 blockade in the treatment of ileus. Intraluminal infusion of capsaicin before abdominal surgery ameliorated the severity of POI in experimental rats.[651] This finding highlights the importance of visceral afferent fibers in the development of POI.

Ileus can also occur with intestinal obstruction or displacement. Mild to moderate distention of the bowel, such as that occurring in the early stages of an intraluminal obstruction, evokes an increase in local contractile activity.[652,653] Excessive distention results in inhibition of motility within the distended segment of bowel. Intestinal stasis is not always detrimental and under certain conditions may be protective.

Endotoxemia is a feature of many diseases of the equine gastrointestinal tract, and endotoxins can independently exert a negative effect on intestinal motility and transit.[654] Various mediators are likely involved, but activation of α_2-adrenoreceptors and production of prostanoids appear to be important, as the inhibitory effects of experimental endotoxin infusion are ameliorated by pretreatment with yohimbine or NSAIDs (phenylbutazone or flunixin), respectively.[655,656] Endotoxin infusion induced an inflammatory response in the intestine of rats that mimicked that induced by handling during laparotomy.[657]

The pathophysiology of cecal emptying defect is not known. This syndrome may best mimic POI in humans, which is generally considered a large intestinal disorder. An important difference in horses is that laparotomy is a rare predisposing factor, and most cases occur in horses undergoing routine extraabdominal surgical procedures. General anesthesia itself is a potent inhibitor of gastrointestinal motility in horses, but the effects are short-lived and reversible within hours of anesthetic withdrawal.[658] The return of normal motility in horses after experimental ileus was most delayed in the cecum, suggesting that this may be a common site of ileus in horses.[659] A link between routine postoperative medications, such as phenylbutazone and aminoglycoside antibiotics, has been suspected but not established. An inhibitory effect of NSAIDs on large colon contractility has been demonstrated using in vitro techniques, although the effect of selective COX-2 inhibitors was variable and not as marked as that of mixed isoform inhibitors.[660,661] Primary sympathetic overstimulation could be involved, as many of the affected animals are young, male horses or animals with painful diseases.

The development of small intestinal POI, but not cecal emptying dysfunction, is influenced by the duration of surgery.[628,632] Technique may have a weak influence on small intestinal POI after jejunojejunostomy. The duration of intestinal ileus was shorter in animals that received a side-to-side stapled anastomosis than in those that had a hand-sewn end-to-end procedure.[629] The duration of ileus after stapled end-to-end anastomosis was not different from that after either procedure.

Reported risk factors for the development of POI in horses include age (>10 years), small intestinal resection and anastomosis, breed, and duration of anesthesia and surgery.[628,662] A pelvic flexure enterotomy and emptying the colon and intraoperative lidocaine infusion had a protective effect against POI.

The inhibitory effects of α_2-adrenergic agonists, such as xylazine and detomidine, on intestinal motility in horses are well described.[663–671] The activation of postganglionic cholinergic nerves in the myenteric plexus by this class of drugs results in reduced ACh release from autonomic and enteric nerves. Intravenous xylazine inhibits cecal and large colon motility for 20 to 30 minutes without seriously disrupting small intestinal myoelectric activity, and detomidine can reduce large intestinal myoelectric activity for up to 3 hours. The α_2-antagonist yohimbine has a weak but positive effect on cecal emptying in normal ponies, suggesting that normal motility is under constant α_2-adrenergic tone.[665] Atropine is a postganglionic blocking agent that binds to muscarinic receptors. When administered at 0.04 mg/kg, individual small intestinal, cecal, and colonic contractions are inhibited for about 120 minutes, but small intestinal and colonic migrating complexes are suppressed for up to 8 hours.[672]

739

740

32.76.1 Diagnosis

The diagnosis of ileus is based on history and physical examination findings. Important tests include determination of pulse rate and rhythm, auscultation and percussion of the abdomen, rectal palpation, and passage of a nasogastric tube. A CBC with fibrinogen estimation and cytologic analysis of peritoneal fluid may improve the accuracy of diagnosis. Affected animals may be colicky because of accumulation of fluid in the upper gastrointestinal tract (classical POI) or cecal contents (cecal emptying defect). Decompression of the stomach is important diagnostically and therapeutically in horses with POI after small intestinal surgery. Failure to relieve pain with gastric decompression could point toward mechanical obstruction, severe inflammation of the intestine, or peritonitis. Most animals with ileus are depressed and have reduced fecal output and intestinal borborygmi. Intestinal sounds should, however, be interpreted with caution, because the presence of borborygmi does not always equate to progressive intestinal motility and may merely reflect local, nonpropagated contractions. Rectal palpation findings in cases of persistent POI or DPJ are usually nonspecific but may reveal dilated, fluid-filled loops of small intestine. Roughened peritoneal surfaces can occasionally be palpated if there is peritonitis. Cecal distention with digesta can be palpated in horses with advanced cecal dysfunction.

It is important to distinguish functional ileus from mechanical obstruction. This can be extremely difficult, but horses with mechanical obstruction typically have sustained high volumes of gastric reflux that vary little over time.

32.76.2 Treatment

The management of gastrointestinal ileus is dependent on the segment of gastrointestinal tract involved. Therapy for ileus of the proximal gastrointestinal tract typically involves a combination of gastric decompression, fluid and electrolyte therapy, and antiinflammatory drugs. Nasogastric decompression is the mainstay of management to prevent overdistention of the stomach and small intestine. This often necessitates placement of an indwelling nasogastric tube, a procedure that some have speculated may in itself delay gastric emptying. The placement of an indwelling tube for 18 hours did not adversely affect the emptying of liquids, but in a recent study a delay was noted when the tube was left in place for 72 hours.[673,674] Both studies used apparently healthy animals.

Electrolyte balance is important, particularly with respect to maintaining adequate extracellular concentrations of potassium, calcium, and magnesium. Calculation of the volume of fluid to be administered should include

maintenance requirements (40 to 60 mL/kg/day) plus an estimate of losses, especially those lost through gastric decompression. Overhydration should be avoided in horses with small intestinal ileus. Fluid therapy is the key component in the management of cecal emptying defect, usually in combination with lubricants or laxatives, such as mineral oil or magnesium sulfate, and with careful use of antiinflammatory drugs. Horses with primary cecal impaction or impaction secondary to an emptying defect may require surgery in order to prevent rupture. The surgical management of these cases is controversial and may include typhlotomy alone, typhlotomy with a bypass procedure such as ileocolic or jejunocolic anastomosis, or a bypass without typhlotomy.[675] Most horses that undergo simple typhlotomy have an uneventful recovery, although a small number will reimpact and require a second laparotomy.[633]

A significant clinical or economic benefit of parenteral nutrition in adult horses with gastrointestinal disease has also yet to be demonstrated.[676–678] Parenteral nutrition should be considered when feed has been withheld for more than 96 hours, particularly in the horse with a surgical wound. Limited exercise, in the form of hand-walking, may provide some benefit to these animals, although there is no evidence that exercise has a direct impact on intestinal motility in either horses or humans with POI.[679]

Drugs that may retard normal intestinal motility should be avoided in horses with gastrointestinal ileus. These include the anticholinergics, such as atropine, and opiate receptor agonists, such as morphine and meperidine.[680,681] Butorphanol appears to have little or no adverse effect on either small or large intestinal motility.[682,683] α2-Adrenergic agonists should be used sparingly because of their inhibitory effects on large intestinal motility.

The pivotal role of intestinal inflammation provides a strong rationale for the use of antiinflammatory drugs in affected animals. Flunixin meglumine is widely used in equine practice as an analgesic and antiinflammatory agent, and it also ameliorates many of the adverse systemic effects of endotoxin. A potential negative effect of NSAIDs on large intestinal contractility has been suggested on the basis of in vitro studies[660]; however, a similar response has not been reported in whole animal studies.[663,665,684] There may be a role for novel agents in the future. Carbon monoxide (CO) has prevented POI in experimental animals, a benefit not only when CO was inhaled but also when CO was dissolved in a peritoneal lavage solution, making potential administration considerably easier and safer.[685] CO has potent intestinal antiinflammatory properties and is derived from the degradation of heme by the enzyme heme oxygenase. Expression of a heme oxygenase isoform (HO-1) can be induced by a variety of stimuli.

Broad-spectrum antimicrobial drugs are indicated when sepsis is suspected or if the immune system is compromised, as in cases with moderate to severe endotoxemia. Theoretic concerns have been raised regarding the use of aminoglycoside antibiotics in animals with ileus. Inhibition of intestinal contractions occurred when sections of intestine were exposed to high concentrations of aminoglycoside antimicrobial drugs, but this inhibitory effect is unlikely to occur at clinically relevant doses.[686] The administration of benzyl penicillin and/or ceftiofur was associated with an increased risk of colic in the week after anesthesia for diagnostic imaging or nonabdominal surgical procedures.[687]

Motility-modifying drugs could play an important role in the prevention and treatment of gastrointestinal ileus. An effective prokinetic agent could shorten the length of hospitalization, thereby reducing the cost of treatment and the number of potential complications such as weight loss, thrombophlebitis, and laminitis. There is also evidence that the development of abdominal adhesions could be minimized with the use of an effective prokinetic drug.[688,689] A potential negative impact of prokinetic use in the postoperative period after anastomosis is increased predisposition to dehiscence.[690]

Most motility-modifying drugs require a healthy intestinal wall in order to enhance intestinal contraction. There are several examples in horses in which the expected contractile response to certain drugs is blunted in the face of disease. It is reasonable to assume that many putative prokinetic drugs would be partially or totally ineffective in horses with abdominal disease. This would include intestine that has undergone prolonged or excessive distention or that is in any inflammatory condition, such as after intestinal manipulation or associated with primary inflammatory diseases such as DPJ or *Salmonella* enteritis. Numerous drugs have been investigated in humans with POI, but currently there is no prokinetic agent that has been found to be safe and effective.[691] The financial pressures associated with equine patient management often compel attending veterinarians to "experiment" with a range of putative prokinetic drugs.

Bethanechol is a methyl derivate of carbachol and is an ACh receptor agonist. The drug acts both at the level of the myenteric plexus and directly on intestinal smooth cells through muscarinic receptors. The actions are primarily mediated through activation of M_3 receptors, although M_2 receptors are also involved to a lesser extent.[692] There is evidence in other species that activation of M_2 receptors not only facilitates intestinal contraction but also may lead to antinociception.[693] Bethanechol is not degraded by the enzyme anticholinesterase. As anticipated the drug has a range of cholinergic side effects, including abdominal discomfort, sweating, and salivation, although these are minimal when the drug is administered at 0.025 to 0.05 mg/kg of body weight SC. Bethanechol is one of the most useful prokinetic agents in equine practice, as it exerts effects throughout the gastrointestinal tract; however, it does not appear to be commonly used.[694] It is most commonly used in the management of delayed gastric emptying and slowed small intestinal transit. Experimentally the drug has been shown to significantly increase gastric contractility and hasten the emptying of liquid and solid phase markers from the stomach of normal horses.[695,696] The drug has potent effects in the hindgut as well. Bethanechol increases both the relative strength and duration of wall contractions in the cecum and right ventral colon and consequently speeds up cecal emptying.[665] When given to ponies at a dose of 0.05 mg/kg SC, the drug increased electrical activity in the large colon for approximately 80 minutes.[684] There are wide ranges in reported dose rates of bethanechol, with doses up to 0.25 mg/kg recommended for oral administration in the management of delayed gastric emptying.

Neostigmine increases receptor levels of ACh by inhibiting cholinesterase. The drug (0.022 to 0.025 mg/kg IV) promotes cecal and colonic contractile activity and enhances cecal emptying in normal ponies.[665] Neostigmine has been used in the management of small intestinal ileus but significantly delayed the emptying of 6-mm beads from the stomach of normal adult horses.[697] A survey of prokinetic use indicated that neostigmine was more commonly used in the management of large intestinal disease.[694]

Metoclopramide is a moderate partial 5-hydroxytryptamine 4 (5HT-4)–receptor agonist, a moderate 5HT-3–receptor antagonist, and an antagonist of both dopamine 1 (DA_1) and 2 (DA_2) receptors. It has been suggested that the 5HT-4 agonist properties are primarily responsible for the prokinetic effects of metoclopramide. Antagonism of prejunctional DA_2 receptors facilitates ACh release and smooth muscle contraction. The effect on dopamine receptor antagonism is absent in newer benzamides. Metoclopramide crosses the blood brain barrier, where its antagonist properties on central DA_2 receptors can result in extrapyramidal signs, including seizure. These have been observed when the original reported dose of 0.25 mg/kg, given by intravenous infusion over 30 minutes, was used in practice.[698] These signs were responsible for poor acceptance of the drug in equine practice. An experimental bolus of endotoxin caused a delay in gastric emptying, as assessed using the acetaminophen absorption test; this delay was partially ameliorated through pretreatment with metoclopramide

(0.125 mg/kg in 1 L infused over 15 minutes), but again the investigators reported adverse side effects.[699] Most investigators have failed to demonstrate significant effects of metoclopramide in experimental animals, but constant intravenous infusion (0.04 mg/kg/hr) in a population of postoperative horses significantly decreased the volume and duration of gastric reflux over control and intermittent drug infusion groups.[700] Infusion was well tolerated and was superior to intermittent infusion or no treatment at all.

Cisapride is a second-generation benzamide that is commonly reported to act as a primary 5HT-4 agonist and 5HT-3–receptor antagonist. Furthermore, stimulation of 5HT-4 receptors within the enteric nervous system enhances release of ACh from the myenteric plexus, thereby promoting intestinal contraction. In vitro studies of equine jejunum concluded that the contractile actions of cisapride in the species were primarily mediated through 5HT-2 and not 5HT-4 receptors and that the response was noncholinergic.[701] Several reports suggest efficacy of cisapride in the management of intestinal disease in horses, including the resolution of persistent large colon impaction, treatment of equine grass sickness, and prevention of POI in horses after small intestinal surgery (0.1 mg/kg body weight IM during postoperative period).[702–705] Cisapride has the potential to cause adverse cardiac side effects mediated through blockage of the rapid component of the delayed rectifier potassium current that include lengthening of the QT interval and development of torsades de pointes, a potentially fatal arrhythmia. These adverse effects have resulted in drug withdrawal in the United States and in many other countries. Another benzamide, mosapride, resulted in increased myoelectric activity of the small intestine and cecum of horses after oral administration. The authors reported that mosapride is a selective 5HT-4 agonist; consequently the reported effects are surprising given that the actions of 5-HT on the equine jejunum were reported to be primarily mediated through activation of 5HT-2 and 5HT-3 receptors.[701] Mosapride is marketed in several Asian countries and is not available in the United States.

Domperidone acts as a competitive antagonist at peripheral DA_2 receptors; these receptors are inhibitory. The drug has been used to manage gastroparesis in humans for many years.[706] The primary use in equine practice is in the management of mares grazing endophyte-infected tall fescue (1.1 mg/kg/day PO), principally because of drug-enhanced prolactin release from the anterior pituitary. The potential prokinetic effects of domperidone have not been extensively studied in horses, but a modest efficacy of domperidone (0.2 mg/kg IV) was demonstrated in a model of experimental ileus in two ponies.[702]

Erythromycin is a direct motilin receptor agonist acting directly on smooth muscle cells as well as within the enteric nervous system to facilitate the release of ACh and motilin. Erythromycin enhances gastric emptying in normal horses but in contrast to most other species has a more pronounced effect on the hindgut.[695,707] This is somewhat surprising given that a higher density of motilin receptors was reported in the duodenum than in either the cecum or pelvic flexure of adult horse.[708] Erythromycin lactobionate (1 mg/kg IV) hastens cecal emptying in normal animals and induces propagating colonic MMC-like activity across the colon. Administration is often associated with defecation and abdominal discomfort.

Several problems limit use of erythromycin as a prokinetic agent in equine practice. The principal use in human medicine has been restricted to management of acute exacerbations of diabetic gastroparesis, facilitation of feeding tube placement, and upper gastrointestinal endoscopy.[709] Although it has been shown to enhance emptying in normal horses, it was not as effective as bethanechol.[695] Given its potent prokinetic effects in the cecum, erythromycin may be helpful at preventing cecal impaction in horses after anesthesia. However, its effectiveness on cecal motility appears to be markedly reduced in the immediate postoperative period.[659] High doses, constant infusion, or prolonged use of erythromycin also induces receptor tachyphylaxis and therefore reduced efficacy. There is also evidence that as little as 2 hours of intraluminal distention leads to a reduction in

the total number of motilin receptors and in the amount of motilin receptor mRNA, although erythromycin binding to remaining motilin receptors is not affected.[710] Erythromycin can induce diarrhea in adults; therefore administration over many days should be avoided. The diarrhea induced by erythromycin is most likely mediated by *C. difficile* overgrowth and toxin elaboration.[711]

Given that opiates have an inhibitory effect on normal intestinal motility, it is not unreasonable to assume that antagonists may have the potential for prokinetic activity. Naloxone (0.05 mg/kg IV) have been shown to induce contractile activity in the cecum and left colon.[712] The administration of naloxone was often followed by defecation within 15 to 20 minutes. Naloxone has not been beneficial in preventing POI in human beings.[713] An in vitro study reported a direct contractile effect of the peripherally acting opioid antagonist *N*-methylnaltrexone on the circular muscle layer of the jejunum and large colon.[714] The authors suggested a potential role for the drug in preventing intestinal complications associated with the use of morphine for pain relief.

α_2-Adrenoreceptor antagonists, such as yohimbine and telazoline, counteract increased sympathetic outflow in response to nociceptive stimulation. Yohimbine (75 μg/kg by slow intravenous infusion) hastens cecal motility and emptying in normal ponies and also attenuates the negative effects of endotoxin on motility.[655,665]

Lidocaine (also referred to as *lignocaine* in some countries) appears to be the most commonly used putative prokinetic agent in the management and prevention of POI.[694] Intravenous infusion of lidocaine may suppress primary afferent neurons, thereby limiting reflex efferent inhibition of motility. It is also possible that lidocaine may block the inhibitory effect of NANC neurotransmitters on smooth muscle.[715] Any positive effect of lidocaine could also be related to the drug's significant antiinflammatory properties. These include amelioration of the cytokine response to endotoxemia, reduced neutrophil free-radical production, impaired leukocyte phagocytic function, and inhibition of leukocyte migration through suppression of chemokines.[716] As discussed earlier, inflammation may be the most important initiator of intestinal stasis in the postoperative period.

A combination of intraoperative and postoperative lidocaine infusion is commonly used as a preventative strategy against POI. Postanesthetic treatment typically involves a slow intravenous bolus of 2% lidocaine (1.3 mg/kg) followed by a constant infusion at 0.05 mg/kg/min for 24 hours. The recommended target range for serum concentration of lidocaine is 1 to 2 mg/dL. In a prospective study of horses undergoing laparotomy for colic, the authors failed to demonstrate any difference between lidocaine and saline infusion with respect to return of borborygmi, time to first feces, or gastric reflux.[717] The authors did, however, report some positive differences in several ultrasound parameters, including jejunal diameter and the apparent volume of peritoneal fluid. Unfortunately only several of the horses in the study had a small intestinal lesion that required resection and anastomosis, and only two animals developed significant POI, one in each group. Lidocaine infusion was also contrasted with saline infusion in a group of horses with DPJ or POI.[715] Criteria for inclusion in that study included animals with net gastric reflux of more than 2 L/hr for 24 hours or a cumulative reflux volume of more than 20 L in less than 24 hours. Significant benefits of lidocaine infusion included a reduction in the duration of refluxing, hastened passage of feces, and a shorter total period of hospitalization for survivors. There were horses that did not improve in response to lidocaine infusion, and animals that continued to produce net gastric reflux throughout the 24-hour infusion period had a poorer outcome.

The rate of lidocaine infusion requires close monitoring, because infusion can be associated with reversible side effects that include muscle fasciculations, ataxia, and seizure. The drug is highly protein-bound, so hypoproteinemic horses may be more susceptible to signs of toxicity.

32.77 MEDICAL DISORDERS OF THE LARGE INTESTINE

Samuel L. Jones

32.78 ACUTE DIARRHEA

Diarrhea in the horse can be defined as the passage of fecal material that has increased water content. It can vary from soft, formed stools with a mild to moderate increase in water content to projectile fecal passages that contain little solid matter. The passage of excessive water in the feces reflects disruption of the normal balance of fluid and electrolyte secretion and absorption in the intestinal tract. In adult horses diarrhea results almost exclusively from disorders of the large intestine, although diarrhea may be a feature of some descending small colon disorders. Diarrhea can result in significant losses of water, electrolytes, and plasma protein and is often accompanied by local and systemic inflammatory responses.

Diarrhea disorders in adult horses can be divided into those characterized by inflammation of the cecum and large intestine (typhlitis, colitis) and those in which there typically is not an inflammatory response. Inflammatory disorders can be those characterized by an acute inflammatory response (salmonellosis, Potomac horse fever [PHF], and clostridiosis, described later), disorders associated with endoparasitism (small and large strongyle larval migration or encystation), disorders arising from toxicity (cantharidin toxicity, described later, and nonsteroidal antiinflammatory toxicity, described on p. 754), and disorders included under the umbrella term *inflammatory bowel disease* (see p. 730). Disorders that can manifest with diarrhea but that typically do not have colonic inflammation include those in which there is increased intestinal hydrostatic pressure (congestive heart failure, cirrhotic liver disease), intraluminal osmolarity, and poorly defined disorders in which fluid secretion may be stimulated by the enteric nervous system.

742

743

Colitis is active inflammation within the colon that is usually associated with myriad local and systemic pathophysiologic events. Diarrhea is an important problem in horses with colitis, but impaired cardiopulmonary function, coagulopathies, and other sequelae of activation of inflammatory mediator cascades and septicemia can be most life-threatening. Complications that occur in colitis patients, regardless of cause, include overwhelming sepsis triggered by endotoxemia, septicemia and hematogenous organ colonization by bacteria, immune suppression and susceptibility to superinfection with bacteria or fungi, cecum or colon infarction, jugular vein thrombosis, and laminitis.

A variety of inflammatory cells and mediators affect the equine colon. With acute colitis the neutrophil is the effector cell, and the cascade of activation of inflammatory mediators associated with acute colitis is designed to bring neutrophils to where chemical signals indicative of bacterial infection have been detected. Signs of sepsis associated with endotoxemia (see p. 712) frequently accompany, or even precede, diarrhea in horses. Severe tissue inflammation can result in ulceration of the mucosal epithelium, resulting in chronic malabsorption and protein-losing enteropathy. Malabsorption of volatile fatty acids (VFAs) and metabolic alterations that result from excessive production and release of inflammatory mediators can lead to an energy deficit and catabolism of body tissues.

Specific diseases affecting the equine large colon (e.g., salmonellosis, PHF, clostridial colitis, and cantharidin toxicity) may have different activators of local and systemic inflammatory responses, and they can produce unique toxins that further contribute to tissue injury. Regardless of the cause, the clinical problems of affected horses are often similar, and the clinician must consider treatments that modify inflammatory changes and replace losses of

fluid, electrolytes, and plasma protein. In many cases the cause of the diarrhea is not determined. Descriptions of important causes of diarrhea in horses follow.

32.78.1 Salmonellosis

Salmonella bacteria possess an array of virulence factors that confer attributes of mucosal adhesion and invasion, produce enterotoxins that stimulate intestinal fluid secretion, activate local inflammation, including recruitment of inflammatory cells and the release of their mediators, cause local cytotoxic effects, and initiate systemic responses attributable to LPS.

32.78.2 Epidemiology

Numerous *Salmonella* serotypes have been associated with equine colitis, and overall more than 2500 serotypes of *Salmonella* have been described. *Salmonella* Typhimurium is the most frequently isolated serotype in horses, with dozens of other serotypes isolated sporadically. There are many reports describing clusters of cases of equine salmonellosis in which specific *Salmonella* serovars predominate. Nosocomial infections associated with *Salmonella* Krefeld,[718–720] *Salmonella* Typhimurium,[719] *Salmonella* Anatum,[721] and *Salmonella* Infantis[722] have been reported in recent years. Pertinent features of these bacteria are the ability to withstand a wide range of environmental conditions, the ability to rapidly invade and spread within the host (and thus be shed into the environment through the feces), and the range of severity of illness that results from infection.

Other key elements that influence whether clusters of cases will occur given the presence of a particular *Salmonella* serovar in the environment are availability and population density of susceptible hosts and the size of infective dose of the pathogen. It is for these reasons that veterinary hospitals, breeding farms, and other facilities that may have a high density of horses are most vulnerable to the development of *Salmonella* outbreaks. In one study at a veterinary teaching hospital, horses that were at greatest risk for developing salmonellosis were those treated with antimicrobial drugs or admitted for treatment of colic.[723] Such horses will include the majority of patients in any equine referral hospital. Breeding farms are susceptible to *Salmonella* outbreaks (or other enteric infections) because of the concentration of large numbers of immunologically immature newborn animals. In either case the particular *Salmonella* organism involved in disease outbreaks may not have to be especially virulent, because the inherent susceptibility of the host provides the microbe the opportunity to colonize and invade the host. Also of importance is the ability of the organism (inherent or acquired) to persist in the environment, lying in wait for both susceptible hosts and environmental conditions that favor its propagation and dissemination.

Serovars or strains of *Salmonella* that have newly acquired virulence plasmids can rapidly become established and spread among farms, sales areas, veterinary clinics, and veterinary teaching hospitals. Often the origin of these “new” bacteria is undetermined, but in some cases the organism can be traced to contaminated feed,[724] a specific shedder introduced into the environment, domestic or feral animals (barn cats), birds, and wildlife.

Salmonellae are ubiquitous in the environment, and the prevalence of fecal shedding varies by the group of horses sampled and the method of detection. Prevalence of fecal shedding, based on fecal culture, in asymptomatic horses admitted to teaching hospitals varied from 1% to 5%.[725,726] In a nationwide survey of prevalence of *Salmonella* in fecal samples from horses on farms and ranches. *Salmonella* bacteria were cultured from less than 1% of horses.[727] Use of PCR to detect *Salmonella* DNA in horse feces resulted in a prevalence rate of 17% in horses admitted to a teaching hospital for lameness examination and greater than 60% in

hospitalized horses with gastrointestinal disease.[728] In that report the PCR technique was determined to be specific for *Salmonella* DNA, but the test cannot differentiate between shedding of live bacteria and DNA from dead organisms.

Horses are not considered to be carriers per se of *Salmonella*, because no host-adapted *Salmonella* species have been identified in horses. *Salmonella* Abortus equi has now disappeared in the United States. Horses that shed *Salmonella* species in the feces usually do so transiently for several days to weeks; infrequently horses may shed salmonella bacteria for several months.

In acutely affected horses, large numbers of highly infective salmonellae can be shed in the diarrheic feces. Susceptible animals such as young foals, hospitalized horses receiving antimicrobial drugs, and horses under stress can become ill after becoming infected by numbers of salmonellae 100 to 1000 times less than those required to infect immunocompetent normal horses. Thus particular care should be taken in the management of horses and foals with diarrhea in environments in which there are animals at risk (e.g., hospitals, breeding farms, racetracks). Asymptomatic shedders generally pass relatively small numbers of salmonellae in the feces and do not appear to pose an important threat to healthy horses, although asymptomatic shedders have been responsible for outbreaks of salmonellosis in hospitals and on breeding farms.

743

744

32.78.3 Clinical Findings

Salmonellosis typically is characterized by an acute colitis that results in profuse diarrhea and occasionally abdominal pain. Horses with salmonellosis often have signs of sepsis associated with endotoxemia and suffer from cardiovascular shock, vascular leak syndrome, and coagulopathies. Horses are usually febrile, tachycardic, moderately to severely obtunded, and dehydrated. With other clinical syndromes of salmonella infection, diarrhea is not a feature. These syndromes include fever and leukopenia, colic, and proximal enteritis with gastric reflux.

32.78.4 Diagnosis

Confirmation of salmonellosis requires bacteriologic culture of *Salmonella* bacteria. Multiple fecal cultures for *Salmonella* species should be performed on all horses with diarrhea. It is recommended that at least three to five fecal samples collected 12 to 24 hours apart be submitted to increase the sensitivity of culture.[729] Samples with little solid matter often yield negative culture results, even when the horse is infected with *Salmonella*. Formed fecal samples are more likely to result in a positive culture result from infected horses. A 5- to 10-g amount of feces should be submitted for culture in selective media such as tetrathionate broth or selenite broth and brilliant green agar or XLD agar. Culture of a rectal mucosa biopsy may be a useful adjunctive test for *Salmonellosis*. PCR is a sensitive screening tool for detection of fecal *Salmonella* DNA and is important for environmental monitoring and biocontrol measures in hospitals.

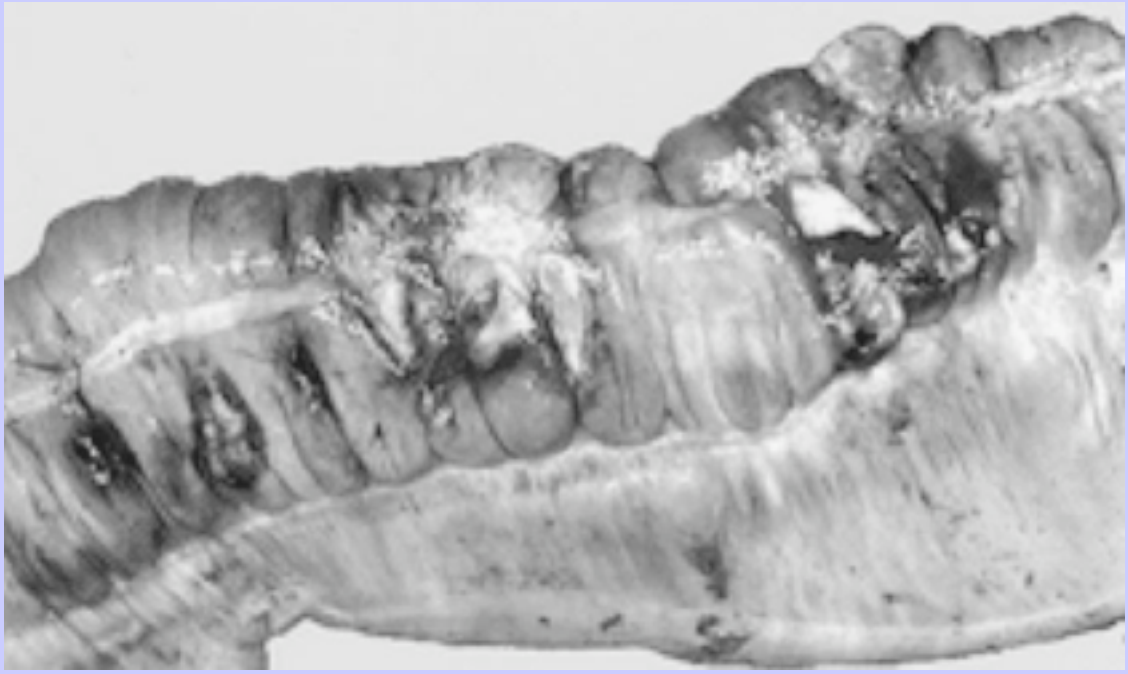
32.78.5 Treatment and Prevention

In most cases of salmonellosis, aggressive treatment facilitates resolution of the severe diarrhea and associated metabolic disorders within 7 to 10 days of the onset of illness. Intravenous administration of polyionic fluids is required to replace fluid and electrolyte losses and to augment preload in horses with poor venous return (see the Fluid Therapy for Horses with Gastrointestinal Diseases section [p. 767] and Chapter 44 for more comprehensive information about fluid therapy in horses with diarrhea). Plasma may be required to replace lost plasma proteins and increase plasma colloidal pressure. Alternative colloidal fluids, such as hetastarch, may be quite useful and

more cost-effective than plasma in horses with vascular leak syndrome and hypoproteinemia. Flunixin meglumine is often used to treat inflammation in horses with signs of sepsis. Flunixin and other NSAIDs should be used with caution and at the lowest dose possible to prevent worsening of colonic mucosal damage or inhibition of mucosal repair. Other antiinflammatory strategies may be used to treat sepsis associated with salmonellosis. Total or partial parenteral nutritional support is often indicated to provide adequate calories and amino acids during the most debilitating period of the illness. Antimicrobial administration to horses with suspected or known salmonellosis is not universally practiced. Antimicrobial administration may decrease the spread of salmonella bacteria to other organs and may have some direct effect on salmonella bacteria in the colon. Traditionally, use of antimicrobial drugs such as chloramphenicol, trimethoprim-sulfa (TMS), gentamicin, and cephalosporins has not appeared to accelerate resolution of signs of colitis. Fluoroquinolones, such as enrofloxacin, although potentially arthropathic in young horses, may be more effective because of high lipid solubility and bactericidal activity against *Salmonella* bacteria.

Horses that have severe diarrhea and sepsis for 10 days or longer are unlikely to survive, even with intensive therapy, because they often have extensive ulceration of colonic mucosa and chronic, severe inflammation within the wall of the colon. Ulceration may be exacerbated by administration of NSAIDs. Complications such as catheter-associated thrombophlebitis, colonic infarction (Fig. 32-55), colonization of other organs by salmonellae or other enteric bacteria, and laminitis can occur.

Fig. 32-55 Colonic infarction in a horse with salmonellosis. Tenesmus and rectal prolapse were early clinical signs of colonic infarction. Courtesy of Dr. M.J. Murray.



Measures designed to prevent the spread of *Salmonella* in an environment with potentially susceptible hosts need not be excessively laborious or expensive. The goal is to minimize the size of the infective dose of an enteric pathogen to which a susceptible host may be exposed. Thorough cleaning of areas where fecal contamination is

likely and prevention of mechanical distribution of contaminated material are the most important measures that should be taken. Extensive use of disinfectants may not be necessary if cleaning measures are adequate. Cleaning must include removal of organic debris, which can be accomplished with several products designed for that task. Areas that require particular attention are stalls, including water buckets or automatic watering systems, drains, and cracks in the floors and wall; stall implements; surgical areas, including drains; and nasogastric tubes and pumps.

If a diarrheic horse is in the environment, it should be isolated to the degree possible. Bedding material should be removed frequently to minimize accumulation of potential enteropathogens. Personnel entering the stall should be restricted to the professional staff, and they should wear disposable plastic boots. Footbaths with disinfectant often are not effective because they quickly accumulate organic material that interferes with the disinfectant activity of the footbath. Once a horse vacates a stall, the stall should be thoroughly cleaned, allowed to dry, disinfected, and determined to be negative for *Salmonella* by culturing selected sites in the stall (floor, drain, waterer). Personnel should use common sense when dealing with diarrheic animals. If bedding is being blown about by wind or if mechanical blowers are used to clean aisles, then potential enteric pathogens may be readily spread to other horses.

32.78.6 Potomac Horse Fever

PHF is an infectious enterocolonic disorder caused by *N. risticii* (formerly *Ehrlichia risticii*).[730,731] The organism is an obligate intracellular parasite, infecting peripheral monocytes and macrophages, colonic and small intestinal epithelial cells, and colon mast cells.[732] The pathophysiology of the disease is incompletely understood, although horses infected with *N. risticii* often have clinical signs and complications similar to those in horses with salmonellosis. After experimental inoculation with *N. risticii* horses had a mild, transient fever 2 to 4 days after infection.[733] By 10 to 14 days after experimental infection horses became febrile, had a poor appetite, and exhibited mild to severe gastrointestinal signs ranging from mild colic and soft stool to profuse diarrhea.

744

745

In clinical cases of PHF, there are signs of sepsis, including fever, leukopenia, congested mucous membranes, and hypercoagulability. The early fever observed in experimental cases is usually not detected by owners, and when clinical signs are seen it is presumed that the horse was infected 10 to 14 days previously. Hypoproteinemia is a frequent finding in horses with clinical cases of PHF, which reflects loss of serum prote in through inflamed intestinal mucosa. It is interesting to note, however, that the magnitude of intestinal inflammation is typically much less than with salmonellosis, yet the magnitude of hypoproteinemia (total protein <3 g/dL) can be as severe.

Laminitis is a frequent sequela and may occur in 30% in horses with PHF. *N. risticii* has also been associated with abortion in mares, although this is an unusual occurrence.[734] In some horses that show significant seroconversion to *N. risticii*, laminitis is the only clinical sign.

32.78.7 Mode of Transmission

Although originally described as a disease of horses living near the Potomac River in Maryland and Virginia, horses with serologic evidence of exposure to *N. risticii* have been reported in most states. Because early research on PHF demonstrated that infection was readily transmitted through blood,[733] it was presumed that the natural mode of transmission involved an insect or arthropod vector. However, several studies have failed to demonstrate any such vectors.[735,736]

The association between an affected horse and proximity to a river (within 5 miles) remains strong. Recently investigators have found a possible link between this association and how the disease may be transmitted. *N. risticii* and *Neorickettsia helmintheca* were found to share a high degree of DNA homology.[737] *N. helmintheca* is transmitted to mammals via a trematode that parasitizes fish and aquatic snails.[737] This prompted investigators to search for evidence that *N. risticii* might reside in trematodes and their hosts found in riverine inhabitants. *N. risticii* DNA was detected in operculate snails (Pleuroceridae: *Juga* species) collected from stream water in a northern California pasture in which PHF is enzootic.[738] Moreover, *N. risticii* was detected in trematode stages found in the secretions of freshwater snails and in aquatic insects.[739,740] The sequences of these genes were virtually identical to those of the genes of an equine *N. risticii* strain isolated from horses located on a property near the snail collection site. Further work demonstrated *N. risticii* DNA in two trematodes. *Acanthatrium* species and *Lecithodendrium* species, found in bats and swallows, suggesting that these animals may serve as a reservoir for the organism.[741] Oral transmission of *N. risticii* with infected cell cultures has been produced experimentally,[742] supporting a role for ingestion of *N. risticii*, rather than blood transmission, as the route of natural infection. Oral transmission and clinical signs of PHF were demonstrated in horses fed infected aquatic insects (caddis flies), suggesting that ingestion of infected aquatic insects may be the natural route of infection.[743,744] Ingestion of water containing infected trematode stages released from aquatic snails may also be a route of infection.

32.78.8 Diagnosis

Accurate confirmation of PHF can be difficult, because clinical signs of disease are nonspecific and available diagnostic tests are not entirely reliable. Conventional recommendation is that paired acute and convalescent blood samples should be submitted for IFA or ELISA testing for antibodies to *N. risticii*. However, serologic evaluation to confirm the disease is not as straightforward as in many other infectious diseases. A fourfold increase in titer between acute and convalescent sera is considered to confirm infection with *N. risticii*, but failure to seroconvert does not rule out infection. Because the onset of clinical signs can be delayed as long as 14 days after infection, horses may seroconvert by the time an acute sample is obtained.[742] The magnitude of titer does not always correlate with active infection, because many horses in endemic areas have high titers but no disease. Vaccination also can affect the titer. There is significant interlaboratory variability in results of IFA tests, and false-positive results occur frequently.[745] Therefore it has been suggested that IFA for antibodies to *E. risticii* not be performed in areas that are not endemic for *E. risticii*.[745]

The current standard for diagnosis of PHF used by most clinicians is PCR testing of whole blood samples to detect *N. risticii* DNA in leukocytes.[746] PCR testing appears to be sensitive and specific in horses with compatible clinical signs, but a thorough evaluation of the test has not yet been completed.

32.78.9 Treatment and Prevention

Treatment with oxytetracycline, 7 to 11 mg/kg IV twice daily for 4 days, effectively eliminates *N. risticii* from the horse. Fever should resolve within 48 hours of beginning treatment with oxytetracycline, and diarrhea typically resolves within 24 to 72 hours of beginning treatment. In one horse we treated, clinical signs persisted until the dose of oxytetracycline was increased to 15 mg/kg twice daily. Orally administered doxycycline (10 mg/kg q12h) may be effective, although in horses with severe gastrointestinal signs, absorption of doxycycline may be adversely affected. Doxycycline must not be given IV because it will cause the horse to collapse. Some

horses have had clinical relapses 2 to 3 weeks after initial resolution of clinical signs that were responsive to tetracycline. Horses do not remain chronic carriers of *N. risticii*.

In most cases of PHF, intravenous administration of polyionic fluids is required to replace fluid and electrolyte losses and to augment preload in horses with poor venous return. Plasma may be required to replace lost plasma proteins. Other colloidal fluids may also be used in patients with hypoproteinemia or sepsis. Because horses improve rather quickly once treatment with oxytetracycline is begun, parenteral nutritional support is usually unnecessary.

Vaccination has appeared to diminish the incidence and severity of disease, but PHF may still develop in vaccinated animals. Experimental results with vaccine were mixed, and the duration of immunoprophylaxis was very limited.[747] Disease severity has appeared to be less in vaccinated animals, although in the summer of 1994 many vaccinated horses developed severe cases of PHF. All of these horses were located in the area where PHF was originally described, and a new strain of *N. risticii* was identified.[748] PCR analysis has revealed multiple strains of *N. risticii*, which may account for the unreliable efficacy of the vaccine.[749] Horses in endemic areas should be vaccinated in the early spring and early to mid summer on an annual basis.

32.78.10 Clostridial Diarrhea

Enteric clostridiosis was reported as a clinical problem in the 1970s, and clostridial bacteria were implicated as the causative agents of colitis X.[750] Difficulty in substantiating clostridial bacteria as the cause of enterocolitis in horses led to a deemphasis of this potential cause for diarrhea in adult horses. In the 1990s, improved laboratory techniques for identification of clostridial toxins resulted in increased confirmation of clostridial bacteria as common causative agents of colitis in foals and adult horses.

745 746

The two most important clostridial species affecting the equine intestinal tract are *C. difficile* and *C. perfringens*. Most reported cases in horses have involved *C. difficile*, although in a recent report the prevalences of *C. difficile* toxin A and *C. perfringens* enterotoxin in fecal samples from horses with diarrhea were similar, and in some horses toxins from both clostridial species were identified.[751]

32.78.11 Pathogenesis

C. difficile is a sporulated obligate anaerobe responsible for most cases of antibiotic-associated colitis, for 15% to 25% of cases of antibiotic-related diarrhea, and for a substantial proportion of nosocomial infections in humans.[752] *C. difficile* produces two important toxins, named toxin A and toxin B. Most isolates of *C. difficile* produce both toxins, but some isolates produce only either toxin A or toxin B. Toxin A can elicit both fluid secretion and a pronounced inflammatory response in the bowel. Toxin A has intestinal secretory and cytotoxic effects,[753,754] increases intestinal permeability,[755] and can activate epithelial cells, neutrophils, mast cells, monocytes, and macrophages to release a multitude of proinflammatory cytokines and vasoactive mediators.[756–758] An interesting feature of toxin A is its induction of the neurotransmitter substance P in both the intestine and dorsal root ganglia, and the apparent dependence on substance P for expression of the full pathologic effects of toxin A in the intestine of rodents.[759] Effects of toxin A appear to be mediated both through direct effects on intestinal cells and via the enteric nervous system.

Toxin B exhibits enterotoxigenic (secretory) activity but recently also has been demonstrated to have potent cytotoxic effects on human colonic epithelium.[760] Toxin B has little relevance to the pathogenicity of *C. difficile*

in animal models, however, and the roles of toxins A and B in the pathogenesis of equine clostridial enterocolitis are not known.

Strains of *C. perfringens* are classified on the basis of the toxins that are produced, with at least a dozen identified to date.[761] *C. perfringens* type A and type C have been recovered from equine specimens,[762] and several *C. perfringens* toxins have been identified in equine specimens.[763,764] *C. perfringens* type A is the most frequently isolated type, and its enterotoxin is released on sporulation of *C. perfringens* within the intestine. Other exotoxins of *C. perfringens* have phospholipase activity (alpha-toxin), necrotizing cytotoxic effects (beta-, epsilon-, and iota-toxins), and hemolytic effects (theta-toxin).

32.78.12 Clinical Features

Clostridial enterocolitis affects foals and adult horses. In some reports, toxigenic *C. perfringens* organisms were isolated from more than 50% of foals with diarrhea.[764,765] The clinical presentation in foals with *C. perfringens* is predominantly a hemorrhagic diarrhea with sepsis. *C. perfringens* can cause septicemia and can often be cultured from the blood of foals with hemorrhagic diarrhea. In some foals, classic necrotizing enterocolitis will be manifested by gas- or fluid-distended intestines and thickened intestinal mucosa. These changes can be appreciated radiographically and ultrasonographically, and intramural gas produced by clostridial bacteria may be detected with ultrasonography as hyperechoic areas within the bowel wall. *C. difficile* infection is also a cause of acute enterocolitis in foals.[766] Adult horses with clostridial enterocolitis frequently have diarrhea but may have abdominal discomfort or fever as the primary presenting problems. There are no clinical features that consistently distinguish clostridiosis from salmonellosis, and a spectrum of clinical signs exists, from moderate illness to severe toxemic colitis. Most horses with clostridial enterocolitis develop diarrhea, but in some cases enteritis manifested by ileus and gas-distention of the small intestine may be the primary problem. Although both *C. perfringens* and *C. difficile* and their toxins have been detected in a significant number of adult horses with colitis. *C. difficile* appears to be more common.[767,768] Indeed, *C. difficile* appears to be the most common cause of antibiotic-associated diarrhea in adult horses.[769] Strain differences among isolates of *C. difficile* cultured from the diarrheic feces of horses in intensive care units are associated with toxigenicity, severity of disease, and metronidazole resistance.[770] *C. perfringens* and *C. difficile* have been implicated in duodenitis proximal jejunitis (see p. 725), but a cause-and-effect association has not been proven.

Similar to salmonellosis, clostridial enterocolitis can develop into a widespread problem affecting several animals in a hospital or an equine facility.[771] Risk factors for developing nosocomial clostridial enterocolitis are similar to those for nosocomial salmonellosis: antimicrobial administration, concurrent gastrointestinal disease, and age susceptibility (foals). In addition, *Clostridium* species are well suited to persist in the environment because of the production of spores that are resistant to environmental extremes and many disinfectants.

32.78.13 Diagnosis

Diagnosis of clostridial enterocolitis requires identification of toxigenic clostridia from intestinal contents or tissue. Several direct and indirect methods are used to detect toxigenic clostridia and include culture, identification of toxins, and identification of toxin genes. Culture of *C. difficile* or *C. perfringens* requires anaerobic conditions, and the ability to culture these organisms from ingesta or fecal specimens rapidly diminishes with increased time from collection to arrival at a laboratory. It is recommended to transport samples, chilled (not frozen) on ice, immediately or by overnight delivery for best recovery of clostridial organisms. Tissue specimens submitted for culture, toxin identification, or toxin gene identification should be handled

similarly. Because nonpathogenic Clostridia are common,[772] isolates should be tested for toxin production either by PCR or bioassay before a definitive diagnosis is made. Commercially available tests for clostridial toxins include an ELISA for *C. difficile* toxin A,[*] a latex-agglutination test for *C. perfringens* enterotoxin,[†] and an ELISA for *C. perfringens* enterotoxin.[‡] Toxin tests have the advantages of being rapid and, at least in the case of *C. difficile*, both sensitive and specific.

† *C. perfringens* enterotoxin kit, Oxoid Division, Unipath, Ogdensburg, NY.

† *C. perfringens* enterotoxin test, TechLab, Inc., Blacksburg, VA.

32.78.14 Treatment

Supportive care may be required, as with other cases of acute diarrhea in horses. Treatment with metronidazole (15 mg/kg q6-8h) appears to be effective in eliminating enteric clostridial infection in most cases. In one veterinary teaching hospital, isolates of *C. difficile* were resistant to metronidazole,[773] and vancomycin was used with reported success. Large-scale resistance to metronidazole has not been reported elsewhere, and it should be the first choice in the treatment of suspected clostridial enterocolitis. *Saccharomyces boulardii* is a nonpathogenic yeast used in the treatment of *C. difficile* diarrhea and colitis in humans. The yeast releases a protease that specifically degrades *C. difficile* toxins A and B, and this has been shown to be protective in experimental *C. difficile* colitis in rats and to prevent damage to human colonic epithelium by *C. difficile* toxins A and B in vitro.[774] Use of *S. boulardii* in horses has not been reported. A typical dose in humans is 1 g PO once daily.[775] DTO smectite powder (Biosponge) has been shown to bind clostridial toxins[776] and may be useful for treating clostridiosis in horses. DTO smectite is available as a powder or paste and should be administered according to the manufacturer's instructions for 3 to 5 days.

746 747

32.78.15 Cantharidin (Blister Beetle) Toxicity

32.78.15.1 Pathogenesis

Cantharidin is the toxic principle found in beetles of the genus Epicauta, commonly known as blister beetles.[777–779] Ingestion of the beetles in contaminated alfalfa hay results in absorption of cantharidin through the gastrointestinal tract. Blister beetles feed on the flowers of alfalfa and are incorporated into baled alfalfa hay if the hay is cut and processed simultaneously.[777–779] Large swarms of beetles may be found in relatively small portions of hay. The lethal dose of cantharidin is less than 1 mg/kg, but the concentration of cantharidin varies from species to species of blister beetles.[777,778] Therefore as many as 100 to as few as six to eight beetles may be lethal. Often more than one horse will be affected. The fatality rate may be 50% or greater.[777,780]

Cantharidin is a potent irritant, causing cell damage and necrosis on contact.[777,779,780] The mucosa of the gastrointestinal tract is most commonly affected in horses because they ingest the toxin. Ulceration throughout the alimentary tract has been observed in natural and experimental cantharidin toxicity. Diarrhea probably results from the severe ulceration and inflammation of the large intestine, causing increased secretion of water, electrolytes, and protein. Large volumes of fluid and protein are lost in the gastrointestinal tract, causing hemoconcentration and profound hypoalbuminemia in some cases.[777,778,780] Cystitis, nephrosis, and myocarditis occur in natural and experimentally produced cases of cantharidin toxicity.[777,779,780] Cystitis and nephrosis occurs from the high concentration of cantharidin in the urine. The cause of the myocarditis and

myocardial necrosis is unknown, but they may also be direct effects of the toxin on the myocardium. Elevated plasma CK activity is often observed and has been postulated to arise from the damaged myocardium.[777,778] Horses have a characteristically stiff gait, but histopathologic evidence of skeletal muscle injury that explains the elevated plasma CK activity has not been observed.[778] Hypocalcemia and hypomagnesemia are characteristic features of cantharidin toxicity in horses that have not been explained.[777,778,780] Hypocalcemia may occur from hypoalbuminemia, but the ionized calcium concentration is often decreased, along with the total calcium concentration, indicating that hypoalbuminemia is not responsible for the hypocalcemia.[778]

32.78.16 Clinical Features

Cantharidin toxicity can cause a range of clinical signs, from mild depression and abdominal discomfort to fulminant signs of toxemia and rapid death, depending on the ingested dose of toxin.[777,778,780] Most commonly, clinical signs include depression, sweating, irritability, abdominal pain, elevated heart and respiratory rates, fever, polyuria, polydipsia, and profuse diarrhea.[777,778,780] Blood is rarely seen in the feces. Affected horses frequently posture to urinate; indeed, stranguria and pollakiuria are characteristic of cantharidin toxicity.[777] Signs of hypocalcemia include synchronous diaphragmatic flutter and tremors. A stiff and stilted gait may be evident. Neurologic signs such as head pressing, swaying, and disorientation may be noted.[780] Signs of systemic inflammation from endotoxemia may be seen in severe cases. Some horses develop severe depression and toxemia and may die within hours after ingestion of cantharidin without developing diarrhea.[777,780] Hematologic abnormalities are similar to those of other causes of acute diarrhea, reflecting dehydration and sepsis. Hypocalcemia (both ionized and total calcium concentrations) and hypomagnesemia are characteristic biochemical features of cantharidin toxicity and may be profound. Azotemia with a urine specific gravity in the hyposthenuric range is common.[777,778,780] Microscopic hematuria and mild proteinuria may be evident.

32.78.17 Diagnosis

Tentative diagnosis can be made based on clinical signs and the finding of blister beetles in the hay. Determining the species of the insects may be necessary to estimate the amount of cantharidin ingested. All species of *Epicauta* contain cantharidin, but some have small amounts. Definitive diagnosis requires the measurement of the cantharidin concentration in gastric or intestinal contents and urine.[777,781]

32.78.18 Treatment

Fluid therapy and maintenance of electrolyte balance are important, as in all cases of acute diarrhea. Particular attention should be paid to the degree of hypocalcemia and renal function as a fluid therapy plan is developed. Specific therapy is limited. Administration of absorbent powders via nasogastric tube is important early to prevent further systemic absorption of cantharidin and local toxicity. Mineral oil administration may also help reduce absorption of the toxin. Pain control may be needed for colic or urinary pain. Nonsteroidal antiinflammatory therapy should be used judiciously to avoid further injury to the intestinal mucosa and renal toxicity. Alternative analgesics, such as butorphanol or a lidocaine controlled rate infusion, may be better choices.

32.78.18.1

ANTIMICROBIAL-ASSOCIATED DIARRHEA

The onset of acute diarrhea in the horse has been associated with the use of several antimicrobial drugs. Lincomycin administered orally and tetracycline administered parenterally have been demonstrated to induce severe diarrhea in horses.[782,783] The oral administration of TMS, erythromycin, metronidazole, and penicillin and parenteral administration of ceftiofur have been implicated with onset of diarrhea, including fatal colitis, in horses. In one report there was no association between TMS and diarrhea.[784] However, in other reports, prior administration of antimicrobial drugs was positively associated with onset of colitis and negatively associated with prognosis for survival in horses with colitis.[785]

Antimicrobial-associated diarrhea is presumed to be secondary to disruption of normal colonic microflora and the proliferation of an enteropathogen, such as *Salmonella* species, *C. perfringens*, and *C. difficile*. Of interest, it was reported that mares whose foals were treated with erythromycin for *Rhodococcus* infection developed severe, acute colitis, from which *C. difficile* and its toxins were isolated.[786] The mares had erythromycin detected in their feces, and exposure to the erythromycin was presumed to have occurred by the mares licking erythromycin from the foals' faces.

32.78.18.2

OTHER CAUSES OF ACUTE DIARRHEA

NSAID toxicity (see p. 754) has been associated with diarrhea secondary to damage to the colonic mucosa. Grain (carbohydrate) overload may cause acute diarrhea resulting from overproduction of lactate in the colon. A combination of hyperosmolarity of the luminal contents and damage to the colonic mucosa account for the pathophysiology of grain overload. The clinical signs are similar to those of other acute diarrheal diseases in horses and depend on the severity of the overload. Hyperlactemia, metabolic acidosis, and sepsis are key features of grain overload, and laminitis is a common sequela. Acute diarrhea in the adult horse has also been associated with conditions such as lymphosarcoma enterocolitis and other IBDs, intestinal lymphosarcoma, peritonitis, heavy metal intoxication, anaphylaxis, and stress.

747 748

32.78.18.3

CLINICAL ASSESSMENTS IN ACUTE DIARRHEA PATIENTS

The diagnostic evaluations performed on horses with acute diarrhea are intended to provide the clinician with information to accurately assess the horse's condition and thus direct therapy toward specific requirements. The first part of the evaluation is a thorough physical examination, with particular attention paid to the horse's hydration status (skin turgor, gum moisture, capillary refill time), evidence of sepsis (fever or hypothermia, hyperemic mucous membranes, prolonged capillary refill time), cardiovascular system (heart rate and rhythm, character of peripheral pulse, capillary refill time), and signs of laminitis (lameness, digital pulse, palpable temperature of hoof walls). Horses with colitis are often moderately to severely dehydrated, with either purplish or brick-red mucous membranes. Purple mucous membrane color reflects venous congestion and poor venous return, whereas brick-red membrane color reflects venous congestion and poor venous return plus arteriole and venule shunting and poor tissue oxygen exchange.

Blood pressure should be monitored, and whereas direct measurements via an arterial catheter are most accurate, indirect pressure measurements obtained using a Doppler transducer placed over the coccygeal artery are satisfactory. Hypotension and hypertension each occur in horses with colitis, and the blood pressure status

of a patient often is unpredictable. Blood pressure can be monitored as frequently as labor permits and should be done hourly if vasoactive pharmaceutical agents are used.

Laboratory tests that should be performed include CBC and plasma protein and total solids. Total hemoglobin and PCV are used to assess hydration status. Total protein is used to assess hydration status and degree of protein loss through inflamed intestinal mucosa, and in more chronic cases through protein catabolism. Comparison of clinical hydration, PCV, and total protein is useful in determining the extent of protein loss, and daily evaluations can be used to determine the rate of protein loss. Colloid oncotic pressure measurements are useful, particularly if colloidal fluids other than plasma are given.

Total WBC count, WBC differential, and WBC morphology are used to assess severity of sepsis; plasma fibrinogen is used to assess the severity of inflammation. Typically the total WBC and neutrophil counts decrease initially. This is primarily attributable to bacterial endotoxins and the host's mediators of systemic inflammation and occurs in most cases of acute colitis, not just in those caused by *Salmonella* species. The morphology of the WBCs reflects the severity of the inflammatory response. “Toxic” changes such as basophilia, granulation, vacuolation of the cytoplasm, and scalloped borders of the cell membrane or adherence of neutrophils to RBCs do not reflect injury to the neutrophils by toxins but reflect the cells' responses to stimulation by proinflammatory agents (TNF, IL-1) and the production of inflammatory mediators by the neutrophils that are toxic to bacteria. The degree of these changes in circulating neutrophils can be used to assess the severity of disease and also to assess the progress the horse is making. Often the initial sign that the horse is improving is a decrease in the “toxic” appearance to the neutrophils and a regenerative neutrophil response. A horse that continues to have severe neutropenia with a degenerating left shift or neutrophils, with cytoplasmic vacuolation, granulation, and basophilia, for more than 10 days has severe colitis that is unlikely to resolve.

Serum chemistry tests that should be performed include electrolytes (sodium, chloride, potassium, and calcium), BUN and creatinine, blood lactate concentration, and assessment of acid-base status (blood pH and bicarbonate, or total CO_2). Horses with diarrhea often are hyponatremic, hypochloremic, and hypokalemic. With decreased feed intake, hypocalcemia occurs. A high gap metabolic acidosis with hyperlactemia may be noted, particularly in horses with sepsis. The severity of these electrolyte disturbances should be monitored, often daily, to allow for appropriate therapy. Parameters that assess renal function, BUN and creatinine, are frequently increased in horses with diarrhea for several reasons. Prerenal azotemia resulting from dehydration and decreased filtration across the glomerulus accounts for some of the increase in these parameters. Hyponatremia and hypochloremia can cause a decrease in glomerular filtration and an increase in BUN and creatinine secondary to tubuloglomerular feedback. Horses that are adequately hydrated yet moderately hyponatremic (serum sodium 120 to 128 mEq/L) often remain azotemic until sodium levels increase above 130 mEq/L. In addition, horses with toxemic colitis often have damage to renal parenchyma, presumably the result of the effects of inflammatory mediators and alterations in renal blood flow.

The acid-base status can be evaluated by estimating serum bicarbonate on the basis of the total CO_2 or directly from a venous or arterial blood gas analysis. Evaluation of a venous blood gas sample is useful in assessing perfusion and oxygen extraction. An increased venous oxygen partial pressure (>60 mm Hg) is indicative of poor capillary perfusion and oxygen delivery to the tissues. Affected horses usually have brick-red mucous membranes.

32.78.18.4 PRINCIPLES OF THERAPY FOR ACUTE DIARRHEA

Because the pathophysiology of equine colitis is complex, treatment is often multifaceted. Many of these treatments provide well-documented benefit, whereas with others the efficacy is based on empiric judgment only. Outcome is determined not only by the severity of the primary disease causing colitis but also by complications that may arise from the disease.

In cases of acute colitis, fluid administration remains the treatment of primary importance. Most patients require intravenous administration in the early stages. The fluids used must replace fluid, sodium, chloride, and potassium losses. Often, large volumes are required for several days. More specific guidelines for fluid therapy in colitis patients are covered in the Fluid Therapy for Horses with Gastrointestinal Diseases section (p. 767) and in Chapter 44.

Most horses with colitis become hypoproteinemic secondary to protein leakage through the inflamed colon and catabolism of albumin secondary to negative energy balance. Hypoproteinemia frequently leads to edema formation in several areas of the body, including the intestinal tract, and can compromise the clinician's ability to keep the patient properly hydrated through fluid administration. Intravenous plasma therapy is often beneficial. Plasma, 3 to 10 L, should be given IV. Other colloidal fluids may be more cost-effective for increasing colloidal oncotic pressures in hypoproteinemic horses but do not have the additional properties of plasma that may be beneficial.

Plasma contains proteins besides albumin and therefore can be of benefit beyond improvement of plasma oncotic pressure. The immunoglobulin present in plasma is of recognized benefit in the treatment of failure of passive transfer in foals. The role of nonspecific immunoglobulin in the treatment of colitis is not known. Fibronectin is essential to the normal function of the monocyte-macrophage system in the processing of a variety of antigens. Other plasma proteins such as elastase and proteinase inhibitors, complement inhibitors, AT-III, and other inhibitors of hypercoagulability may be beneficial to colitis patients. 748 749

The nutritional requirements of the colitis patient need to be considered, particularly in a case that may be protracted. Horses with colitis are typically anorectic, and the disruption of normal physiologic processes in the inflamed cecum and colon limits the effectiveness of these organs in the digestion and absorption of nutrients. In addition, several mediators of inflammation and septicemia alter protein and calorie metabolism, resulting in a catabolic state. Therefore even if the horse eats, it is likely to be in a severe caloric deficit for some time. Normally an average horse requires approximately 15 Mcal/day. An endotoxemic horse may require 25 Mcal/day. In a catabolic patient, muscle and fat tissue are mobilized and used in lieu of ingested nutrients. The plasma protein pool, including albumin and immunoglobulins, also is catabolized. In many cases of colitis the decrease in plasma protein may be as much a result of catabolism as of leakage through the inflamed colon. A variety of products can be used for enteral feeding (see Chapter 50).

Colitis is an inflammatory disease, and limiting inflammation is desirable when treating patients, particularly those with severe disease. Moreover, horses with acute colitis, regardless of the cause, have signs compatible with systemic inflammation associated with sepsis. Flunixin (0.25 to 0.5 mg/kg q6–8h) is the most commonly used antiinflammatory therapy in horses with colitis. However, the use of flunixin should be judicious and must be carefully monitored to avoid unwanted side effects on the gut mucosa and kidneys (see p. 754). Other antiinflammatory therapies, such as lidocaine controlled rate infusions, may also be beneficial.

Sepsis is a common clinical feature in horses with acute colitis. Most of the clinical signs of sepsis are likely attributable to the effects of endotoxin. Therefore specific therapy for endotoxemia may be warranted (see p. 719).

The use of antimicrobial drugs in the treatment of colitis is controversial. In cases of colitis caused by *N. risticii*, the efficacy of tetracycline, 6.6 to 11 mg/kg IV once or twice daily, is documented clinically and experimentally. In other cases of colitis, including *Salmonella* colitis, in which specific antimicrobial sensitivities to the *Salmonella* species have been established, the efficacy of antimicrobial administration is less well documented. Many clinicians believe that the use of an antimicrobial for which the *Salmonella* species have demonstrated sensitivity, such as chloramphenicol, enrofloxacin, gentamicin, amikacin, or a third-generation cephalosporin, does not significantly alter the course of the disease or hasten the elimination of the organism from the body. However, there is no published evidence either supporting or not supporting the efficacy of antimicrobial treatment for salmonellosis, and the use of antibiotic therapy remains a judgment of the clinician. In patients with sepsis the use of broad-spectrum antibiotics is justified to prevent bacteremia or organ colonization by *Salmonella* species or other enteric organisms.

Medications that minimize or abolish colonic fluid secretion would be of tremendous benefit in the treatment of equine colitis. Medications such as kaolin, bismuth subsalicylate, and activated charcoal are frequently used in cases of colitis in adult horses, but their efficacy as antisecretory agents in this context has not been established. These medications are more effective in foals with diarrhea, probably as a result of an effect on the small intestine rather than the colon. Absorbent powders such as activated charcoal or DTO smectite (Biosponge) may be useful to absorb bacterial toxins, particularly in horses with clostridiosis.

32.78.19 Chronic Diarrhea

Chronic diarrhea is one of the most frustrating disorders encountered by equine practitioners, with regard to both determining the cause and therapeutically managing the diarrhea.[789] Chronic diarrhea may be defined as persistent diarrhea of at least a month's duration. Although there are many causes of chronic diarrhea, these cases can generally be divided into two groups: diarrhea resulting from a chronic inflammatory condition and diarrhea resulting from a disruption in normal physiologic processes. With inflammatory conditions there will be histologic changes in the colon mucosa, including pleocytosis (neutrophils, eosinophils, and lymphocytes), mucosal congestion, and mucosal erosion and ulceration. Submucosal edema, capillary congestion, and lymphatic congestion may be present. With physiologic disorders there are no morphologic changes in the colon, and diarrhea is presumed to result from abnormal VFA synthesis or absorption. A small percentage of horses with chronic diarrhea have a primary disorder of a system other than the intestinal tract, such as congestive heart failure or hepatic disease. A thorough physical examination and evaluation of a minimum database (CBC, serum chemistry profile, urinalysis) should differentiate horses with primarily nonenteric disorders.

32.78.20 Causes

Inflammatory disorders that can cause chronic diarrhea include disorders caused by infectious agents such as chronic salmonellosis; chronic parasitism with *S. vulgaris, Strongylus edentatus*, and larval cyathostomiasis; abdominal abscessation; and, in weanling foals. *R. equi* infection of abdominal viscera and rotavirus infection.

Noninfectious inflammatory causes include cellular infiltrative disorders such as granulomatous enteritis and lymphosarcoma, as well as sand enteropathy. Sand causes diarrhea through continued irritation of the mucosal lining of the colon. In weanling foals, gastric ulceration and gastric emptying disorders have been associated

with chronic diarrhea that resolved when H_2 antagonist therapy was started. NSAIDs can cause chronic diarrhea, which is accompanied by varying degrees of pathologic change in the large intestine.

Noninflammatory chronic diarrhea of colonic origin is thought to be a result of abnormal fermentation of cellulose by the resident bacteria in the large intestine. In vitro fermentation of feces from normal horses and horses with chronic diarrhea revealed that feces from the diarrheic horses produced more gas, acetate, and propionate than feces from normal horses.[790] Whether this reflects fermentative activity within the colon is not known, but an abnormal increase in acetate could lead to fluid retention within the colonic lumen, because acetate inhibits colonic absorption of sodium and water.

32.78.2 Diagnosis

The diagnostic approach to cases of chronic diarrhea should be based on an attempt to differentiate inflammatory from physiologic causes. The evaluation can be extensive and expensive, and the owner should be prepared for the cause of the diarrhea to remain undetermined. Horses with chronic diarrhea may be adequately hydrated if water consumption has matched water losses. Often, however, such horses are brought to the veterinarian in a condition of mild to moderate dehydration. Moderate weight loss also has often occurred. On physical examination, signs of toxemia (injected mucous membranes, congested or hyperemic mucous membranes) should be noted.

749

750

A CBC should be evaluated for signs of chronic inflammation. Such changes include a decrease in the RBC count and PCV as a result of decreased erythrogenesis secondary to sequestration of iron by bone marrow macrophages (anemia of chronic inflammation). The WBC count may be normal or moderately increased. The fibrinogen can be normal or increased. Changes in WBC count and fibrinogen levels are influenced by the degree of inflammation and whether the inflammatory response is localized. Therefore a normal CBC does not rule out an inflammatory cause of the chronic diarrhea.

Peritoneal fluid analysis may reveal an increase in protein or WBCs, which is indicative of an inflammatory process within the peritoneal cavity. Often, however, colon inflammation is not reflected by alterations in the peritoneal fluid.

Serum chemistry values vary in horses with chronic diarrhea. Many affected horses have evidence of hyponatremia, hypokalemia, hypochloremia, azotemia, and metabolic acidemia. Other horses with less severe chronic diarrhea may have no serum chemistry abnormalities.

The total serum protein is usually decreased with a chronic inflammatory disorder of the colon, reflecting protein leakage from the capillaries and disruption of the colonic mucosal integrity. This is usually reflected by hypoalbuminemia. In some cases, hyperglobulinemia occurs and total protein concentration may be normal.

Increases in hepatic-associated enzymes, including sorbitol dehydrogenase, GGT, and AST, and serum bile acids indicate that hepatic disease is present. Hepatic changes and dysfunction such as inflammation, fibrosis or fatty infiltration, or biliary inflammation can be associated with diarrhea.

Feces should be examined for parasite ova; cultured for *Salmonella* species. *C. difficile*, and *C. perfringens;* and tested for clostridial toxins. In cases of acute diarrhea, it has been recommended that five consecutive fecal samples be cultured for *Salmonella* species, but in cases of chronic diarrhea, many more are often necessary. As many as 15 fecal cultures may be needed to get a positive *Salmonella* species culture. In addition, a rectal mucosal biopsy should be cultured. In weanlings the feces should be examined for rotavirus by transmission

electron microscopy or ELISA. Although it is an unusual cause of diarrhea in weanlings, rotavirus should be considered when dealing with a problem of chronic diarrhea in several foals on the same farm.

An oral glucose absorption test can be done to determine if there is small intestinal malabsorption, which would indicate a widespread small and large intestinal disorder if both diarrhea and glucose malabsorption are present.

A rectal mucosal biopsy may provide evidence of a widespread inflammatory disorder, such as one of the IBDs (see p. 730).[791] Biopsies should be evaluated by a pathologist experienced in examining equine tissue specimens, and some caution should be taken to avoid overinterpretation of the presence of few lymphocytes, plasma cells, and eosinophils.

Frequently the results of the previously mentioned diagnostic procedures do not determine the cause of the chronic diarrhea. In such cases an exploratory laparotomy may be warranted. This is particularly true if episodes of abdominal discomfort accompany the chronic diarrhea. In addition to exploration of the abdomen for the presence of masses or abscesses, the colon and cecum should be thoroughly examined. Biopsies from several sites of the colon, cecum, and mesenteric lymph nodes should be submitted for histopathology and culture for *Salmonella* species.

32.78.22 Treatment

Treatment of horses with chronic diarrhea is often empiric, because either a cause has not been determined or the cause is not amenable to treatment. With inflammatory causes such as lymphosarcoma and granulomatous enteritis, the disease is usually untreatable. Some cases of eosinophilic colitis have been treated successfully with corticosteroids.

Chronic parasitism may be resolved with appropriate anthelmintic therapy, although damage to the mucosa may have become too extensive to allow normal absorption to occur. Administration of larvicidal doses of fenbendazole (15 mg/kg PO daily for 5 days) is usually effective. Concurrent administration of prednisolone (1 mg/kg PO once daily for 5 to 7 days) may minimize inflammation secondary to killing migrating larvae within the vasculature and mucosa of the colon.

Chronic salmonellosis does not lend itself to specific treatment, because antimicrobial therapy is generally unrewarding in resolving *Salmonella* infection in horses.

Administration of products containing bismuth subsalicylate is effective in some cases of chronic diarrhea. The action of bismuth subsalicylate is mediated through inhibition of prostaglandin synthesis and possibly by other undefined mechanisms. In full-size horses a large volume, 1 to 4 L/day, must be administered to be effective.

Iodochlorhydroxyquin* is effective in managing some cases of chronic diarrhea caused by maldigestion of cellulose by colonic microorganisms.[792] The actual mechanism of action of iodochlorhydroxyquin in resolving the diarrhea is not known. The drug was originally administered to horses with chronic diarrhea because an increase in fecal trichomonads was observed. However, this observation likely reflected that trichomonads were washed out of the cecum and colon rather than that they were the cause of the diarrhea. Iodochlorhydroxyquin has minimal effect on colonic protozoal populations. It is not uniformly effective, and in many cases its effectiveness is only transient. Stools may initially become formed, but the diarrhea often recurs within several days. An initial dose of 20 mg/kg/day is recommended. If diarrhea recurs, decreasing the dose to 10 mg/kg/day is sometimes effective. If the medication is effective, it must be continued, because if it is discontinued, the diarrhea resumes.

Changes in diet occasionally are helpful in horses with noninflammatory chronic diarrhea. Feeding a complete pelleted feed may positively affect the constituent VFAs produced in the colon and thus facilitate water absorption. Alternatively, trying different types of roughage may result in selecting one that creates a more favorable metabolic environment in the large intestine.

The removal of sand from the colon by nonsurgical means is difficult, and in one report the administration of psyllium was not effective.[793] Other treatments used with anecdotal, but undocumented, success include fecal transfaunations, probiotics, cultured yogurt, and brewer's yeast.

32.79 SURGICAL DISORDERS OF THE LARGE INTESTINE

Anthony T. Blikslager

32.80 SIMPLE OBSTRUCTION

Simple obstructions of the large intestine tend to have a more gradual onset than those of the small intestine and in the case of large colon impactions are frequently amenable to medical therapy.[794,795] Cecal impactions present much more of a dilemma because of the greater propensity of this organ to rupture[796] and the relative difficulty of surgically manipulating the cecum.[797]

750
751

32.80.1 Cecal Impaction

Cecal impaction may develop as a primary condition or may arise as a complication in hospitalized horses, particularly those that have undergone surgery.[798] Reasons for development of cecal impaction in hospitalized horses are unclear, although motility disturbances arising from postoperative pain may play a role. Cecal impactions may occur as one of two types: impaction of the cecum with firm ingesta or gross distention of the cecum with fluid ingesta. The latter has been termed *cecal dysfunction* and may be initiated by abnormalities in cecal motility. Evidence in favor of this supposition includes the fact that the right ventral colon is typically empty in horses with cecal dysfunction, suggesting a lack of aborad movement of digesta through the cecocolic orifice. However, clinical differentiation of cecal impaction and cecal dysfunction may be very difficult.[799] Horses with dry-ingesta—filled cecal impactions tend to be presented with the condition as the primary complaint, and there is often a gradual onset of abdominal pain over a number of days. Such impactions have a propensity to rupture before the development of severe abdominal pain or systemic deterioration and therefore must be closely monitored. In horses with cecal dysfunction, there is frequently an association with surgery, particularly orthopedic surgery. For horses that develop this condition in the postoperative period, it is often very difficult to detect because there is an expectation for horses to show some degree of depression after surgery and because horses are often already on analgesics such as NSAIDs or opiates. The simplest method to detect these cases is to closely monitor fecal output in the postoperative period.[800] A normal horse should produce six to eight piles of manure per day, whereas an abnormal horse may have no evidence of defection or a marked reduction in fecal production (<three piles of manure per day). These horses should be carefully evaluated for both pain and intraabdominal evidence of an impaction and treated accordingly.

The diagnosis of primary cecal impaction is based on palpation of a firm, impacted cecum or a grossly distended fluid-filled cecum per rectum. According to one study such findings were detected in 89% of horses with cecal

impaction that underwent per rectum palpation of the abdomen.[799] In some cases, cecal impactions may be difficult to differentiate from large colon impactions. However, careful palpation will reveal the inability to move the hand completely dorsal to the impacted viscus because of the cecum's attachment to the dorsal body wall.

Treatment for horses with dry-ingesta—filled cecal impactions may include initial medical therapy, including aggressive administration of intravenous fluids, judicious use of analgesics, and administration of oral laxatives (e.g., 2 to 4 L of mineral oil per 500 kg).[801] Other oral laxatives have also been recommended, including magnesium sulfate (1 mg/kg in 4 L of water PO up to twice daily for up to 3 days) and psyllium (1 kg q6-8h). However, if the cecum is grossly distended or if medical therapy has had no effect within a reasonable period of time, surgical evacuation of the cecum via a typhlotomy is indicated. In addition, it is advisable to perform an ileocolostomy in order to bypass the cecum, as postoperative cecal motility dysfunction with recurrence of the disease is common.[802] However, this aspect of surgical treatment remains controversial, and there are cases of cecal impaction if identified early that can be treated via typhlotomy alone.

In horses with cecal dysfunction, immediate surgery is indicated. In addition, cecal bypass is often warranted because it is suspected that motility disturbances initiate the disease, and therefore recurrence in the absence of cecal bypass may occur. However, this decision can be made based on the appearance of the cecum at surgery.

The prognosis depends on the type of cecal impaction encountered. In a recent report in which dry-ingesta—filled cecal impactions were treated by typhlotomy and ileocolostomy or jejunocolostomy, seven of nine horses lived long-term. The cecum of horses in which cecal dysfunction develops have a great propensity to rupture, which is universally fatal. Because these cases can be difficult to identify before surgery, the prognosis for this condition tends to be unfavorable.

32.80.2 Large Colon Impaction

Impactions of the large colon with ingesta occur at sites of anatomic reductions in luminal diameter, particularly the pelvic flexure and the right dorsal colon.[803] Although there are a number of reported risk factors, most have not been proven. However, a sudden restriction in exercise associated with musculoskeletal injury appears to be frequently associated with onset of impaction. A further consideration is equine feeding regimens, which usually entail twice-daily feeding of concentrate. Such regimens are associated with secretion of large volumes of fluid into the small intestine, resulting in transient hypovolemia (15% loss of plasma volume).[804] This leads to activation of the renin-angiotensin-aldosterone system, and because aldosterone stimulates absorption of fluid from the large colon, this may dehydrate colonic contents.[804,805] Large concentrate meals may decrease small intestinal transit time, resulting in increased presentation of soluble carbohydrate to the cecum and large colon. Large shifts of fluid into the colon occur as concentrates are readily fermented in the large intestine, which would be expected to activate the renin-angiotensin-aldosterone system. This in turn triggers net fluid absorption from the large colon. The effects of these large fluid fluxes on development of large intestinal disorders remains to be fully characterized, but undoubtedly they play some role in the syndrome of colic. From a practical standpoint, intestinal fluid fluxes may be reduced with frequent small feedings in those horses requiring concentrate to maintain condition.[804]

Clinical signs of large colon impaction include slow onset of mild colic that is typically well controlled with administration of analgesics but becomes increasingly more severe and refractory if the impaction does not resolve. The diagnosis is based on palpation of a firm mass in the large colon per rectum. However, the extent of the impaction may be underestimated by rectal palpation alone because much of the colon will be out of reach.

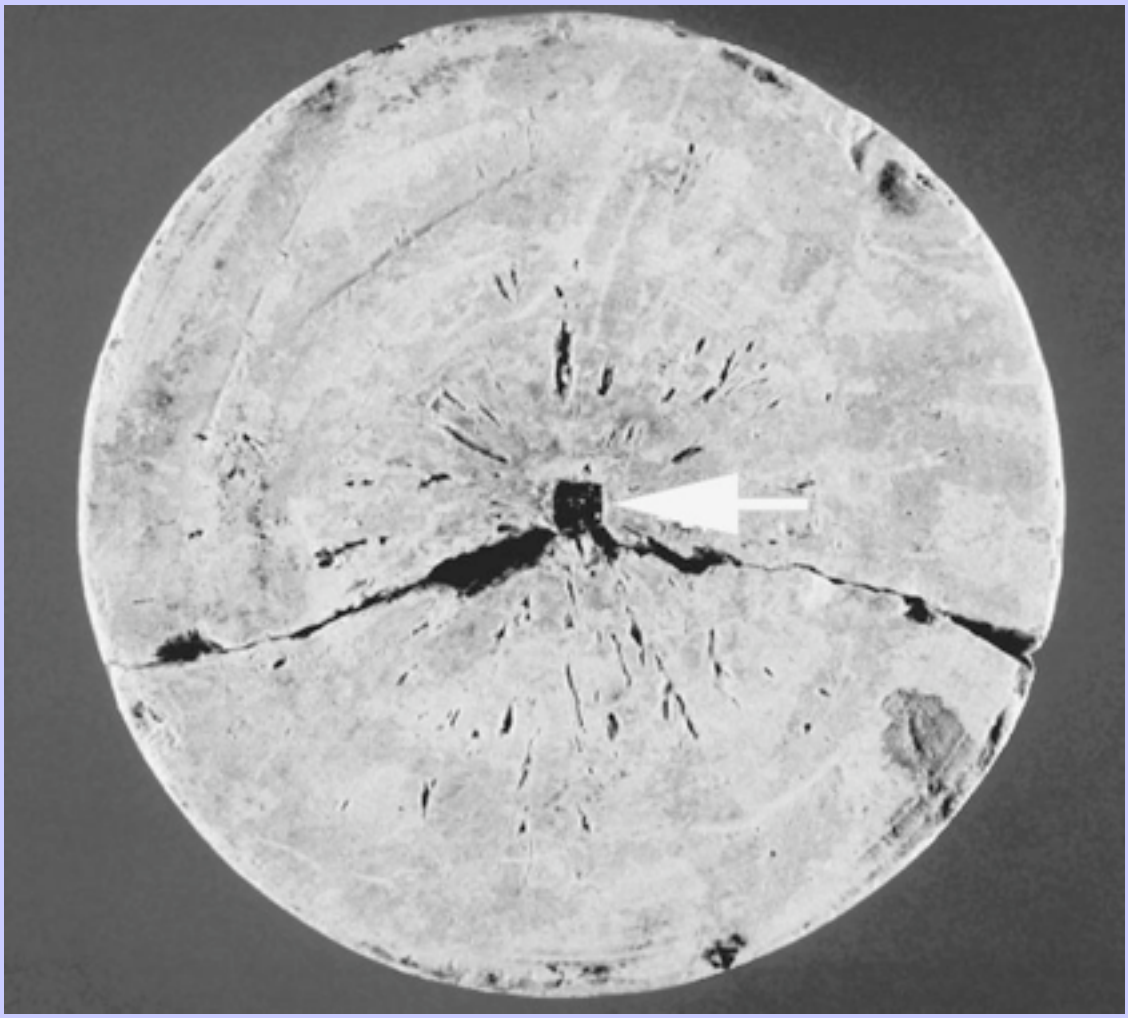
Adjacent colon may be distended if the impaction has resulted in complete obstruction. Initial medical treatment should be attempted. Intermittent abdominal pain is controlled with administration of analgesics (flunixin meglumine 0.25 mg/kg IV q6h to 1.1 mg/kg IV q12h; butorphanol 0.05 mg/kg IV as needed [prn]; xylazine 0.3 to 0.5 mg/kg IV prn). Detomidine (10 to 20 mg IV prn) can be administered with great caution, since this agent readily masks severe pain. In addition to analgesics, mineral oil (2 to 4 L/500 kg PO), water with dioctyl sodium sulfosuccinate (180 to 240 mL in 4 L of water, PO), or magnesium sulfate (1 mg/kg in 4 L of water PO) may be administered by stomach tube for laxative effects. Access to feed should not be permitted. For impactions that persist, aggressive oral and/or intravenous fluid therapy should be instituted. One study demonstrated the increased efficacy of a continuously administered oral rehydration solution in softening feces as compared with 751
intravenous fluids, which are probably best suited to restoring the systemic extracellular fluid compartment.[806] If 752
the impaction remains unresolved, the horse becomes uncontrollably pained, or extensive gas distention of the colon occurs, surgery is indicated. At surgery the contents of the colon are evacuated via a pelvic flexure enterotomy. The prognosis is good for those horses in which impactions resolve medically (95% long-term survival in one study) and fair for horses that require surgical intervention (58% long-term survival in the same study).[795]

32.80.3 Enteroliths

These mineralized masses are typically composed of ammonium magnesium phosphate (struvite).[807] One study has suggested that an increase in magnesium in the diet may predispose to the formation of enteroliths.[808] Enteroliths almost always form around a nucleus such as a silicon dioxide stone, a nail (Fig. 32-56), or piece of rope that has been ingested and are most commonly found in the right dorsal and transverse colons. Although enterolithiasis has a wide geographic distribution, horses in California have a high incidence. In one California-based study, horses with enterolithiasis represented 28% of the surgical colic population. In addition, Arabians, Morgans, American Saddlebreds, and donkeys are at risk of this disease.[809] A more recent study performed in California indicated that horses fed a diet composed predominantly of alfalfa hay are at risk for development of enterolithiasis, and allowing horses to graze on pasture was protective against this disease.[810]

Initially, clinical signs include intermittent abdominal pain in mature horses (almost always greater than 4 years of age),[811] with few abnormalities on rectal examination. As enteroliths become larger, they may occlude the lumen of the colon and cause acute pain and large colon distention that necessitate surgical exploration. In some cases an enterolith is forced into the small colon, where it causes acute small colon obstruction. Enteroliths may be diagnosed by abdominal radiography or at surgery. On rare occasions, an enterolith may be palpated per rectum, particularly if it is present in the distal small colon.

Fig. 32-56 Cut section of an enterolith. Note the presence of a nail head *(arrow)* that served as a nucleus for the formation of a struvite enterolith. Courtesy Dr. David G. Bristol.



In general, surgery is required for these cases, although there are reports of enteroliths being retrieved per rectum. In fact, in one study 14% of horses presented for treatment of enterolithiasis had a history of passing an enterolith in the feces.[809] However, enteroliths are typically located in the right dorsal colon, transverse colon, or small colon. At surgery the enterolith is gently pushed toward a pelvic flexure enterotomy, but removal frequently requires a separate right dorsal colon enterotomy to prevent rupture of the colon. After removal of an enterolith, further exploration must be conducted to determine if other enteroliths are present. Solitary enteroliths are usually round, whereas multiple enteroliths have flat sides. The prognosis is good (92% 1-year survival of horses recovered from surgery in one study of 900 cases) unless the colon is ruptured during removal of an enterolith. In one recent study, rupture occurred in 15% of cases.[809]

32.80.4 Sand Impactions of the Large Colon

Sand impactions of the large colon are common in horses with access to sandy soils, particularly horses whose feed is placed on the ground. Sand accumulates in the large colon, particularly the right dorsal colon and pelvic flexure.[812,813] In addition, sand may trigger diarrhea, presumably as a result of irritation of the colonic mucosa.[814] In horses with sand impactions, clinical signs are similar to those of horses with large colon impactions. In addition, sand may be found in the feces, and auscultation of the ventral abdomen may reveal sounds of sand moving within the large colon.[815] Sand also may be detected on abdominal radiography. The diagnosis is definitively made at surgery but may be tentatively based on clinical signs compatible with a large colon impaction together with evidence of sand in the feces. To determine the presence of sand, several fecal balls are placed in a rectal palpation sleeve or other container, which is subsequently filled with water. If sand is present, it will accumulate at the bottom of the container. In addition, mineral opacity may be detected within the colon on abdominal radiographs.

Initially, medical therapy is warranted. Administration of psyllium hydrophilic mucilloid in water by stomach tube may facilitate passage of sand, although a recent experimental study failed to show a benefit of this treatment.[816] If colic becomes intractable, surgical evacuation of the large colon should be performed. The prognosis is good.

32.81 NONSTRANGULATING OBSTRUCTION OF THE COLON

Several configurations of displacements, including nephrosplenic entrapment of the colon, obstruct the colonic lumen but do not compromise the colonic blood supply. Therefore, technically these are simple obstructions. However, the lumen may not be completely obstructed, and some degree of venous congestion is common.[817] In some cases nonstrangulating obstructions are difficult to differentiate from large colon volvulus, because a volvulus of more than 270 degrees will not result in strangulation of blood supply but can cause considerable abdominal pain and gas distention of the abdomen. In this regard, nonstrangulating obstructions represent early stages of strangulating obstructions. Clinical signs include mild to moderate colic with evidence of large colon distention on palpation of the abdomen per rectum. The diagnosis is confirmed at surgery.[818] If pain is recurrent, particularly if it is of increasing intensity and frequency, or if there is evidence of intestinal compromise (particularly progressive changes in abdominal fluid and cardiovascular parameters indicating systemic deterioration), the horse should be taken immediately to surgery. The prognosis is good, with more than 80% of horses surviving to hospital discharge in a multicenter study.[794]

752
753

32.81.1 Right Dorsal Displacement of the Large Colon

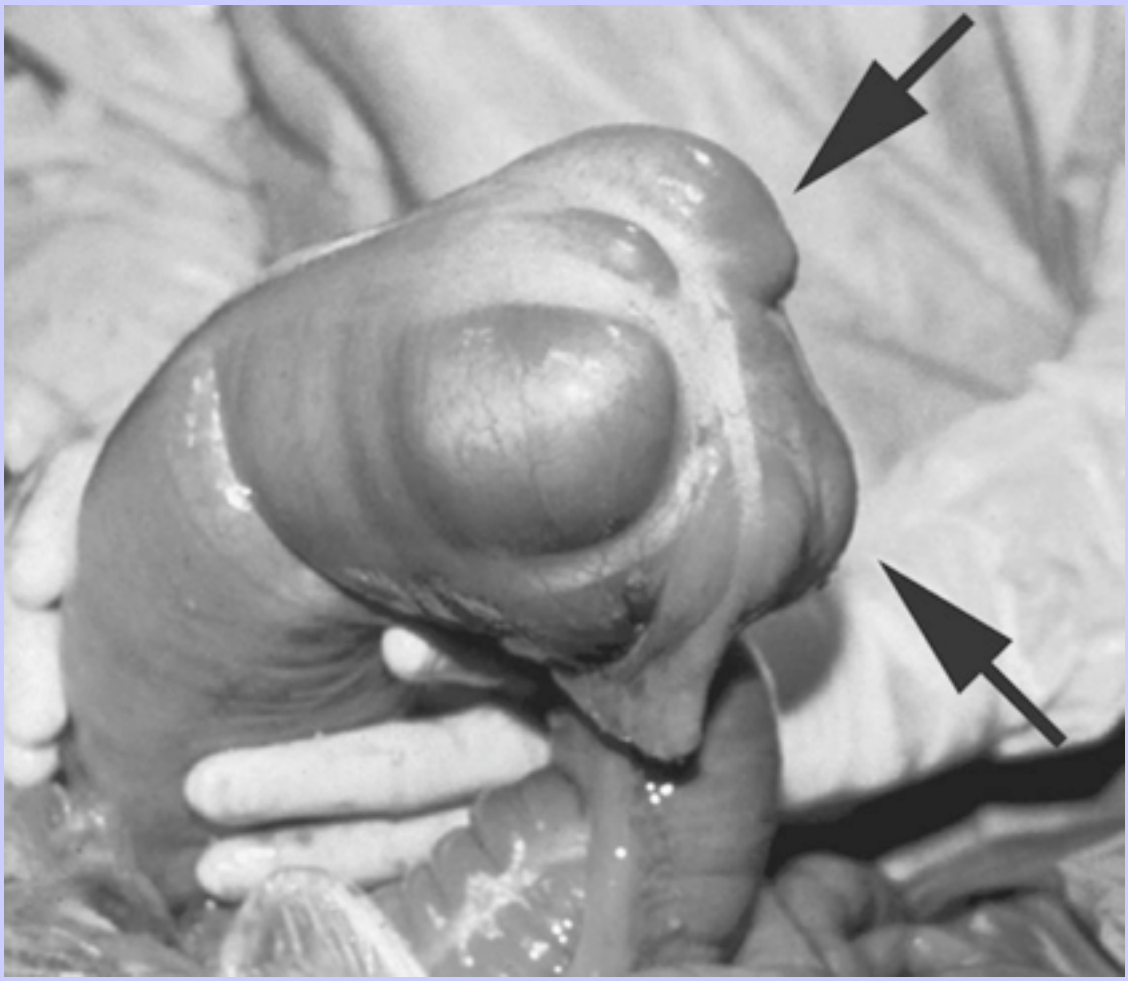
With right dorsal displacement of the colon, the colon displaces to the right of the cecum. Findings on per rectal palpation typically include colonic bands coursing horizontally across the abdomen, with evidence of colon lateral to the cecum. In the most common configuration of right dorsal displacement, the large colon wraps around the cecum (pivoting counterclockwise around the cecum, looking from above the horse) with the pelvic flexure lying in the left dorsal quadrant. Alternatively, the colon may wrap around the cecum in the opposite direction, with the pelvic flexure lying in the right dorsal quadrant.[819]

32.81.2 Nephrosplenic Entrapment (Left Dorsal Displacement) of the Large Colon

On the left side, colon displacements most commonly involve entrapment of the colon over the nephrosplenic ligament, although left dorsal displacements may be detected before the colon is fully entrapped. Clinical signs include gradual onset of mild to moderate colic as the entrapped colon fills with gas. Palpation per rectum will reveal gas-distended ventral colon and displacement of the spleen toward the center of the abdomen. Careful palpation following colonic bands up to the left dorsal quadrant often reveals the presence of colon between the left kidney and the spleen. Diagnosis may be based on palpation per rectum of the colon traversing the nephrosplenic ligament. Alternatively, a tentative diagnosis can be reached using abdominal ultrasonography.[820] The spleen can be visualized on the left side of the abdomen, but the left kidney will be obscured by gas-distended bowel. Evaluation of this technique indicates that there are no instances of false-positive results, although false-negative results may occasionally occur. Therefore, as with other examination techniques, ultrasonography is not uniformly reliable. A definitive diagnosis may require surgery. Treatment has traditionally been surgical intervention, during which the colon is gently rocked free of the nephrosplenic space. More recently, nonsurgical intervention has been successful in select cases.[821,822] If such manipulations are to be attempted, the clinician must be certain of a diagnosis. The horse is anesthetized and placed in right lateral recumbency. The horse is rotated up to dorsal recumbency, rocked back and forth for 5 to 10 minutes, and then rolled down into left lateral recumbency.[823] The nephrosplenic space should be palpated per rectum to determine whether or not the entrapment has been relieved. Phenylephrine (3 to 6 mg/kg/min over 15 minutes) may be administered to decrease the size of the spleen.[824] If the entrapment remains, further attempts may be tried, but in cases where the displacement is not corrected, the horse should be taken to surgery. More recently, phenylephrine has been used in conjunction with 30 to 45 minutes of light exercise (jogging) to successfully reduce nephrosplenic entrapments in four of six horses. This technique can be used on horses with mild to moderate colonic distention, particularly if signs of colic can be readily controlled.

Regardless of technique, the prognosis is good. In one study, survival was in excess of 90%.[822] There are cases in which nonsurgical interventions do not completely correct the problem and others in which nonsurgical manipulations correct the entrapment but result in large colon volvulus or displacement.[825] Such patients should be taken to surgery promptly.

Fig. 32-57 Operative view of a foal with atresia coli. Complete atresia of the pelvic flexure has resulted in a blind-ended ventral colon *(arrows)* resulting in gas distention of the colon. The ventral colon was subsequently anastomosed to the dorsal colon in this foal.



32.81.3 Atresia Coli

Atresia of any segment of the colon is a rare congenital abnormality in horses (Fig. 32-57).[826] The heritability and causes of the condition are unknown. One potential mechanism for development of the lesion is intestinal ischemia during fetal life, which secondarily results in necrosis of a segment of intestine. Clinical signs include a failure to pass meconium and colic within the first 12 to 24 hours of life. Secondary abdominal distention results from complete intestinal obstruction, and abdominal radiographs may reveal gas-distended colon. The diagnosis is made at surgery. Any portion of the colon may be absent, but the distal segment of the large colon and/or the proximal small colon is usually most severely affected. If sufficient tissue is present, anastomosis to the proximal

blind end of the colon may be attempted. The prognosis depends on which segment of the colon is absent but is usually poor because of an absence of distal colon.

32.82 STRANGULATING OBSTRUCTION

Although simple obstruction of the large colon carries a very favorable prognosis, strangulating obstruction of the large colon is associated with high fatality rates. Two forms of strangulating obstruction are recognized: hemorrhagic strangulating obstruction, in which the arterial blood flow remains patent while veins are collapsed, and ischemic strangulating obstruction, in which both the arteries and veins are collapsed. The differentiating factor between the two is likely how tightly twisted the volvulus is. It has been suggested that ingesta-filled intestine is more likely to develop a hemorrhagic lesion during volvulus because the intestinal contents prevent the intestine from twisting tightly.[827]

32.82.1 Large Colon Volvulus

Clinical signs include rapid onset of severe, unrelenting abdominal pain.[828] Although postparturient broodmares appear to be at risk, this association has not been conclusively determined. Once the large colon is strangulated (>270 degrees volvulus), gas distention is marked, leading to gross distention of the abdomen, compromised respiration as the distended bowel presses against the diaphragm, and visceral pooling of blood as the caudal vena cava is compressed. Horses with this condition are frequently refractory to even the most potent of analgesics. These horses may prefer to lie in dorsal recumbency, presumably to take weight off the strangulated colon. An abbreviated physical examination is warranted in these cases, because the time elapsed from the onset of strangulation to surgical correction is critical. Experimentally the colon is irreversibly damaged with 3 to 4 hours of 360-degree volvulus of the entire colon.[829] Despite severe pain and hypovolemia, horses may have a paradoxically low heart rate, possibly related to increased vagal tone. In addition, results of abdominocentesis are often not indicative of the degree of colon compromise,[830] and in many cases abdominocentesis should not be done because of extreme colonic distention. Palpation per rectum will reveal severe gas distention of the large colon, often restricting access to the abdomen beyond the pelvic brim. The diagnosis may be tentatively based on signalment, severity of pain, and degree of distention.

753

754

At surgery the volvulus is typically located at the mesenteric attachment of the colon to the dorsal body wall, and the most common direction of the twist is dorsomedial using the right ventral colon as a reference point. However, the colon may twist in the opposite direction, twist more than 360 degrees (up to 720 degrees has been reported), or twist at the level of the diaphragmatic and sternal flexures. In all cases the colon should be decompressed as much as possible, and in many cases evacuation of colon contents via a pelvic flexure enterotomy will facilitate correction of the volvulus. A determination must be made after correction of the volvulus as to whether the colon has been irreversibly injured. This is frequently based on mucosal color and bleeding (if an enterotomy has been performed), palpation of a pulse in the colonic arteries, serosal color, and appearance of muscular motility. However, determination of viability based on these parameters is unreliable. Currently, one of the most reliable techniques for determining viability is histologic evaluation of frozen sections of colonic mucosa. Biopsies may be obtained at the pelvic flexure because it has been determined that mucosal changes are uniform throughout strangulated colon. A prediction of viability is based on the degree of crypt epithelial loss and the interstitium:crypt ratio (based on measurements of the crypt width and the width of interstitial space between crypts). In one study, 16 of 18 horses that had >50% loss of crypt epithelium and an interstitium:crypt ratio of >3 typically did not survive, whereas 43 of 46 horses that had less severe mucosal changes survived, suggesting high accuracy.[831] In addition, it has been suggested that accuracy of viability

determination can be increased by combining histologic evaluation with surface oximetry or laser Doppler determination of blood flow.[832] Unfortunately, frozen histologic sections are not available at most referral centers on an emergency basis. One recent study assessed intraoperative colonic intraluminal pressure as a more practical potential indicator of outcome in horses with large colon volvulus but found this measurement to be of little benefit in accurately making this determination.[833]

If the colon is judged to be irreversibly damaged, the feasibility of a large colon resection can be considered. Although 95% of the colon can be resected (that part of the colon distal to the level of the cecocolic fold), damage from the volvulus usually exceeds what can be resected. In these cases surgeons may elect to resect as much damaged bowel as possible or may advise euthanasia.

The prognosis for survival is guarded to poor because of the rapid onset of this disease. In one study the survival rate was 35%.[830] In a more recent report, the survival rate was 36% for horses with 360-degree volvulus of the large colon compared with 71% for horses with 270-degree volvulus.[828] However, one study in central Kentucky documented a high success rate, most likely because of early recognition of the disease and the proximity of the hospital to the surgical caseload.[834] Postoperative complications include hypovolemic and endotoxemic shock, extensive loss of circulating protein, disseminated intravascular coagulation, and laminitis. In addition, large colon volvulus has a propensity to recur. Although one study documented a recurrence rate of less than 5%,[830] some authors believe recurrence may be as high as 50%. Therefore methods to prevent recurrence should be considered.[835,836]

32.82.2 Intussusception

The most common intussusception of the large intestine is cecocolic intussusception, although when this is compared with all forms of colic, it is a relatively rare condition of the horse, accounting for 11 of 842 horses (1.3%) taken to surgery because of colic at one hospital.[837] The condition tends to occur in young horses (2 to 3 years of age) and may be associated with intestinal parasites, particularly tapeworms. Clinical signs include acute onset of colic that varies in severity according to the degree of intussusception. Initially, the cecal tip inverts, creating a cecocecal intussusception, which does not obstruct flow of ingesta. As the intussusception progresses, the cecum inverts into the right ventral colon (cecocolic intussusception), which obstructs flow of ingesta and often causes severe colic. In one report on cecocolic intussusception, 10 of 11 horses had severe colic.[837] The cause of abdominal pain is often difficult to differentiate in these cases, although it is sometimes possible to detect a mass on the right side of the abdomen and the concurrent absence of a palpable cecum. Treatment involves manual surgical reduction by retracting the intussusceptum directly or via an enterotomy in the right ventral colon.[838] The prognosis is usually regarded as poor because of severe compromise to the cecum and the risk of cecal rupture or severe contamination during surgery. However, a recent report has indicated that seven of eight horses that underwent right ventral colon enterotomy and cecal resection survived long term.[838]

Colocolic intussusceptions are rare but have reportedly affected the pelvic flexure and the left colon.[839–842] Although the condition is reportedly more common in young horses, older horses may be affected. Clinical findings may include a palpable mass on the left side of the abdomen. Ultrasonography may also be useful. Treatment requires manual reduction of the intussusception at surgery, or resection of affected bowel.

32.83 NONSTEROIDAL ANTIINFLAMMATORY DRUG TOXICITY

Samuel L. Jones

Use of NSAIDs is common in equine practice because of their antipyretic, analgesic, and antiinflammatory properties. These drugs are used to treat horses with colic, endotoxemia, musculoskeletal disorders, and other medical problems. In addition to these therapeutic properties, NSAIDs also exhibit unwanted toxic side effects. The NSAIDs have a relatively narrow therapeutic range, and when they are administered at excessive doses, toxicosis can occur within a few days. Although generally safe when administered at recommended doses,[843] some horses may exhibit signs of toxicosis at these doses within days or weeks.[844,845] The risk of toxicity is exacerbated in animals that are dehydrated or septic (e.g., endotoxemic patients). Recommended doses for NSAIDs commonly administered to horses include the following:

754

755

- Phenylbutazone, 2.2 to 4.4 mg/kg q12h
- Flunixin meglumine, 1.1 mg/kg q12h or 0.25 mg/kg q8h
- Ketoprofen,* 2.2 mg/kg q24h
- Meclofenamic acid,† 2.2 mg/kg q12-24h
- Naproxen,‡ 5 to 10 mg/kg q12-24h
- Aspirin, 12 to 25 mg/kg q12-48h

32.83.1 Pathophysiology and Predisposing Factors

The principal mechanism of the therapeutic and toxic effects of NSAIDs is related to their inhibition of prostaglandin synthesis by inhibition of the COX enzyme. Two isoforms of the COX enzyme have been identified: COX-1 and COX-2.[846] COX-1 is generally constitutively expressed and is thought to play an important role in maintaining physiologic homeostasis; it is found in such tissues as the gastrointestinal mucosa and kidney and in the endothelium and platelets. In contrast, COX-2 is primarily an inducible enzyme that has a critical role in inflammation and is produced by a variety of cells including monocytes, neutrophils, epithelial cells, fibroblasts, synoviocytes, and chondrocytes.

It has been postulated that drugs that nonselectively inhibit both COX-1 and COX-2 have greater toxic potential because they inhibit prostaglandins necessary for physiologic homeostasis as well as prostaglandins that mediate inflammation and pain.[846] Both COX-1– and COX-2–dependent prostaglandins play an important role not only in maintaining the epithelial barrier in the gut, but also in healing the epithelium when the mucosa is damaged (e.g., because of ischemic injury or infection). All of the commonly used NSAIDs in horses are considered to be nonselective. NSAIDs that are COX-2 selective are less ulcerogenic in other species and may be so in horses. For example, COX-2 selectivity decreases the adverse effects of NSAIDs in a model of epithelial repair in horses.[847] COX-2 selective NSAIDs are being developed for use in horses but are not yet approved for use in the United States.

Although the COX-1–versus—COX-2 scheme is currently considered valid, evidence exists that it may be overly simplistic. For example, COX-1 may play an important role in inflammation and is at least partly

inducible.[848] In contrast, COX-2 can be induced physiologically in various organs and tissues and by stimuli other than inflammation.[846,849] In horses, gastric ulcerogenicity of even the nonselective NSAIDs varies (phenylbutazone > flunixin meglumine > ketoprofen).[850] This difference in toxicity among drugs may relate not only to the COX selectivity, but also on other factors such as tissue distribution.

The gastrointestinal tract and the kidneys are the most common targets for NSAID toxicity. NSAID-induced injury can develop anywhere in the gastrointestinal tract (from the mouth to the rectum). Two well-recognized syndromes may be attributed at least in part to NSAID toxicity. The first is gastric ulceration. In the stomach, inhibition of COX can increase acid secretion, decrease output of mucus and bicarbonate, impair vasodilation, and diminish epithelial restitution, cell division, and angiogenesis.[851] Inhibition of COX also impairs the healing of existing ulcers. A second syndrome attributed to NSAID toxicity is right dorsal ulcerative colitis (RDUC). Although the right dorsal segment of the large intestine is most commonly affected, other segments may also be involved. Ulcerative lesions in the large intestine can be particularly troublesome because they can cause chronic debilitation, are difficult to diagnose, and can be refractory to treatment. In the kidney, PGE_2 and PGI_2 (prostacyclin) produce vasodilation in the autoregulatory response of renal blood flow to hypoperfusion; consequently, hypovolemia, hemorrhage, or renal disease will increase the risk of renal NSAID toxicosis. Damage is greatest at the renal crest (papilla), and papillary crest necrosis may be associated with subsequent nephrolithiasis or ureterolithiasis and chronic renal failure.[852] In humans the most common side effect of NSAIDs is bleeding, caused in part by reduced function of platelets and in part by gastrointestinal hemorrhage.

Not all of the adverse effects of NSAIDs are attributable to COX inhibition. The NSAIDs also cause injury from a variety of mechanisms, including microvascular damage, increased intracellular concentration of reactive oxygen and other free radicals, direct local injury (particularly with ion trapping in the stomach), inhibition of cell division, and reduced hydrophobicity of the gastric mucous coat.[849,851] Inhibiting COX may shunt arachidonic acid metabolism toward the lipoxygenase pathway, thereby producing other biologically active eicosanoids. The clinical significance of this shunting is unclear, but the potential for deleterious effects exists.

Although the toxicity of NSAIDs is related to the dose and duration of administration, some horses develop toxicosis at recommended doses. Predisposing factors such as dehydration, renal disease, hepatic disease, or sepsis may contribute to the development of NSAID toxicity. Dehydration, renal disease, and hepatic disease predispose to NSAID toxicosis because of reduced tissue perfusion and reduced drug elimination. Sepsis may predispose to NSAID toxicosis because of secondary hypovolemia, decreased tissue perfusion, and direct and indirect effects of various mediators produced in response to sepsis (e.g., platelet aggregating factor). In humans, risk of NSAID-induced ulceration is increased among those with various gastrointestinal disorders (e.g., IBDs). NSAIDs inhibit the ability of injured equine intestinal mucosa to repair, which may increase the risk of ulceration in horses with ischemic damage or intestinal infections. Body weight may be a predisposing factor in that NSAIDs are often administered to ponies, miniature horses, and small horses at doses higher than those recommended for their body weight. Inadvertent overdosing can occur regardless of body weight or size (e.g., administration of a 12-g tube of phenylbutazone paste when administration of an anthelmintic paste was intended).

Some horses may have an idiosyncratic predisposition, particularly for ulceration of the right dorsal colon. Experimentally, arthritic laboratory animals were more susceptible to NSAID-induced gastropathy than healthy animals.[853] This finding may have relevance to horses because NSAIDs are often administered to chronically lame horses. Two or more NSAIDs are used concurrently in some situations. It is important to recognize that the effects of combining NSAIDs are additive, such that administering two NSAIDs at each of their recommended

doses is similar to giving twice the recommended dose of one NSAID. Combination of two NSAIDs will prolong their pharmacologic effect and increase the risk of toxicity.[854]

32.83.2 Clinical Signs

Clinical signs of NSAID toxicity are usually referable to the alimentary system and vary depending on the segment involved. Oral or lingual ulceration may lead to difficulty in prehension and mastication. Esophageal ulceration may result in excessive salivation and apparent signs of pain (stretching of the neck, groaning) during swallowing. Gastric ulceration may result in slow consumption of feed, inappetence (particularly for grain in some horses), or anorexia. Horses that have gastric outflow obstruction associated with gastroduodenal ulceration may exhibit ptyalism, reflux esophagitis, and, in severe cases, spontaneous nasogastric reflux. Horses with ulceration anywhere in the gastrointestinal tract may exhibit signs of colic, which may be intermittent and varying in severity. Horses with colonic ulceration may have soft stool or diarrhea and ventral edema secondary to enteric protein loss. Diarrhea can be severe, even fatal. Endotoxemia may result from intestinal mucosal damage caused by NSAIDs. Clinical signs of endotoxemia (e.g., tachycardia, altered appearance of mucous membranes, fever, and dehydration) may be seen in some horses with NSAID enteropathy. In some horses, hematuria may be seen.

755 756

Horses may have clinical signs days to weeks after having been administered NSAIDs. Such horses typically are presented because of recurring colic, weight loss, or loose manure. It is particularly important in these horses to determine whether there is any history of NSAID administration, even if it was several weeks previous to the time of presentation.

32.83.3 Diagnosis

Diagnosis is usually made on the basis of history of NSAID use, clinical signs, and clinicopathologic findings. The most consistent clinicopathologic abnormalities in horses with NSAID toxicosis are hypoproteinemia and hypoalbuminemia, presumably from loss of protein through inflamed intestinal mucosa. These findings are more commonly observed with damage to the distal intestinal tract and are not reliable for diagnosis of NSAID gastropathy. Some horses have decreased serum concentration of calcium, presumably attributable to intestinal loss of protein-bound calcium. In horses with NSAID-induced diarrhea, hyponatremia, hypochloremia, hypokalemia, acidemia, and hypovolemia may be observed if the diarrhea is severe. In such cases, hypovolemia may make the serum protein concentration appear to be higher than its actual value would be were the horse adequately hydrated.

In chronic cases, horses may be anemic from inflammation, intestinal loss of blood through ulceration, or reduced function of platelets. Occult blood may be found in the feces of horses with lesions in the more distal portions of the intestinal tract. Tests for occult blood often lack sensitivity, and false-positive results may be expected for up to 24 hours after rectal palpation.

The concentration of leukocytes is usually within the reference range, although leukocytosis and hyperfibrinogenemia, associated with inflammation, and leukopenia and neutropenia, presumably caused by endotoxemia, can be seen in some horses with acute NSAID toxicosis affecting the distal intestine. Generally, results of peritoneal fluid analysis are within reference ranges, but increased concentration of nucleated WBCs,

total protein, and fibrinogen may be seen when there is advanced intestinal damage or intestinal vascular infarction. When findings of cytologic examination of peritoneal fluid are abnormal, results are more consistent with nonseptic than septic inflammation; however, septic inflammation may be observed when severe intestinal ulceration leads to transmural lesions and septic peritonitis.

Several clinicopathologic changes may accompany NSAID-induced renal damage. The most consistent finding is decreased urine specific gravity, from 1.008 to 1.020. Inability to properly dilute urine can be found with acute NSAID toxicosis for years after the original insult. This results from preferential damage to areas of the kidney that contribute most to concentrating urine (medulla, papilla). In chronic cases urine specific gravity typically ranges from 1.013 to 1.020. Some horses with NSAID toxicosis are azotemic. In acute cases azotemia can result from dehydration, NSAID-induced alterations in renal blood flow, and tubuloglomerular feedback mechanisms. Chronic azotemia, with serum creatinine ranging from 2.1 to 3.5 mg/dL, results from tubuloglomerular feedback mechanisms that reduce glomerular filtration to compensate for reduced reclamation of solutes in the medullary collecting ducts. In acute NSAID toxicosis, there may be overt hematuria. In other cases, urinalysis may reveal occult blood, increased renal cells, and increased WBCs. In chronic cases other than decreased urine specific gravity, urinalysis results are typically normal.

Endoscopy can be useful to visualize the location and extent of esophageal and gastric lesions. NSAID-induced gastric lesions are more common in the glandular epithelium, although nonglandular lesions can be observed. Contrast radiography or scintigraphy may be useful to document delayed gastric emptying in some horses. Lesions of the jejunum, ileum, cecum, and colon can be difficult to identify without celiotomy and enterotomy. Isotope-labeled WBC scintigraphic scans may identify colonic ulceration[855]; the sensitivity and availability of the procedure is limited, however. Ultrasonography may reveal thickening of the right dorsal colon or other colonic segments, but the technique appears to lack sensitivity.[856] Horses with renal crest necrosis may have increased ultrasonographic echogenicity of the renal crest and echogenic debris in the renal pelvis.

32.83.4 Management

Administration of NSAIDs should be discontinued if NSAID toxicosis is suspected. Gastric lavage and administration of 1 gallon of mineral oil per 450 kg of body weight via nasogastric tube may be of benefit in horses with acute NSAID overdose to reduce the absorption of the administered NSAID. Treatment for gastric ulceration with a proton-pump inhibitor (e.g., omeprazole[*]), an H_2-receptor blocker (e.g., ranitidine), or sucralfate should be implemented for horses with gastric ulceration.

Regardless of the site of NSAID toxicity, administration of misoprostol[†] may be of benefit because administration of a synthetic analog of PGE_2 has been demonstrated to prevent phenylbutazone-induced gastrointestinal lesions in horses.[857] Misoprostol, a synthetic analog of prostaglandin E_1, can be administered orally starting at doses of 5 µg/kg q12h or 2 µg/kg q6h. Some horses will develop signs of abdominal discomfort or diarrhea at these doses; another protocol is starting at 1.5 µg/kg q8h for 2 to 4 days and increasing at increments of 0.5 µg/kg q8h every 2 to 4 days until a maintenance dose of 2.5 to 3 µg/kg q8h is achieved. Because of the paucity of experimental and clinical data for this drug, dosage schedules should be individually tailored for the horse's illness and tolerance to the drug.

For horses with hypovolemia secondary to colitis, administration of crystalloid fluids is indicated. Infusion of plasma may benefit horses with NSAID-induced enteropathies and signs of endotoxemia. The aim of plasma transfusion in a hypoproteinemic horse with colitis need not be to increase the plasma concentration into the reference range, because this may be cost-prohibitive and infused protein may be rapidly lost via the intestinal

tract. Smaller volumes of plasma (1 to 3 L in an average-size horse) may exert beneficial effects by increasing colloid oncotic pressure and perhaps by modulating the effects of endotoxemia. Alternative colloidal fluids may be beneficial as well. Hetastarch (5 to 10 mL/kg IV q48-72h) may maintain plasma colloid oncotic pressure in the acute stages of the NSAID toxicity. Administration of broad-spectrum antimicrobial drugs may be indicated when signs of endotoxemia are observed. Parenteral administration of antimicrobial drugs is preferable to oral administration in horses with colitis because of the presumed increased risk of antimicrobial-associated diarrhea with the oral route. Oral administration of metronidazole (10 to 15 mg/kg PO q8-12h) might be an exception to this guideline, because evidence exists that metronidazole may exert an antiinflammatory effect and enhance healing in NSAID-induced intestinal ulceration.[858]

For horses with RDUC, dietary management directed toward providing a low-bulk diet in the form of a pelleted concentrate and restricting or eliminating ingestion of roughage is recommended. The aims of this approach are to decrease the mechanical and physiologic load of the colon. A complete pelleted diet (i.e., a diet that contains both concentrate and adequate but relatively low dietary roughage) will decrease intestinal fill in the colon. A diet lower in fiber should decrease the physiologic load of the colon because the cecum and large colon are the primary sites in horses of fiber digestion and exchange of fluid and electrolytes. Concentrate should be fed in smaller amounts and frequently (four to six feedings per day). Addition of corn oil may provide additional calories and may also aid in healing of the damaged intestinal mucosa by promoting PGE_2 production. Some horses will not eat complete pellets, and some horses that have roughage withheld will eat bedding or wood as a consequence. These horses should be allowed to eat fresh grass in small amounts on a frequent basis (four to six times daily). The importance of and optimal duration for restriction of roughage is unknown, but it likely requires months for the colon to heal. Horses should be changed from and returned to their usual diet over a period of several days to decrease the risk of inducing other digestive disorders.

Feeding psyllium mucilloid may promote colonic healing in horses with RDUC. In other animal species, psyllium mucilloid has been demonstrated to increase the concentration of short-chain fatty acids of the large bowel, and increased short-chain fatty acids can promote colonic mucosal repair.[859] The amount and duration of psyllium mucilloid administered orally that is required to alter the colonic concentration of short-chain fatty acids and the role of short-chain fatty acids in repair of RDUC in horses is unknown. Continuous feeding according to manufacturer's recommendations for 3 to 6 months is suggested, or feeding 1 to 2 oz of psyllium mucilloid once or twice daily for the same duration may be considered.

Horses with strictures of the pylorus, duodenum, jejunum, or colon may require surgical management. Bypass or resection of affected intestinal segments may be necessary.

Limiting the extent of predisposing factors, such as dehydration, should decrease the risk of NSAID toxicosis. Avoiding use of NSAIDs or limiting the dose and duration of treatment to the minimum that is required to control the primary problem is recommended to decrease the risk of NSAID toxicosis. Other approaches to analgesia, such as regional (epidural or perineural nerve blocks of distal limbs) anesthesia or administration of butorphanol,* should be considered.

32.84 DISORDERS OF THE DESCENDING (SMALL) COLON

Vanessa L. Cook

Colic resulting from a problem with the small colon is comparatively rare, being identified in only 4.2% of surgical colics.[860] However, American Miniature Horses (AMHs) seem to be at increased risk for obstruction of the small colon,[861] with a prevalence of 60% of surgical colics in that breed.[862] The Arabian breed may also be overrepresented compared with the hospital population.[860,861] It is interesting to note that horses over 15 years of age also seem to be at an increased risk for small colon conditions,[861] especially strangulating lipoma, foaling injury, and submucosal hematoma.[860] Mares may also be at increased risk for small colon lesions, possibly because of hormonal fluctuations affecting gastrointestinal motility,[861] because of the small colon's predisposition to injury during foaling, or because of the small colon's ability to become entrapped by an ovary.

One of the biggest challenges with small colon lesions is that the associated clinical signs and rate of physiologic deterioration are less severe than with a higher obstruction, often resulting in later referral.[860,861] A complete examination including rectal examination and abdominocentesis provides useful information in determining the diagnosis and indicating surgical intervention.[860] However, because the small colon lies caudally in the abdomen, transabdominal ultrasonography may be less useful than it is for lesions in other sections of the intestinal tract. Transrectal ultrasonography, performed with care, may be a more sensitive method to detect compromised small colon and may aid in earlier diagnosis.[863]

Conditions affecting the small colon can be divided into congenital diseases, simple obstructions, vascular lesions, and strangulating lesions.

32.85 CONGENITAL DISEASES

32.85.1 Atresia Coli and Aganglionosis

Atresia coli is much more rare in foals than it is in calves, with a reported incidence of 0.44%.[864] There are several theories on the pathogenesis of this disease, but an ischemic vascular accident that results in atrophy of the affected segment is the most widely accepted.[865] There are four types of atresia,[866] with type 3, blind end atresia with no connection of the atretic segments, being the most common in foals.[864,867] Atresia coli may be confused with overo lethal white syndrome, in which affected foals have myenteric aganglionosis of the distal intestinal tract resulting from a mutation in the endothelin receptor type B gene.[868,869] However, in this condition the intestinal tract is patent but nonfunctional. Loss of neurons in the myenteric plexus of the small colon can also be found in equine dysautonomia (grass sickness), although it is usually less severely affected than the ileum.[870]

Foals with atresia are usually normal at birth but develop progressive abdominal distention and colic within 24 hours of birth. Atresia can be differentiated from other causes of colic in foals by the lack of feces with no meconium staining even after an enema.[865] It may be possible to confirm a blind ending rectum or distal small colon by digital palpation or passage of a soft catheter or endoscope. However, the defect is usually too proximal to visualize this way, and perforation of the friable colonic mucosa can easily occur; therefore I do not use this method for diagnosis. Plain radiographs do not usually identify the atresia but can help to differentiate it from a meconium impaction. Retrograde contrast radiography, as described later in this section for meconium impaction, may give a more definitive answer.[871] A large volume of barium sulfate, up to 20 mL/kg, may be needed if the atresia is proximal to the transverse colon. If atresia is present, the contrast agent will be seen to end abruptly at the atretic segment.

The only chance for survival in cases of atresia is early exploratory celiotomy to assess the affected segment and determine if surgical correction is possible. In calves with atresia, the prognosis is vastly improved if the diagnosis is made early and the animal is alert and is stabilized medically before surgery.[872,873] However, in foals, despite attempting surgical resection of the atretic segment and anastomosis, the prognosis is grave, with a 100% mortality rate reported in several studies.[864,867]

32.86 SIMPLE OBSTRUCTIONS

32.86.1 Simple Impaction

Small colon impaction is the most common abnormal condition of the small colon in adult horses, affecting 1.9% to 2.5% of all horses seen for colic at referral institutes.[874,875] Several studies report a strong association between small colon impaction and diarrhea. The most recent study documents that horses with diarrhea are 10 times more likely to develop a small colon impaction than horses without diarrhea.[876] In other studies, diarrhea developed during hospitalization in 70% of all horses with small colon impaction, and 43% of those treated surgically cultured positive for *Salmonella* species.[874] These studies suggest that impaction of the small colon may be a sequela to colonic inflammation, such as *Salmonella* infection. Therefore it is advisable to use isolation protocols for all horses with a small colon impaction. Previous reports have documented a dramatic increase in the incidence of small colon impaction in the fall and winter, possibly because of decreased water intake or close housing that increases the incidence of infectious colitis, but a definitive reason is unknown. It is interesting to note that this seasonal incidence was not significant in the most recent study, possibly because of the milder winters in the south.[876]

Diagnosis of a small colon impaction is most easily made by rectal palpation, with an accuracy of 79% to 87%.[874,876] A solid tube of ingesta with loss of the normal sacculations is found. However, great care should be taken when performing a rectal examination because the rectal mucosa may be edematous, and frequently the horse will strain.[877] It now appears that the best parameter for determining when surgical treatment of these cases is required is the presence of abdominal distention. Recently it has been reported that horses with a small colon impaction and abdominal distention are five times more likely to require surgical correction than horses without abdominal distention.[876] Unlike other types of colic, this single factor is more significant than heart rate, temperature, or duration of colic when determining the need for surgical intervention.[876]

Medical therapy should consist of aggressive intravenous and enteral fluid therapy, including correction of electrolyte abnormalities, combined with laxatives and lubricants, and analgesics as necessary.[874,875] The length of time for the impaction to resolve with medical treatment is often longer than for large colon impactions, averaging over 2 days.[876] Surgical correction of the impaction via exploratory celiotomy is usually performed via a high enema combined with extra luminal massage by the surgeon. The impacted small colon is extremely friable, and great care should be taken by the surgeon when manipulating the bowel in order to avoid serosal tears. Application of sterile carboxymethylcellulose to the serosal surface may help lubricate the intestine and reduce the trauma of manipulation. In severe cases, infusion of the impacted contents with isotonic fluids or an enterotomy in the small colon may be necessary to facilitate evacuation of the impaction.[877] An additional concern is the risk of reimpaction of the small colon as ingesta from the large colon move aborally after surgery. Therefore if there are ingesta in the large colon at the time of surgery, a pelvic flexure enterotomy is recommended to empty the large colon and reduce the risk of recurrence.[874] Surgical correction of the impaction

can be time-consuming; therefore to reduce anesthesia time it is advisable to assemble the items needed for a high enema, such as a stomach tube with a rounded atraumatic end, stomach pump, and buckets of warm water, in the operating room before induction.

The prognosis for medical and surgical treatment appears to be similar in most studies.[874,876] It is interesting to note, however, that overall prognosis appears to have improved in recent years, increasing from approximately 75% in cases from 1986 to 1996[874] to approximately 95% in cases from 1999 to 2004.[876] Therefore, overall, the prognosis for small colon impaction is excellent, even if surgical treatment is necessary. However, because of the underlying inflammatory cause of this condition, length of hospitalization and associated costs tend to be higher than those incurred with a simple large colon impaction.[876]

32.86.2 Fecaliths, Enteroliths, and Foreign Bodies

Simple obstruction of the small colon also occurs from inspissated feces (fecaliths), enteroliths, foreign bodies, or, less frequently, concretions of plant material (phytobezoars) or masses of matted hair (trichobezoars).

Fecaliths are improperly formed fecal balls that are larger than normal at 4 to 6 cm diameter in miniature horses.[878] They are a common cause of colic in young miniature horses,[878] with an occurrence rate of 63% in a study of surgical colic in miniature horses.[879] Causes of the formation of fecaliths are probably similar to those of other impactions and include poor-quality roughage, dental disease causing problems with mastication, and reduced water intake.[878,879] Fecaliths that become lodged in the small colon usually cause complete intestinal obstruction and require surgical removal as described later. When managing colic in miniature horses, regardless of the cause, the patient should have serum triglyceride concentration monitored to allow early detection and treatment of hyperlipemia.[880]

Enteroliths are mainly composed of magnesium ammonium phosphate deposited in concentric layers around a nidus such as a small rock.[881] The incidence is very high in certain areas, such as California, where enterolithiasis constitutes 15.1% of all colic seen at the University of California, Davis[882] compared with less than 2% of colic cases at Texas A&M University.[883] Several studies report an increased incidence in Arabians, although the reason for this is unknown. Enteroliths can lodge in the large colon, transverse colon, or small colon, but the last is a relatively common site, with over 45% of cases involving an obstructive enterolith in the small colon.[882] Horses with enteroliths were found to have certain changes in the composition of their colonic contents, compared with other surgical colic cases, which may predispose them to enterolith formation. These differences included a more alkaline pH, more colonic fluid, and higher mineral concentrations.[884] Certain management practices may also predispose to enterolith formation, including feeding a high proportion of alfalfa and giving less access to pasture.[883,884] Clinical signs of enterolithiasis are similar to those seen with other nonstrangulating obstructions of the large or small colon. However, many horses with enterolithiasis have a history of intermittent colic, and some may even have passed enteroliths in the feces.[882] Abdominal radiographs may be a useful aid in diagnosis, although the sensitivity is reduced when the enterolith is in the small colon.[885] Medical management aimed at reducing colonic pH has been suggested to try and prevent recurrence after surgery. However, when an enterolith lodges in the small colon it usually causes complete obstruction and acute colic that requires surgical intervention as described later. Rupture of the gastrointestinal tract is particularly common if the enterolith is lodged in the small colon and surgery is delayed.[882] Such cases should therefore be prioritized as requiring emergency surgery, even when there is a history of chronic colic.

Obstruction of the small colon can also occur from ingestion of foreign material such as rope, twine, rubber fencing, cloth, or tires.[886,887] This is usually a problem of younger horses, possibly because they are more inquisitive and will eat nonfood items found in their environment. It is possible for the foreign body to cause signs of small intestinal obstruction first, followed by a period of quiescence while it passes through the large colon before it finally causes complete obstruction of the small colon and acute onset of severe colic[888] and abdominal distention.[886] The fibers become covered in crystalline material during their transit through the intestinal tract, and the resulting irregular sharp projections cause mucosal ulceration,[860] which can be seen during exploratory celiotomy oral to the site where the foreign body has finally become lodged. These sharp projections make it virtually impossible to manipulate the foreign body orally or aborally within the lumen, making removal more complicated.

The majority of these obstructions require exploratory laparotomy and an enterotomy to allow the obstruction to be removed.[878,882,886] Regardless of the cause of the obstruction, the overlying intestine is friable and can easily rupture either during induction of anesthesia[886] or during surgical manipulation.[882,887] If possible, the mass should be gently manipulated more proximal or distal to the original site at which it lodged, so that the enterotomy can be performed in uninjured intestine.[860] However foreign bodies in particular may be difficult to manipulate, and the enterotomy may have to be performed directly over the top of the obstruction. The site selected for the enterotomy should be isolated from the abdomen with sterile towels before the enterotomy incision is made. The incision should be made longitudinally through the antimesenteric taenia in order to preserve luminal diameter, reduce hemorrhage, and maximize speed and ease of the procedure.[889,890] The enterotomy can be closed in one layer using an inverting suture pattern.[890] Problems arise, however, when intraluminal obstructions occur at the proximal portion of the descending colon, where the lumen narrows between the transverse and descending colon. Here, manipulation of the obstruction aborally into a section of small colon that can be exteriorized may be impossible. In such cases an antimesenteric teniotomy, through the seromuscular layer alone, can be performed. This will allow the obstruction to be advanced aborally into a section that can be exteriorized, while the intact mucosa prevents abdominal contamination.[891] The enterotomy and seromuscular incision are then closed as described earlier.

32.86.3 Meconium Retention

Meconium is composed of substances that are present in the intestinal tract at birth, such as glandular secretions, sloughed cells, and swallowed amniotic fluid, and is therefore sterile. It is thick and tarry and is usually passed within 48 hours of birth. Several studies indicate a higher incidence of meconium retention in colts than fillies, presumably because of the longer narrower pelvis in males.[892,893] Any factors that reduce intestinal motility, such as failure to ingest colostrum, and dysmaturity, can result in difficulty passing meconium, which is described as meconium retention. This results in progressive clinical signs of colic such as tail flagging, straining, and reduced suckling. This can progress to more severe signs of colic over time, such as rolling and abdominal distention. These signs are similar to those seen with ruptured bladder, and the two conditions can occur together; therefore a complete examination of the foal is important.

It may be possible to palpate meconium retained at the pelvic inlet by careful digital rectal examination. If the meconium is retained more proximally, it may be identified on a plain lateral radiograph. Confirmation of the obstruction may be provided by retrograde contrast radiography, which provides excellent sensitivity and specificity for evaluation of the transverse and descending colon.[871] After plain radiographs are obtained, a Foley catheter is placed into the rectum and inflated. Up to 20 mL/kg (approximately 1 L) of 30% barium sulfate

is carefully allowed to flow in by gravity until it squirts around the catheter or discomfort is observed.[871] Lateral and, more important, ventrodorsal radiographs are then obtained. If a meconium impaction is present, the contrast agent is stopped before it reaches the transverse colon.

Supportive medical management of all foals should be performed first, including correction of fluid and electrolyte imbalances, provision of nutritional support, and correction of failure of passive transfer if indicated.[894] Judicious use of analgesics such as flunixin meglumine or butorphanol and oral laxatives such as mineral oil may aid resolution of the impaction. However, the most effective treatment is administration of an enema. The enema can be a commercial phosphate enema or simply soap and water administered through a Foley catheter using gravity flow as described previously. In cases that are refractory to simple enemas, an acetylcysteine enema may be effective. Acetylcysteine is a mucolytic, which acts by breaking disulfide bonds to make meconium less viscous. These enemas are available commercially (E-Z Pass Foal Enema Kit, Animal Reproduction Systems, Chino, Calif.) or can be formulated by adding 20 g of baking soda to 200 mL of water, and then adding 8 g of acetylcysteine powder to make a 4% solution.[892] The solution is infused slowly through a Foley catheter, which is then clamped to allow the solution to be retained for up to 45 minutes to allow maximum activity of the acetylcysteine. Successful resolution of the meconium retention occurred in all acetylcysteine-treated foals in one study, although 5% of foals did require three enemas before resolution.[892]

Previous reports have indicated that approximately one third of foals with meconium retention require exploratory celiotomy for resolution.[893] However, this was before the increased use of acetylcysteine retention enemas, and it is likely that the current rate of surgical intervention is much lower. Considering the high rate of adhesions in neonatal foals undergoing exploratory laparotomy,[893,895] this should result in an improved prognosis for this condition.

32.86.4 Other Causes of Simple Obstruction

Because of the proximity of the descending colon to the urogenital tract, it is possible for the descending colon to be obstructed by structures such as an ovary or retained testicle. Although such conditions occur infrequently, the most common is for the small colon to become entwined around an ovary.[860] The intestine can be freed and is not usually compromised, but the ovary itself is usually nonviable and requires resection.[896] A similar problem has been reported from the spermatic cord of a retained teratoma occluding the small colon.[897]

32.87 VASCULAR LESIONS

32.87.1 Intramural Hematoma

Intramural hematoma of the small colon is relatively rare, although some cases may not be diagnosed if they do not cause complete obstruction and if they resolve without intervention.[898] Hemorrhage occurs between the mucosa and muscularis layers, which expand to occlude the lumen and cause complete obstruction. The length affected has been reported to range from 24 to 65 cm. The cause is unknown, although in people, blunt abdominal trauma has been associated with the condition.[899] In one equine case series, iatrogenic rectal trauma was implicated as the cause.[900] There is an increased incidence in older horses, with those affected having an average age of 11 years in one study.[860] Affected cases frequently have blood in the rectum and may show signs of vascular compromise from blood loss.[860,900]

Exploratory celiotomy with complete resection of the affected segment and end-to-end anastomosis is necessary. Because of the long length of the affected segment, it may be difficult to exteriorize and resect all damaged intestine. However, if the entire affected segment can be removed, the prognosis is good, with 75% of horses surviving in one study.[898]

32.87.2 Mesocolic Tears and Rectal Prolapse

Tears in the mesentery of the small colon can occur as a complication of parturition, especially in multiparous mares,[901,902] and result in segmental ischemic necrosis of the small colon. Trauma and straining during parturition can result in tearing of the mesocolon and devitalization of the associated descending colon, which may progress to an intussusception of the small colon, which manifests as a type III or IV rectal prolapse. In a type III rectal prolapse the rectal ampulla prolapses, as with a type II prolapse, but in addition a portion of the small colon intussuscepts into the rectum. In type IV rectal prolapse part of the small colon and the rectum intussuscepts through the anus.[901,903] Gentle palpation around the prolapse can help determine the type of prolapse. Although a rectal prolapse is readily identifiable, tears of the mesocolon resulting in devitalization of the small colon result in a more insidious onset of clinical signs, including depression and lack of feces.[901,902]

The mesocolic tear is frequently located caudally, resulting in the affected area being inaccessible via a midline celiotomy. Therefore it may be more prudent to first perform standing flank laparoscopy to determine the location and extent of the lesion.[904] This allows assessment of the lesion to determine if resection and anastomosis of the affected segment via celiotomy is feasible, or if a permanent colostomy is required.[905]

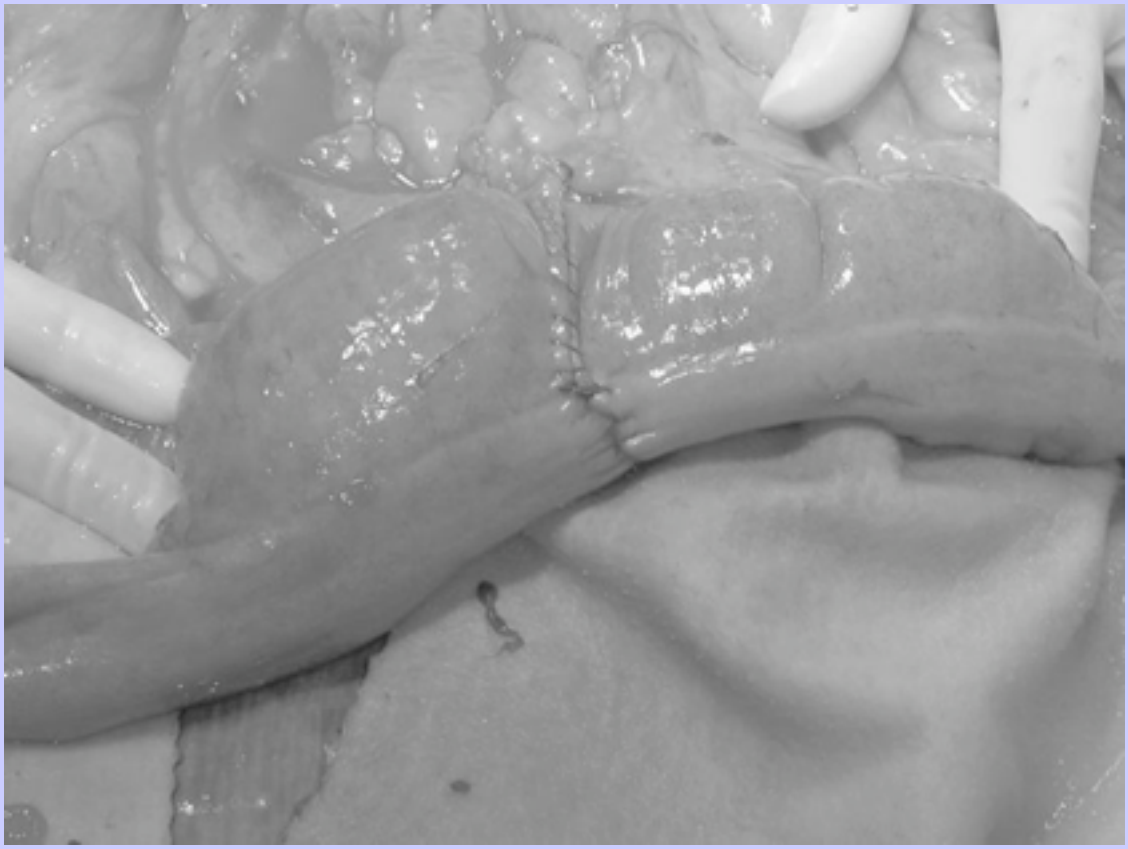
32.88 STRANGULATING OBSTRUCTIONS

32.88.1 Strangulating Lipoma

Pedunculated lipomas can cause a strangulating or nonstrangulating obstruction of the small colon, but this occurs much less frequently than in the small intestine. In a large retrospective study, lipomas were found to involve the descending colon in less than 10% of cases.[906] The overall incidence of lipomas affecting any portion of the gastrointestinal tract is increased in older geldings[906,907] and in Saddlebreds and Arabians.[906] It is therefore likely that lipomas specifically affecting the descending colon have a similar distribution. Fig. 32-58 illustrates a pedunculated lipoma that had strangulated a short section of the small colon. Clinical signs typical of a strangulating obstruction are seen, with a significantly elevated heart rate, abnormal abdominocentesis, and distended large colon on rectal examination.[860] In addition, on rectal examination a constriction of the lumen of the small colon caused by the lipoma may be felt. Surgery is necessary to free the constricting lipoma, followed by resection and anastomosis if the intestine is nonviable (Fig. 32-59). The prognosis is worse if resection is required, with a 50% survival rate in one study, compared with 100% survival for nonstrangulating lipomas.[860]

Fig. 32-58 A short section of small colon that had been strangulated by a pedunculated lipoma.

Fig. 32-59 The same case as in the previous figure after resection of the ischemic segment and end-to-end anastomosis.



32.88.2 Other Causes of Strangulating Obstruction

Several other causes of strangulating obstruction can occur, but each condition is relatively rare. These include volvulus of the small colon[888] and strangulation through internal hernias such as a vaginal tear[861] or tears in the gastrosplenic ligament.[908]

32.88.3 Prognosis

A good survival rate was found in two large studies reviewing small colon disorders, with 71% and 91% of patients being discharged from the hospital.[860,861] The main reason for euthanasia at the time of surgery was an inability to completely exteriorize the affected segment to allow adequate resection and anastomosis.[860] Previous reports have suggested that resection and anastomosis in the small colon may carry a poor prognosis because of a relatively poor blood supply, higher bacterial counts, solid fecal material, and increased collagenase activity compared with the small intestine.[888] However, if the patients euthanized at surgery are excluded, short-term survival after surgery for a small colon lesion is excellent, with a report of 100% survival in one study.[909] In

addition, horses that required resection and anastomosis did not have a worse prognosis for survival[861] and are less likely to develop the complications associated with small intestinal resection, such as POI.[910]

32.89 PERITONITIS IN HORSES

Robin M. Dabareiner

32.89.1 Anatomy and Physiology

The peritoneum is the mesothelial lining of the peritoneal cavity and its contained viscera. It forms a closed sac in males but communicates with the external environment in females via the fallopian tubes. The peritoneum consists of a single layer of mesothelial squamous cells resting on a thin basal lamina, which is attached to a loose connective tissue layer containing collagen, and elastic fibers, allowing a variable degree of motion. The peritoneum is coated with a thin serous film that serves to minimize friction and thus facilitates free movement between abdominal viscera.[911,912] The peritoneum is divided into the visceral peritoneum, which encloses the intraperitoneal organs and forms the omentum and mesenteries, and the parietal peritoneum, which lines the abdominal walls, pelvis, and diaphragm. The visceral peritoneum, mesentery, and omentum are supplied and drained by the splanchnic vasculature.[913] The parietal peritoneum is supplied by arterial branches of the lower intercostal, lumbar, and iliac vessels and is drained by veins entering into the caudal vena cava. Branches of the spinal nerves supplying the abdominal wall innervate the parietal peritoneum, and the phrenic nerve supplies the diaphragmatic peritoneum. As a result, irritation of the parietal peritoneum gives rise to afferent stimuli that are transmitted by the intercostal and phrenic nerves and perceived as somatic pain.[913] In contrast, there are no pain receptors in the visceral peritoneum, and afferent stimuli are conducted centrally by the visceral autonomic nervous system.

Peritoneal fluid is constantly being produced and absorbed. The movement of fluid and solutes occurs by passive diffusion across the semipermeable peritoneal membrane.[914] Solutions or drugs administered into the peritoneal cavity equilibrate rapidly with plasma. Transperitoneal fluid movement can be increased during peritoneal inflammation, causing a rapid and massive transudation of fluid into the peritoneal cavity that can lead to hypotension and shock.[914]

The peritoneal lymphatics, especially the diaphragmatic lymphatics, play a major role in the removal of fluid and solutes from the peritoneal cavity. The diaphragmatic lymphatic valves provide a unidirectional clearance of peritoneal fluid and debris, which empty primarily into the thoracic duct and are probably the first line of defense in peritoneal contamination. These lymphatics are aided by movements of breathing, which encourage cranial flow and clearance of peritoneal fluid.[915–917] Cellular defenses are provided by peritoneal macrophages, mast cells, and mesothelial cells. Activated peritoneal T lymphocytes and local antibody production have also been demonstrated experimentally.[916] Peritoneal macrophages have antimicrobial activity resulting from their complement receptors, phagocytic ability, and T cell—mediated immune responses. In addition, peritoneal macrophages are important in neutrophil chemotaxis and fibroblast stimulation, which aid in bacteria localization. Peritoneal mesothelial cells are an abundant source of plasminogen activator, which is responsible for normal fibrinolytic activity on peritoneal surfaces.[915]

32.89.2 Pathophysiology of Peritoneal Injury

Peritonitis can be induced by a number of infectious (bacterial, viral, fungal, parasitic) and noninfectious (traumatic, chemical, neoplastic) causes. The initial reaction to inflammatory stimulus is the release of histamine and serotonin from peritoneal mast cells and macrophages, resulting in vasodilation and increased vascular permeability with transudation of fibrinogen-rich plasma into the peritoneal cavity. The concurrent loss of mesothelial cells and release of tissue thromboplastin reduce the fibrinolytic capabilities of the peritoneal surface and activate the extrinsic coagulation pathway, thereby shifting the fibrinolysis-coagulation equilibrium toward fibrin formation.[918,919] This response serves to aid in the fibrin seal of the peritoneal defect and provides the framework for fibroblasts to lay down collagen, which produces fibrous adhesions to localize bacteria.

Peritoneal macrophages stimulate neutrophil chemotaxis both directly and indirectly via the release of TNF and IL-1. TNF and IL-1 stimulate neutrophil margination and degranulation and alter the vascular endothelium to promote leukocyte adherence. Metabolism of cell membranes results in phospholipid products such as PAF, prostaglandins, and leukotrienes, which contribute to the vasodilatory response; phospholipase A_2 provides the catalyst for activation of these phospholipid products via the arachidonic acid pathway. Within hours an influx of fluid, protein, and neutrophils enters the peritoneal cavity in response to the inflammatory stimulus.[919]

The combination of enlarged diaphragmatic lymphatics and the cellular defenses described earlier result in rapid clearance of debris from the contaminated peritoneal cavity. If the inflammatory response resolves, the mesothelial cell lining is restored from either free-floating macrophages or differentiated subperitoneal connective tissue cells.[919] The normal fibrinolytic activity of the peritoneal mesothelial cells returns, initiating removal of the accumulated fibrin clots. Severe inflammation, foreign bodies, intestinal ischemia, or infection can result in continued fibrin production from proliferating and migrating fibroblasts, causing fibrous scarring and adhesion formation.[918]

Peritonitis in the horse is usually secondary to intestinal leakage or degeneration, resulting in the transmural passage of bacteria into the peritoneal cavity. Any disease process that causes gastrointestinal, hepatic, or urogenital inflammation or compromise can lead to the development of peritonitis. The adverse effects of intraperitoneal bacteria can be enhanced by the presence of excessive peritoneal fluid accumulation, hemorrhage, [920] fibrin, bile, necrotic tissue, ischemia, anaerobes, and fecal matter. Excessive peritoneal fluid enhances the dissemination of localized bacteria and dilutes opsonic proteins such as complement and immunoglobulins.

761 762

Fibrin formation can be beneficial in confining bacteria; however, excessive amounts can result in abscess formation and prevent phagocytes and antimicrobial drugs from reaching the source of contamination. Fibrinous adhesions may also physically occlude diaphragmatic lymphatics and protect bacteria from opsonins, neutrophils, and antibiotics. Necrotic tissue, fecal matter, and bile all prolong the debridement phase of peritoneal healing and interfere with peritoneal defense mechanisms.

Peritonitis is an inflammation of the peritoneum and can result from many causes, which are classified as primary or secondary, acute or chronic, and localized or diffuse. Primary peritonitis is uncommon in adult horses but may occur by hematogenous spread of bacteria in the septic or immunocompromised neonate or in young horses exposed to *Streptococcus equi* infection.[916] Uroperitoneum and septicemia-induced peritonitis occur predominantly in neonates. Internal abdominal abscesses caused by disseminated *S. equi, Streptococcus zooepidemicus*, or *R. equi* infection are usually found in weanlings or young horses.[921,922]

Peritonitis secondary to another disease process may be caused by perforating abdominal wounds, chemical irritation (bile, urine), neoplasia, breeding and foaling injuries (uterine or vaginal trauma), intestinal parasitism, hepatitis, nephritis, pancreatitis, ruptured bladder or ureter, urinary infection, ruptured or lacerated abdominal viscera (spleen, ovary, liver, diaphragm), castration complications, and factors directly related to gastrointestinal problems, which are divided into preoperative, intraoperative, and postoperative causes (Box 32-4).

Neoplasia

32.89.3 Diagnosis

32.89.3.1 HISTORY AND CLINICAL SIGNS

Clinical signs of peritonitis vary and depend on the cause and duration of the peritonitis. Localized infections often have limited systemic involvement, whereas diffuse peritonitis can elicit generalized signs of endotoxemia and sepsis. Horses with peracute peritonitis caused by intestinal rupture show signs of acute, severe sepsis and cardiovascular collapse with tachycardia, tachypnea, sweating, and varying degrees of abdominal discomfort with death ensuing within hours.

The most common presenting clinical signs for horses with peritonitis described in retrospective studies of 21 and 30 horses (age range, 2 months to 16 years) included pyrexia (rectal temperature exceeding 38.5° C), anorexia, mild abdominal pain, reduced or absent borborygmi, diarrhea, increased heart rate, and clinical evidence of dehydration.[923,924] In another retrospective study of 67 horses with peritonitis, clinical signs of abdominal pain, signs of circulatory shock, and diarrhea were significantly less severe in survivors compared with nonsurvivors, regardless of the cause of peritonitis.[925]

Rectal examination often elicits pain, and if adhesions are present, distended bowel may be present. In cases of intestinal rupture, either roughened peritoneal surfaces or an abnormally empty abdomen can be palpated. Occasionally, abdominal masses or abscesses can be palpated, and mesenteric lymph nodes may be enlarged; however, in many cases, no abnormalities can be detected. Parietal pain may be characterized by a “guarded” or splinted abdomen with pain on abdominal ballottement and a reluctance to move or defecate.

A urogenital examination should be performed in horses with peritonitis of undiagnosed cause to rule out vaginal, cervical, and uterine tears in mares or infected castration sites in males. Gastrointestinal motility is usually decreased secondary to sympathetic stimulation from parietal pain, hemoconcentration, or serosal surface trauma. Ileus frequently results in intestinal stasis with gastric fluid accumulation and intestinal distention, which subsequently intensifies the abdominal pain. The mobilization of fluid into the peritoneal cavity results in an intravascular fluid deficit, causing reabsorption of fluid from the large colon and cecum. Findings of intestinal ingesta impactions secondary to these fluid shifts or ileus are not uncommon in horses with peritonitis.[924]

32.89.3.2

CLINICOPATHOLOGY

Abnormal laboratory values are dependent on the cause and duration of peritonitis. Hematologic abnormalities seen in acute peritonitis include elevated PCV secondary to transudation of fluid into the peritoneal cavity and endotoxemia. Initially a proportional increase in plasma protein levels occurs, reflecting the degree of dehydration; however, in severe cases protein eventually is sequestered into the abdomen because of increased capillary permeability, resulting in systemic hypoproteinemia. Peripheral blood neutropenia with a degenerative left shift is caused by margination of neutrophils and migration of these cells into the abdomen. Increased plasma fibrinogen levels (up to 1000 mg/dL) can occur after 48 hours. Peritonitis of longer duration and internal abscesses are associated with greater variability in laboratory values, but affected horses often demonstrate a normal or increased systemic neutrophil count, monocytosis, and elevated plasma protein levels as a result of increased immunoglobulin production.[922]

Alterations in blood gas analysis and serum chemistry values often depend on the horse's clinical and hydration status at the time of presentation. Elevations in BUN and creatinine occur secondary to dehydration. 762
Hypokalemia, hypochloremia, and hyponatremia may occur in the anorectic, acidotic patient with 763
gastrointestinal dysfunction. Serum creatinine levels, anion gap, and pH were significantly different between survivors and nonsurvivors at the time of presentation in 67 horses with peritonitis.[925]

Abdominocentesis confirms the diagnosis of peritonitis, although the cause may remain unknown. Normal peritoneal fluid is clear, straw colored, and serous in consistency. The total nucleated cell count and total protein in peritoneal fluid of normal horses were reported to be less than 5000 cells/μL and 2.5 g/dL, respectively, with 24% to 60% of the cells being neutrophils.[926] We have found that normal horses typically have peritoneal fluid protein less than 1 g/dL. The cytologic appearance of the leukocytes and mesothelial cells should be normal, although activated mesothelial cells are not an unusual observation.

Colorless fluid is very dilute, and, if it is present in large quantities, the possibility of ascites or uroperitoneum must be considered. Serosanguineous fluid indicates an increase in erythrocytes or free hemoglobin that may be caused by intestinal degeneration and transmural erythrocyte leakage, splenic puncture during abdominocentesis, abdominal viscera laceration, or skin contamination. Green fluid results from enterocentesis or intestinal rupture, and brown fluid is associated with late-stage tissue necrosis. Turbid fluid indicates an increased cell count, and opalescence suggests chylous effusion. Flocculent fluid with fibrin strands indicates an inflammatory, exudative process in the abdomen. The quantity of fluid varies among horses and can be increased in acute peritonitis (transudate or exudate) or absent in chronic peritonitis with excessive fibrin production.

Peritoneal fluid parameters consistent with peritonitis vary widely, depending on the disease process. High nucleated cell counts ranging from 15,000 to 800,000 cells/μL with greater than 90% neutrophils having toxic

or degenerative changes have been reported for horses with peritonitis[923–926] or internal abscesses.[922] Total protein greater than 2.5 g/dL indicates increased capillary permeability of the abdominal viscera or peritoneum resulting in protein exudation and is associated with peritoneal inflammation, intestinal compromise, or blood contamination of the peritoneal fluid. The presence of fibrin and intracellular bacteria is diagnostic for peritonitis. Cytologic evidence of extracellular bacteria can result from skin contamination and should be interpreted in combination with clinical signs.

It may be difficult to distinguish between early and mild septic peritonitis and nonseptic peritoneal inflammation using clinical and clinicopathologic findings alone. In addition, false-negative bacterial cultures in horses with peritonitis are not uncommon, and positive culture results often require several days of incubation. One study investigated peritoneal fluid pH, glucose concentration, and LDH activity in normal horses and horses with either septic or nonseptic peritonitis.[927] Horses with septic peritonitis had significantly lower peritoneal fluid pH and glucose concentration than horses with nonseptic peritonitis or healthy horses. Serum-to-peritoneal fluid glucose concentration differences >50 mg/dL were diagnostic for septic peritonitis. Peritoneal fluid pH >7.3, glucose concentration <30 mg/dL, and fibrinogen concentration >200 mg/dL were highly indicative of septic peritonitis. LDH activity was not useful in the detection of septic and nonseptic peritonitis. These measurements may provide early indication of sepsis, especially if cytologic evaluation or bacterial culture results are unavailable. The acidic peritoneal fluid pH likely reflects lactate production by peritoneal fluid neutrophils via glycolysis and acid metabolite production by bacteria. The low peritoneal glucose concentration may be secondary to glucose use by bacteria and phagocytic cells, glycolytic enzymatic activity in the peritoneal fluid, or low transport of glucose from the blood to peritoneal fluid.

Peritoneal fluid must be interpreted carefully in horses after abdominal surgery, foaling, castration, or multiple abdominocentesis. Nucleated cell counts between 85,000 and 418,000 cells/μL and protein values from 4.7 to 6.5 g/dL were found on postoperative day 5 in six normal horses that had undergone abdominal exploration.[928] Peritoneal fluid 5 days after open castration (N=24) contained 30,000 nucleated white cells per microliter, with more than 85% being neutrophils. By day 7 after castration the cell counts were normal, with no toxic or degenerative changes.[929] Parturition can cause increased nucleated cell and RBC counts, with elevated total protein values in the peritoneal fluid.[930] In a recent study, postpartum mares having uneventful foaling or uncomplicated dystocia had normal peritoneal fluid except for elevation in percent neutrophils. Mares having complicated dystocia had bloody peritoneal fluid with increased total protein (median total protein = 4 g/dL) and WBCs (median WBCs = 40,5000) 1 day after foaling.[931] Schumacher found no significant alterations in peritoneal fluid in normal horses sampled every 24 hours for 5 days; however, 48 hours after enterocentesis, nucleated cell counts were 113,333 in six of nine horses.[932] Cytologic examination of the peritoneal fluid should include a Wright and a Gram stain. Macrophages should be examined closely for evidence of cellular engulfment and erythrophagocytosis. The peritoneal fluid cell morphology is an important diagnostic aid and can be evaluated from the Wright stain. The Gram stain demonstrates the presence of bacteria and can guide initial antimicrobial treatments until culture and sensitivity results become available. Microbiologic culture is performed to identify aerobic and anaerobic bacteria, and antibiotic susceptibility testing is done to identify specific antibiotic therapy. Serial cultures of the peritoneal fluid may be necessary to identify emerging or resistant bacterial strains. Optimal bacteria isolation techniques when peritoneal fluid is cultured require the use of an enriching broth, blood culture medium, and, if appropriate, an antimicrobial removal device.[*]

Bacteria were cultured or cytologically identified in 48 of 67 horses (71.6%) with peritonitis, and *E. coli* and *Staphylococcus epidermidis* were the most common bacteria isolated from peritoneal fluid samples.[925] Others have reported only a 16% to 25% isolation rate for infective agents.[923,924] Anaerobes have been isolated from

approximately 20% of equine peritonitis cases, with *Bacteroides fragilis* most common.[924] Failure to identify or culture bacteria from peritoneal fluid does not rule out septic peritonitis. Ultrasonography may be helpful in obtaining abdominal fluid, detecting fibrin tags, determining if blood is within the abdomen, or finding an abdominal abscess (Figs. 32-60 and 32-61).

Hemoperitoneum is blood in the abdominal cavity caused by intraabdominal hemorrhage. Although rare in horses, it can be life-threatening. Clinical signs are variable and dependent on cause and severity. Affected horses often show signs of anxiety or depression as well as shock and anemia. Clinical signs of abdominal pain result from high intraabdominal pressure or the irritating effect of blood on serosal surfaces. In one study of 67 cases of hemoperitoneum in the horse, 79% were presented with a primary complaint of abdominal discomfort.[933] Other clinical signs were shock and pale mucous membranes in 60% of horses. Mean heart rate 763
was 76 beats/min, respiratory rate was on average 30 breaths/min, and mean hematocrit was 30% with a total 764
protein concentration of 5.8 g/dL. Causes of the hemoperitoneum were trauma (25%); neoplasia (18%); uterine artery rupture (14%); mesenteric injury (12%); disseminated intravascular coagulation (6%); and idiopathic causes (20%). Fifty-one percent survived to hospital discharge, 37% were euthanized, and 12% died. Poor short-term outcome was significantly associated with a high respiratory rate.

32.89.4 Treatment

Horses with peritonitis require early, aggressive therapy. The treatment of peritonitis involves (1) patient stabilization, (2) correction of the inciting cause, and, in most cases, (3) administration of antimicrobial drugs and/or anthelmintic drugs. Surgical intervention may be required to identify or correct the cause of the peritonitis. See the accompanying algorithm for the treatment of peritonitis in horses.

Stabilization includes treatment of systemic hypovolemia and endotoxic shock. Intensive fluid therapy is usually required to replace fluid losses into the peritoneal cavity and combat cardiovascular collapse. Acid-base disorders should be identified and corrected. Electrolytes, especially calcium and potassium, are important for gastrointestinal function and should be supplemented if deficits exist. If intestinal compromise or gram-negative

bacterial infections are suspected as the cause of peritonitis, J5 hyperimmune plasma* (4.4 mL/kg) may moderate the degree of endotoxemia. J5 is a mutant strain of *E. coli* that lacks the variable oligosaccharide side chains and binds to many gram-negative organisms and endotoxins, providing cross-protection.[934] If serum hypoproteinemia (total protein less than 4 g/dL) is present, administration of additional plasma should be considered to minimize peripheral edema.

32.89.4.1

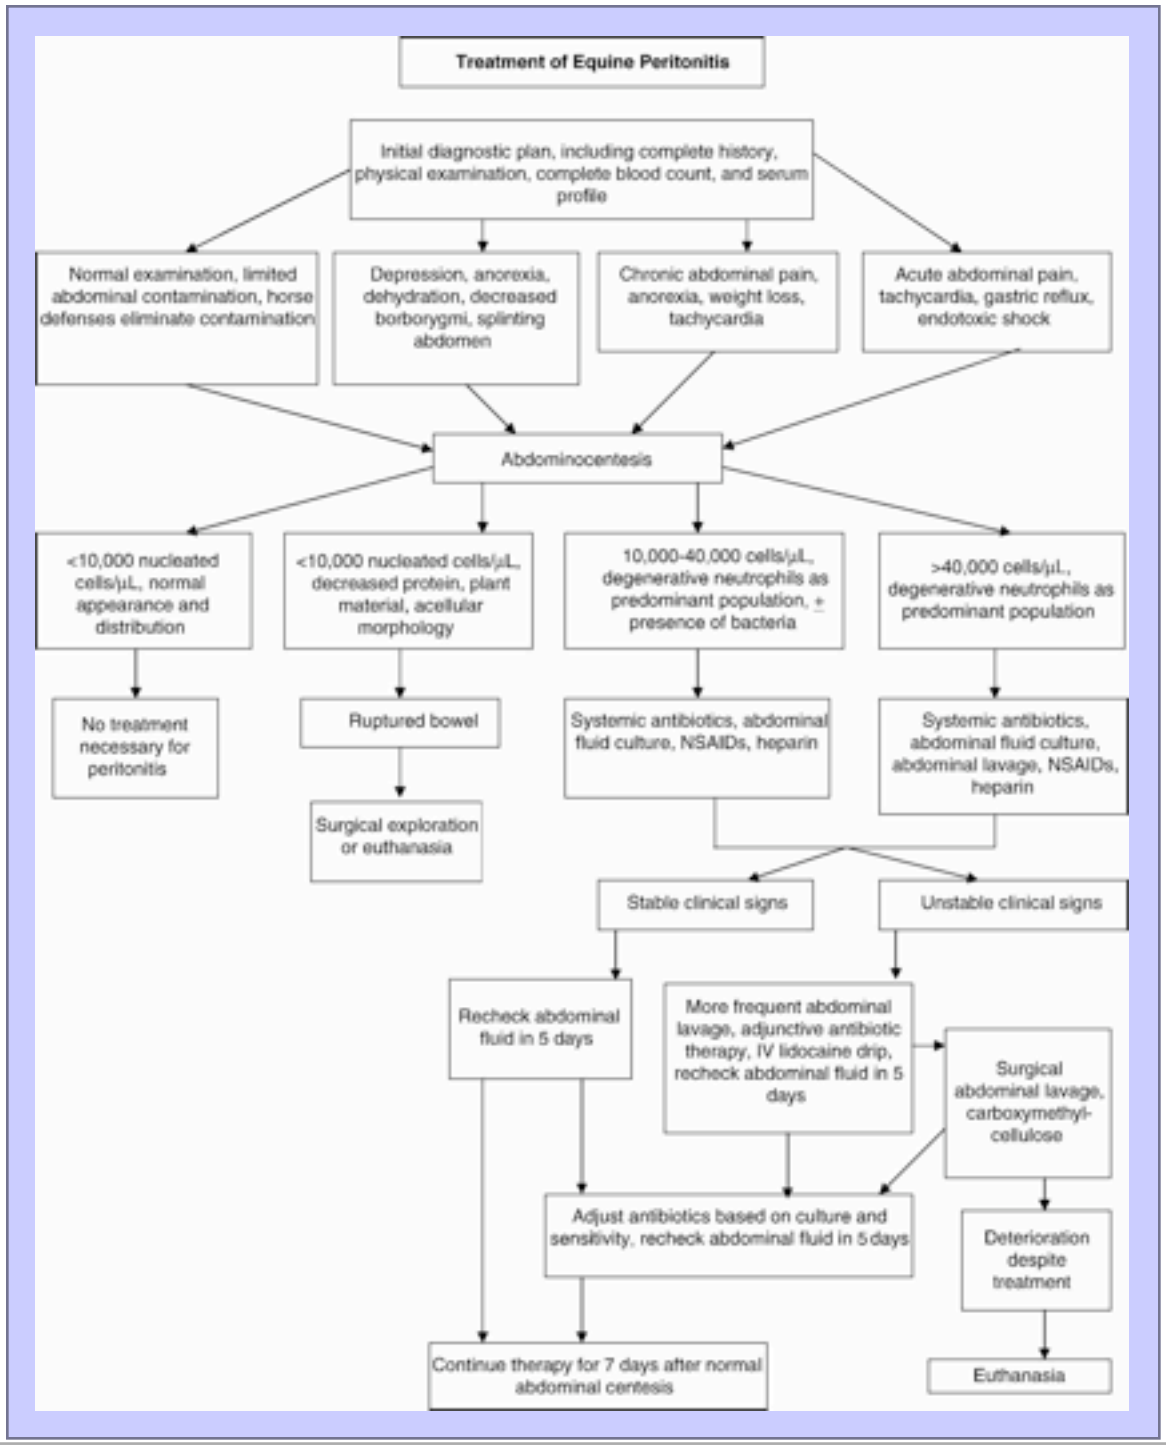
ANTIMICROBIAL THERAPY

Antimicrobial therapy should be initiated as soon as the diagnosis of peritonitis is made and peritoneal fluid is obtained for culture and sensitivity testing. In a study of 30 horses with peritonitis, 70% were treated successfully with antibiotics and supportive therapy.[924] Cytologic examination of the peritoneal fluid can suggest an antimicrobial regimen until the specific causative organism is identified. Intravenous administration is preferred, especially in the hypovolemic or shocked patient with compromised tissue perfusion. The most common organisms isolated from horses with peritonitis include aerobic bacteria *(E. coli, Staphylococcus* species, *Streptococcus* species, *R. equi)* and anaerobic bacteria (*Bacteroides* species, *Clostridium* species, *Fusobacterium* species).[922–925]

Broad-spectrum antimicrobial therapy is recommended, with a combination of an aminoglycoside such as gentamicin (6.6 mg/kg IV q24h) or amikacin sulfate† (9 to 12 mg/kg IV q8h) and potassium penicillin G (22,000 to 44,000 U/kg IV q6h) or ceftiofur (4 mg/kg IV q8h or q12h). After intravenous administration of aminoglycoside antibiotics, antimicrobial activity in the peritoneal fluid reaches 50% to 80% of serum levels, whereas intestinal tissue concentrations are 10% to 25% of serum concentrations.[935]

Aminoglycosides are bactericidal and effective against the majority of gram-negative intestinal aerobes, but pharmacologic monitoring is important especially in the hypovolemic, septic patient. Aminoglycosides can penetrate an abscess capsule but are minimally active in the acidic environment of an abscess. Drugs that penetrate fibrin, such as erythromycin and fluoroquinolones, are effective in the local abscess environment. Important considerations during aminoglycoside use include renal toxicosis and potential neuromuscular blocking effects during general anesthesia.[935,936] Most gram-positive aerobic bacteria are sensitive to penicillins, but the extended spectrum of antimicrobial activity from sodium ampicillin (11 to 25 mg/kg IV q6-8h) or ceftiofur may be beneficial. Trimethoprim-sulfadiazine (30 mg/kg PO q12h), chloramphenicol (25 to 50 mg/kg PO q6h), and enrofloxacin‡ (1.5 mg/kg PO q12h or 5 mg/kg q24h) are broad-spectrum antimicrobial drugs that have good peritoneal penetration and can be useful if warranted from the culture and sensitivity results. Enrofloxacin has been shown to have adverse effects on cartilage surfaces in young animals and should be reserved for adult horses only.[937]

Anaerobic bacteria, especially penicillin-resistant *Bacteroides* species, are reported in 20% to 40% of equine patients with peritonitis.[923,938] Percentages of anaerobic involvement may be artificially low because of difficulty in isolating anaerobic organisms. Metronidazole (15 to 25 mg/kg PO q6–8h) is effective against most anaerobic bacteria but should be



764

766

used in combination with antimicrobial drugs that have antibacterial activity against aerobic bacteria.[938] Of 54 horses with positive anaerobic culture results, 95% also had aerobic bacteria isolated from the same specimen.[938] In the face of ileus, an intravenous route of administration can be used, although cost may be prohibitive. Recently the pharmacokinetics of metronidazole (15 mg/kg, q6–8h) administered to horses per rectum in a suspension of crushed tablets and water (40 mL) was evaluated, and serum minimum inhibited concentration

was reached within 1 hour.[939] Complications attributed to metronidazole administration in horses were reported to be uncommon, with only 4 of 200 horses (2%) that underwent treatment showing appetite suppression.[938] However, peripheral neurologic deficits and central nervous system (CNS) dysfunction have been associated with metronidazole treatment in other species.[938] Protracted antibiotic administration for the treatment of peritonitis is necessary. If an abdominal abscess is identified, 6 to 8 weeks of antimicrobial treatment may be necessary. Horses with diffuse, septic peritonitis are usually treated with antimicrobial drugs for 7 days after clinical signs and peritoneal fluid abnormalities have resolved.

† Baytril, Miles Inc., Shawnee Mission, KS.

32.89.4.2 ANTIINFLAMMATORY THERAPY

Horses with peritonitis often have clinical signs of endotoxemia and tissue trauma eliciting a cascade of inflammatory mediators. Flunixin meglumine,* an NSAID, inhibits COX production of prostaglandins and blocks many detrimental effects of endotoxemia.[940] Flunixin also may decrease adhesion formation within the peritoneal cavity. Low doses of flunixin (0.25 mg/kg IV q6h) inhibited prostaglandin production during experimentally induced endotoxemia in horses.[940] Analgesia is also important in the treatment of peritonitis in horses to inhibit sympathetic stimulation secondary to parietal pain; therefore flunixin at a dose of 0.5 mg/kg q6h may be clinically more beneficial.

* Banamine, Schering-Plough, Omaha, NE.

32.89.4.3 ANTHELMINTICS

Anthelmintics are required if verminous arteritis secondary to *S. vulgaris* migration is the suspected cause of the peritonitis. A history of mild intermittent colic and a poor or unknown deworming program may be apparent. The abdominal pain arises from ischemia or the initiation of focal infarcts. Often this disease cannot be differentiated from other types that cause mild colic. The heart rate is often normal, and rectal examination usually has no abnormal findings unless there is concurrent impaction or gas distention. Fremitus to the cranial mesenteric artery is an inconsistent finding. Laboratory findings can also vary greatly. Evidence of peritoneal inflammation is indicated by increased peritoneal protein and WBC count. The response to antilarval therapy may be the best way to diagnose peritonitis secondary to parasitic migration. Colic in horses that respond will usually cease, and horses will become more active and alert several days to weeks after therapy. The larvicidal treatment is fenbendazole† (15 mg/kg PO for 5 days or 50 mg/kg for 3 days) or ivermectin (0.2 mg/kg PO), and aspirin (60 grains once daily PO).

† Panacur, Hoechst Roussel Vet, Warren, NJ.

32.89.4.4 OTHER MEDICAL TREATMENT

Gastrointestinal ileus results from peritoneal trauma, intestinal compromise, or sympathetic stimulation. Intestinal ileus can cause respiratory compromise from increased abdominal pressure and reduced intestinal perfusion, leading to further compromise. Intravenous lidocaine infusion is useful in providing analgesic support and prokinetic activity in horses with peritonitis. Lidocaine reduces neutrophil infiltration and endothelial permeability by inhibiting sensory neuronal transmission. Administration of intravenous lidocaine

(a loading dose of 1.3 mg/kg followed by a constant-rate infusion of 0.05 mg/kg/min) provides sufficient analgesia and may stimulate intestinal ileus caused by peritonitis. It also potentiates the analgesic response of other analgesics such as xylazine and butorphanol.

Nasogastric intubation is necessary for relief of gastric fluid accumulation and continued intestinal decompression. Parenteral nutritional support should be considered in the compromised, anorectic patient or in horses with severe, prolonged gastrointestinal dysfunction.

32.89.4.5

SURGICAL TREATMENT

Surgical intervention is often required to identify or correct the inciting cause of peritonitis, which is often secondary to compromised intestine or leakage of the reproductive or urogenital systems. Peritoneal lavage and drainage can be accomplished at the time of surgery to remove any accumulated debris or exudate. Surgical drainage of internal abdominal or perirectal abscesses has been described but is difficult and often results in further contamination of the abdomen.[922] Long-term antimicrobial therapy with marsupialization or aspiration may be the preferred approach in these cases.

A successful technique used in the treatment of peritonitis in small animals and people is open peritoneal drainage, which allows continuous drainage of the entire abdominal cavity and provides an unfavorable environment for anaerobic bacteria.[941] The large size, stall environment, and ambulatory nature of the horse precludes its use in the treatment of peritonitis in horses.

The effectiveness of intermittent peritoneal lavage and drainage in horses with peritonitis is well documented.[942] The benefits of abdominal drainage and lavage include (1) reduction of bacterial numbers, enzymes, and toxins from the large absorptive peritoneal surface area; (2) removal of degenerative neutrophils and cellular debris; (3) elimination of accumulated blood; (4) removal of irritating foreign material such as plant material and urine; and (5) dilution of adhesion-forming substrates such as fibrinogen and fibrin. Some claim that only a small part of the equine abdomen is effectively lavaged and that lavage may disseminate a localized infectious focus.[941] In my opinion, peritoneal lavage and drainage constitute an important and potentially life-saving treatment that should be considered in the treatment of horses with peritonitis. The controversial aspects of its use should be when and whether peritoneal lavage is necessary. In our hospital, use of peritoneal drainage and lavage is reserved for acute cases of purulent effusion in the abdomen and in horses not responding to medical therapy as determined by clinical signs and results of abdominocentesis. We also use standing postoperative peritoneal lavage for prevention of abdominal adhesions after surgery for small intestinal obstructions. In an experimental study, horses having abdominal lavage after colic surgery were significantly less likely to develop abdominal adhesions than horses not lavaged.[943] Foley, mushroom, or thoracic catheters can be used. The catheter should have numerous fenestrations for allowing infusion and drainage through the catheter. The catheter should be covered with a sterile bandage between uses to prevent ascending bacterial infection. A recent retrospective study evaluated 67 horses with an indwelling abdominal drain placed at surgery after celiotomy surgery or in the standing horse with signs of peritonitis. Forty-nine percent had minor complications, which included obstruction of the drain, fluid leakage around the drain, and subcutaneous fluid accumulation. Incisional drainage developed in 32% of horses, and incisional herniation occurred in 11%. Lavage solution is usually lactated Ringer's solution, although heparin or antimicrobial drugs may be added to the abdominal solution. If heparin is used to prevent the development of fibrinous isolation of bacteria, the usual dose is 80 U within the lavage solution or a systemic dose of 40U/kg SC q12h. A sudden but transient decrease in PCV should be expected because of severe rouleau formation. Peritoneal lavage is

766

767

usually performed with 10 to 20 L of fluid twice daily for 2 to 5 days. It is usually continued until the peritoneal fluid becomes clear and cell count and total protein concentration return to normal values.

Stabilization, antimicrobial administration, and hydration of the horse should be performed before abdominal drainage or lavage. Placing an ingress catheter in the paralumbar fossa for fluid infusion and an egress catheter on ventral midline for drainage has been described, but is probably not effective because the infused fluid usually finds a direct path through the abdomen to the egress catheter, providing inadequate lavage. Retrograde irrigation and drainage through an ingress-egress catheter placed on ventral midline have been used effectively for removal of peritoneal exudate in horses.[944]

The site of drain placement is on the ventral midline at the most dependent aspect of the abdomen. Ultrasonography may be useful in locating a site free of abdominal viscera or fetus if the horse is in late gestation. A variety of drains can be used; mushroom drains* and argyle drains are most useful, but a large Foley catheter† is also effective. The horse is properly sedated, and the drain site is prepared aseptically and blocked with local anesthetic. A 1-cm stab incision is made through the skin, subcutaneous tissue, and linea alba. Mushroom and argyle drains should be stretched over a female canine or Chambers mare catheter to aid insertion. If the bowel is inadvertently punctured, the drain should not be removed until the horse is anesthetized to allow removal of the drain and closure of the puncture site.

With the drain acting as an ingress cannula, 10 to 20 L of a warmed balanced polyionic fluid is infused. Abdominal discomfort may be encountered after 10 L of fluid or after rapid infusion. Slowing the infusion rate or further sedation may be required. After fluid infusion the drain is filled with full-strength heparin and clamped closed and the horse is walked for 20 to 30 minutes to promote distribution of the lavaged fluid. The drain is then opened and the fluid is allowed to drain into a clean calibrated bucket to record its volume. The majority of the infused fluid should be collected. This process is repeated two or three times daily for 2 or 3 days until the peritoneal fluid white cell count and total protein show improvement. Between treatments the abdominal drain should be filled with heparin, closed, and protected from the environment by a sterile bandage.

The addition of povidone-iodine or nitrofurazone to peritoneal lavage solutions has been associated with chemical peritonitis, hypovolemia, hyperosmolarity, and acidosis in normal horses and is not recommended.[944] Adding antimicrobial drugs to the peritoneal lavage solution is probably not necessary; however, plasma concentrations of antimicrobial drugs should be measured to ensure proper levels in the face of peritoneal lavage and drainage. Horses treated with peritoneal lavage must also be monitored closely for hydration, protein loss (up to 0.5 to 1 g/dL daily), and electrolyte imbalances. Complications of peritoneal drains include visceral puncture during insertion, ascending infection, subcutaneous leakage and edema, and herniation of intestine or omentum through the drain.[944]

Intraperitoneal or systemic administration of heparin has been recommended in the treatment of peritonitis in many species.[945] Heparin is thought to inhibit fibrin deposition, thereby minimizing the localization and entrapment of bacteria, which can decrease the effectiveness of antimicrobial drugs.[919,945] Heparin has also been advocated in the prevention of abdominal adhesions in humans and decreased the formation of adhesions in ponies after experimentally induced intestinal ischemia.[946] There are no controlled studies in horses that describe the outcome of treatment or recommended dosage of heparin therapy in horses with peritonitis, but I use a dose of 20 to 40 IU/kg SC q8h. The horse's hematocrit and platelet count will usually decrease after 4 days of heparin treatment as a result of RBC agglutination but will rebound within 48 hours after the drug is discontinued.

Adhesion prevention should be a primary concern in treating a horse with peritonitis. Abdominal lavage with or without heparin therapy is beneficial in preventing the development of abdominal adhesions secondary to septic peritonitis. Sodium carboxymethylcellulose provides surface protection through a siliconizing effect and decreases contact between serosal surfaces. In an experimental study, instillation of sodium carboxymethylcellulose (7 mL/kg of a 1% solution) into the abdominal cavity after closure of the incision significantly decreased the incidence of abdominal adhesions in ponies.[947] This treatment may be beneficial in horses with peritonitis that have undergone an exploratory celiotomy as part of the treatment regimen.

† Foley Catheter, CR Bard Inc., Murray Hill, NJ.

32.89.5 Prognosis

The prognosis depends on cause, severity, duration, and complications of the peritonitis. The mortality rate was 59.7% in a recent retrospective study of 67 horses with peritonitis.[925] The prognosis for mortality in that study was dependent on the inciting cause of peritonitis, with postoperative peritonitis having a high mortality rate (56%).

Laminitis, diarrhea, ileus, and coagulopathies can occur after endotoxemia, and abdominal adhesions or abscess formation can have a negative effect on long-term prognosis. There are no specific laboratory parameters that can predict prognosis in affected horses; however, a rapid response to therapy is considered a favorable prognostic indicator. With early diagnosis, correction of the inciting cause, aggressive medical therapy, and peritoneal lavage, a fair-to-good prognosis can be given in acute cases of septic peritonitis in the horse.

32.90 FLUID THERAPY FOR HORSES WITH GASTROINTESTINAL DISEASES

Kevin T.T. Corley

32.91 AIMS OF FLUID THERAPY

The primary goal of fluid therapy is to increase cardiac output by increasing and then maintaining cardiac preload (Starling's Law of the heart). This in turn increases oxygen delivery to the tissues. By varying the electrolyte content of fluids, it is also possible to correct electrolyte and acid-base disturbances.

32.92 FORMULATING A FLUID THERAPY PLAN

Fluid therapy should be based on the clinical status of the horse, an assessment of the severity of ongoing losses, and any laboratory information available. The plan consists of four overlapping phases: resuscitation, rehydration, maintenance and ongoing loss provision, and electrolyte replacement. Each phase should consist of a type of fluid, a rate of administration, and an appropriate delivery system. It should also include a schedule of monitoring the effects of the fluid therapy and adjusting as necessary. It is important to consider the practicality of administering fluids in the environmental conditions (e.g., fluids may freeze in cold weather). In horses that are going to be referred from the field, the impact of any delay associated with fluid therapy should be weighed against the perceived benefit, particularly when only small volumes can be administered.

The most important part of successful fluid therapy is to frequently adjust the plan according to the patient's response.

32.93 IDENTIFYING PATIENTS THAT REQUIRE FLUID THERAPY

Gastrointestinal conditions of horses that result in great fluid loss, such as high-volume diarrhea and gastric reflux, obviously require aggressive fluid therapy. However, many other horses with gastrointestinal disease may require fluid therapy because of prolonged mild to moderate fluid losses or sustained reduced fluid intake. It is the identification of these horses that this section addresses.

32.93.1 Clinical Signs

The clinical signs of hypovolemia and dehydration are listed in Table 32-7. Hypovolemia is an emergency, and the aim of treatment should be to reverse hypovolemia in 1 to 2 hours. Dehydration needs to be addressed in the first 12 to 24 hours of therapy. Unfortunately, attempts to link given clinical signs with a percent fluid dehydration have not proved accurate.[948] It is important to assess all clinical signs and make a judgment on the fluid status based on the whole patient, including laboratory parameters if available. For example, tachycardia in horses with colic may be a result of pain or hypovolemia. Clinical signs and response to analgesics or fluid loading may help differentiate the two.

32.93.2 Laboratory Signs of Dehydration

The most commonly used laboratory tests to assess hypovolemia are PCV and plasma total solids. Unfortunately these tests are neither sensitive nor specific. The PCV may be substantially increased by splenic contraction in the horse, making small increases very hard to interpret. A PCV of over 50% in a resting horse usually represents hypovolemia. Plasma total solids (protein measured by refractometer) or total protein (measured by a chemistry analyzer) concentration also increases with hypovolemia. However, significant protein loss can occur in gastrointestinal disease (particularly with colitis), resulting in a low or normal protein concentration despite marked hypovolemia. Furthermore, hypergammaglobulinemia (e.g., in cyathostomiasis) can increase the plasma total protein concentration in the absence of hypovolemia. The PCV and plasma total solids are most useful when greatly increased or when used serially to monitor the response to fluid therapy.

Table 32-7 Clinical Signs of Hypovolemia and Dehydration Horses

Hypovolemia	Dehydration
Tachycardia	Tacky mucous membranes
Decreased pulse pressure	Prolonged skin tent
Reduced jugular fill	Sunken eyes
Tachypnea	
Cold extremities	
Decreased urine output	

From Corley K, Stephen J, eds: *Equine hospital manual*, Oxford, UK, 2008, Blackwell. Used with permission.

Not all signs are consistently present in all horses.

Plasma or serum creatinine concentrations are useful to assess hydration status in the absence of renal dysfunction. High normal (1.5 to 1.8 mg/dL; 130 to 160 µmol/L) creatinine concentrations can be associated with subclinical hypovolemia and should be evaluated in light of the history and clinical signs. Creatinine concentrations up to 3.5 mg/dL (310 µmol/L) are common with moderate to severe hypovolemia, and concentrations as high as 5 mg/dL (450 µmol/L) are possible with prolonged or marked hypovolemia. Even in severe hypovolemia, the creatinine concentration will not increase by much more than 2.3 mg/dL (200 µmol/L) per day.[949] If the creatinine concentration is higher than would be suggested by the clinical signs and other laboratory parameters and if the creatinine concentration does not decrease appropriately with fluid therapy, renal dysfunction should be suspected.

Increased blood lactate concentrations in the nonexercising horse are sufficient evidence of a metabolic disturbance to initiate fluid therapy. Blood lactate concentrations are an indicator of tissue perfusion. The most common causes of increased lactate in the horse with gastrointestinal disease are endotoxemia, which can increase tissue lactate production by inappropriate anaerobic metabolism, and hypovolemia. Increased blood lactate concentrations were associated with worse outcomes in equine colic.[950] Lactate can be measured in the field with hand-held blood gas analyzers.[*] The expected lactate concentration can also be calculated by means of equations based on electrolyte and acid-base measurements. However, when tested in foals, these equations were only moderately accurate.[951] An increased circulating lactate should be suspected in metabolic acidosis (decreased pH, negative base excess) in the absence of hyperchloremia or hyponatremia.[952] Urine specific gravity can easily be measured in the field. High urine specific gravity (>1.040) indicates probable dehydration and normal renal concentration of urine. Isosthenuria (1.010) indicates possible renal damage or a recent high fluid load. Urine specific gravity is useful to monitor the response to fluid therapy because rising or continually high specific gravities in the face of fluid therapy indicate insufficient fluid is being delivered to the horse.

* i-STAT, Heska, Fort Collins, Colo.

32.93.3 Cardiac Filling Pressures

Assessment of cardiac filling pressures and the changes in these pressures in response to fluids is the most accurate method of determining fluid requirements in the hospitalized animal. It is moderately easy to measure CVP in the horse. A piece of sterile polyethylene tubing (PE190, outside diameter 1.70 mm, at least 1.5 m long)

can be passed through a 12-gauge jugular catheter into the thoracic vena cava or right atrium. Correct positioning of the end of the tubing is estimated by measuring the distance against the horse and confirmed by observing changes in pressure with breathing activity. The catheter is connected to a pressure transducer or manometer at the level of the sternal manubrium.[953] The normal CVP of the horse is 5 to 14 mm Hg.[953] In a horse with normal cardiac function, a high CVP indicates fluid overloading and a low CVP indicates insufficient circulating volume. Perhaps more accurate is the change in CVP in response to a "fluid challenge" (bolus of fluids),[954] but this has not been evaluated in the horse. The fluid challenge method of monitoring fluid therapy may prove to be particularly useful when factors such as acute renal failure or pulmonary edema complicate the gastrointestinal disease.

768

769

32.94 TYPES OF FLUIDS

32.94.1 Crystalloids

For most situations in the field, commercial isotonic polyionic crystalloid solutions are the safest fluids to resuscitate hypovolemic or dehydrated adult horses. They increase plasma volume without causing profound electrolyte disturbances, because they contain approximately the same electrolyte concentrations as plasma. It also follows that polyionic crystalloid solutions are often not sufficient to correct electrolyte imbalances. Isotonic (0.9%) sodium chloride has a higher ratio of chloride to sodium than plasma and therefore causes mild hyperchloremic acidosis in normal ponies.[955] Isotonic sodium chloride should not be used for resuscitation unless indicated by measured electrolyte abnormalities. Sodium chloride solution has been advocated in hyperkalemia in order to avoid the potassium-containing polyionic fluids. In adult horses with gastrointestinal disturbances (with the exception of quarter horses with the hyperkalemic periodic paralysis (HYPP) phenotype), hyperkalemia is likely to reflect acidosis, and polyionic fluids are probably appropriate.

Two classes of polyionic fluids are available, those for resuscitation and those for maintenance. Maintenance fluids (e.g., Normosol-M*, Plasma-lyte M†) contain higher potassium and lower sodium and chloride concentrations than resuscitation fluids (e.g., Normosol-R*, Plasma-lyte 148†, Isolec‡, lactated Ringer's solution†). However, maintenance fluids are not currently commercially available in sizes greater than 1 L. This has led to the practice of adding potassium chloride (at 10 to 20 mEq/L) to resuscitation formulas to use as maintenance fluids in adult equine patients.

The different alkalizing agents (or "bicarbonate substitutes") in resuscitation fluids have some clinical relevance. The alkalizing agent in plasma is bicarbonate. Bicarbonate-containing fluids are unstable when stored and may result in profound metabolic alkalosis. Therefore Hartmann, an American pediatrician, replaced the bicarbonate with lactate to make lactated Ringer's solution (also called Hartmann's solution). Lactate is metabolized in the liver, but this process is slow enough to avoid the rapid changes in plasma pH seen with bicarbonate. Sodium bicarbonate and sodium lactate both increase the strong ion difference, resulting in metabolic alkalosis. The cation (sodium) remains in the extracellular fluid, whereas the anion (bicarbonate or lactate) is metabolized.[956] It is the speed of metabolism of the anion and the renal excretion of sodium that determines the ultimate alkalinizing effect. It may seem counterintuitive to administer lactate-containing fluids to a horse with lactic acidosis resulting from poor tissue perfusion. However, clinical trials in human patients in hemorrhagic shock have shown that lactate-containing fluids do not exacerbate the lactic acidosis of hypoperfusion.[957] It appears that the liver's capacity for metabolizing lactate is not overwhelmed in shock, but the delivery of lactate by the circulation to the liver is impaired. Restoring the circulating volume, even with fluids containing moderate amounts of lactate, is sufficient to allow the liver to clear the circulating lactate. In horses with liver disease,

which may have impaired lactate metabolism, lactated Ringer's solution should be used with caution. Alternative alkalizing agents to lactate are found in some commercial polyionic fluids (e.g., acetate and gluconate in Normosol-R). Acetate is metabolized by the muscles and gluconate by a variety of tissues throughout the body. Lactated Ringers' solution contains calcium, whereas Normosol-R contains magnesium. Calcium is incompatible with whole blood and sodium bicarbonate and is contraindicated in hypercalcemia; therefore fluids containing magnesium can be used in more clinical situations than those containing calcium.

Five-percent dextrose (D5W) and 5% glucose (G5W) solutions are used to replace water without accompanying electrolytes and are effectively hypotonic because the dextrose or glucose is rapidly metabolized. They are indicated in cases in which fluid loss exceeds electrolyte loss, which can occur in strangulating intestinal lesions and colitis.[958] Horses receiving D5W or G5W should be monitored carefully because rapid administration can lead to hyperglycemia. If the plasma glucose concentration exceeds the renal threshold (approximately 180 mg/dL [10 mmol/L]), an osmotic diuresis will result, which can reduce the benefit of the fluid administration. D5W contains 0.17 kcal/mL, and G5W contains 0.19 kcal/mL. They should not be considered a form of parenteral nutrition. In order to provide 11.5 Mcal/day, the maintenance requirement for a 500-kg horse standing in a stall,[959] it would be necessary to administer 60 to 70 L of these fluids per day, which would result in serious electrolyte abnormalities. Although the glucose in D5W and G5W has been recommended for resuscitation of some foals, these fluids are poor choices for hypovolemia. Thirty minutes after administration, only 10% of these solutions remain in the circulation. It is better to separate fluid and glucose replacement, if possible. If this is not practicable, 10 to 20 mL of 50% glucose solution should be added per liter of balanced electrolyte solution for acute resuscitation of hypovolemic and hypoglycemic foals.

Sodium bicarbonate has been advocated for correction of the acid-base disturbances associated with equine gastrointestinal disease. However, its use in lactic acidosis is highly controversial,[960] and it should probably be reserved for use in hyponatremia without hypochloremia and for renal tubular acidosis, manifested by hyperchloremia without accompanying hypernatremia.[952] Both of these electrolyte disturbances occur occasionally in horses with severe colitis. Sodium bicarbonate should be avoided in horses with respiratory dysfunction because the bicarbonate is converted to carbon dioxide that, if it is not excreted by the lungs, leads to an increase in plasma carbon dioxide tension and further acidosis.[952] Caution is also necessary in patients with hypocalcemia, because sodium bicarbonate administration can result in tetany; in patients with severe hypokalemia that can be worsened by increasing the plasma pH; and in patients with congestive heart failure, in whom the large sodium load may exacerbate fluid retention.

Homemade or “carboy” fluids, although considerably cheaper than commercial fluids, have been associated with clinical signs of endotoxemia in normal horses[961] and a sevenfold increase in the risk of thrombophlebitis[962] and therefore cannot be recommended.

32.94.2 Hypertonic Saline

The large volumes of isotonic fluids required for resuscitation in the horse and the fact that only approximately 30% of the administered fluid remains in the circulation after 30 minutes[963] have prompted the search for alternative fluids. Hypertonic saline and colloid solutions have received the most attention. 769 770

Hypertonic saline (2 to 4 mL/kg of 7% to 7.5% NaCl) has been advocated as a method of quickly restoring circulating volume in shock patients. Administration of 7% sodium chloride results in an increase in the extracellular fluid of two to three times the infused volume for at least 60 minutes after it is infused. This is the result of fluid shifts from the interstitial fluid, principally from the muscle and liver,[964] without significant fluid replacement. Hypertonic saline should always be followed up by large volumes (at least 10 L for each liter of hypertonic saline) of isotonic polyionic crystalloids within 2.5 hours (the point in experimental studies a which cardiac output begins to fall below baseline).[965] As well as restoring plasma volume, hypertonic saline reduces the capillary endothelial swelling that may occur as part of SIRS and therefore improves tissue microcirculation and oxygen delivery.[966] Administration of 5 mL of hypertonic saline solution per kilogram immediately after experimental endotoxin infusion in horses attenuated the cardiovascular derangements associated with endotoxemia more effectively than an equivalent volume of isotonic saline.[965] However, when compared with pentastarch (a colloid) in horses presented because of surgical colic, hypertonic saline resulted in a lower cardiac output for the first 2.5 hours of anesthesia.[967] Given the beneficial effects of hypertonic saline in experimental endotoxemia and sepsis, it may have a role after initial fluid resuscitation. However, treatment of endotoxic horses with hypertonic saline after fluid resuscitation has not been clinically evaluated.

The combination of hetastarch (10 mL/kg) or pentastarch 10% (10 to 15 mL/kg) with hypertonic saline (4 mL/kg) appears to be an excellent solution for resuscitation of severely hypovolemic horses, especially in severe colitis.

32.94.3 Colloids

Colloids, particularly hetastarch, have recently been advocated for resuscitation and treatment of severe hypoproteinemia in horses.[968] Colloids contain large branched molecules (450 kD average molecular weight for hetastarch compared with 69 kD for albumin). These molecules exert a large colloidal oncotic pressure and do not readily leak out of the vasculature and thus hold fluid in the circulation. Endotoxin[969] and ischemia-reperfusion injury[970] induce capillary damage that allows plasma albumin to leak out into the interstitium. The large colloid molecules may not leak as readily, allowing their oncotic pressure to draw fluid back into the vasculature. They may also plug the gaps in the capillary endothelium. However, if the capillary damage is severe enough, even the larger colloids may leak into the interstitium and exert their oncotic pressure to draw fluid with them.

In normal ponies, hetastarch is safe but prolongs bleeding times at high doses (20 mL/kg).[971] Pentastarch also affects coagulation, but at higher doses than hetastarch.[972] Although these hydroxyethyl starches have been used extensively in horses,[967,968] it is still unclear whether their use alters morbidity or mortality. Pentastarch appears to be superior to hypertonic saline when given before emergency colic surgery, at least in terms of cardiac output during anesthesia.[967] When colloids are used, the plasma total solids or total protein concentration is no longer a useful guide to hydration status or plasma oncotic pressure.[968]

Fresh frozen equine plasma has been used extensively in horses with diarrhea. Although classically prescribed for hypoalbuminemia, its utility for replacing protein is unclear. At least 6 to 8 L need to be given to adult horses to treat clinically significant hypoproteinemia,[973] and the effects may be short-lived. Plasma administration does not have the advantage of the larger colloids of potentially drawing fluid back into the circulation in damaged capillaries, but it prevents low plasma oncotic pressure, which leads to generalized edema. Plasma may have a

role in replacing AT-III and other cofactors that are depleted during the SIRS, and this has led to its continued use in diarrhea cases, with apparently favorable results. Freshly donated, rather than frozen, plasma contains higher concentrations of clotting factors and cofactors and is preferred in diarrhea cases.

32.94.4 Oral Fluid Therapy

It is possible to effectively treat dehydrated (but not hypovolemic) horses with oral replacement solutions.[974] In horses with gastrointestinal disease but no apparent dehydration, administration of an electrolyte paste and provision of fresh drinking water may be sufficient to supplement water and electrolytes.[975] Oral fluids do not need to be sterile and are therefore considerably cheaper than intravenous fluids. It is apparently not necessary to add glucose to oral fluids for the horse,[976] but electrolytes should be added if feasible. It is important to administer hypotonic or isotonic fluids.[976] A possible isotonic solution consists of 4.9 g of table salt per liter and 4.9 g of Lite salt* per liter to give final concentrations of 123 mmol/L sodium, 34 mmol/L potassium, and 157 mmol/L chloride.[976] If sodium chloride is used alone, no more than 9 g should be added per liter. An isotonic solution can be made without the use of weight scales by measuring salt crystals in the barrel of a syringe. Fifteen mL of Lite salt and 15 mL of table salt added to 4 L of water will make an approximately isotonic solution. The fluids should be given via a stomach tube to allow measured quantities to be given. The amount given at one time should not exceed 8 to 10 L in a 500-kg horse, with at least 20 minutes between each administration. Before each dose the stomach should be refluxed and the administration delayed if more than 2 L of fluid are recovered. Some horses will show abdominal pain if large volumes of fluids are given, especially if the fluids are cold.

Oral fluids hydrate the colon contents more effectively than intravenous fluids[977,978] and therefore are an ideal treatment for most horses with large colon impactions.[979] However, oral fluids are not suitable in hypovolemia. The absorption of fluids from the gastrointestinal tract is dependent on its blood supply, and the physiologic response to hypovolemia is to divert blood supply from the gastrointestinal tract to maintain perfusion of other organs.

* Morton Salt, Chicago, IL.

32.94.5 Parenteral Nutrition

Any therapeutic plan in the horse should include a nutritional plan. An enteral diet based on the horse's normal diet is the first choice for nutritional support. However, in adult horses with gastric reflux, ileus, esophageal obstruction, or anorexia, parenteral nutrition should be considered if the interruption to enteral feeding is predicted to last at least 3 days.[980] The use of parenteral nutrition may be especially indicated in acute protein losing enteropathy, where its use may prolong the oncotic effects of exogenously administered plasma, possibly by preventing plasma albumin from being metabolized for energy. Total parenteral nutrition solutions commonly consist of dextrose, amino acids, lipids, and a vitamin-mineral mix. The estimated energy requirement of a normal adult horse standing in a stall is calculated with the following equation[959]:

$$\text{Energy requirement (Mcal / day)} = 0.975 + (0.021 \times \text{body weight [kg]})$$

The protein requirement is calculated with the following equation[959]:

$$\text{Protein requirement (digestible protein [g/day]}) = 18 \times \text{Energy requirement (Mcal/day)}$$

The formulation of parenteral nutrition solutions is described elsewhere.[980] Parenteral nutrition is widely used in some practices for horses with gastrointestinal disease.[981] Although there is much anecdotal evidence that parenteral nutrition (as opposed to no nutrition) may be beneficial in adult horses with gastrointestinal disorders, it has not been formally studied. The administration of parenteral nutrition increases the risk of thrombophlebitis and sepsis in hospitalized human patients.[982]

32.95 FLUID THERAPY DELIVERY SYSTEMS

In the early resuscitation period of moderately to severely hypovolemic horses, it is important to use both a large-gauge catheter and a wide-bore sterile delivery system to be able to provide the fast fluid rates required. A 10- or 12-gauge catheter is recommended for severely hypovolemic adult horses and a 12- or 14-gauge catheter for other horses. Moderately hypovolemic foals, weanlings, and miniature horses can be given 16-gauge catheters. It is necessary to use a large-bore extension set with a large-gauge catheter.

For placement of a catheter, the hair should be clipped over the vein and the area should be given a surgical scrub, ideally with a chlorhexidine scrub solution.[983] The catheter should be handled and placed with sterile gloves. In young and refractory horses, a bleb of local anesthetic placed subcutaneously in the area to be catheterized makes catheterization easier. The sterile scrub should be repeated after the local anesthetic. With 10-gauge and Seldinger ("over the wire") catheters and when local anesthetic is used, a small stab incision through the skin can also be helpful. For fluid therapy the catheter should be directed pointing toward the heart. The catheter should be flushed with heparinized saline (5 units/mL) and fixed either with instant bonding glue (for short-term use) or with suture.

The easiest vein to catheterize in the horse is the external jugular vein. The cephalic and the lateral thoracic veins may also be catheterized and carry less serious consequences if they become occluded by thrombophlebitis. However, the maximum fluid rate attainable in these smaller veins (approximately 5 L/hr) is less than with the jugular vein, and infectious thrombophlebitis may be serious in any site. If one jugular vein is thrombosed or occluded, it is certainly prudent not to catheterize the contralateral jugular vein, because life-threatening head swelling can result from bilateral jugular thrombosis. Both the cephalic and the lateral thoracic vein can be technically difficult to catheterize. Good sedation is required to catheterize the cephalic vein because horses have a tendency to move during catheter placement. The lateral thoracic vein can be hard to identify and has a flat profile, which can make it difficult to pass the catheter into the lumen. The vein can be identified by ultrasonography and is probably best catheterized using the Seldinger (“over the wire”) technique. In both of these veins, valves can impede the passing of the catheter stylet or wire.

Various fluid administration sets are commercially available. Sets that include large-bore tubing and a coil are suitable for most situations in adult horses and their use is recommended. The flow rate can be estimated by

counting the number of drips per 10 seconds in the drip chamber (Table 32-8) or can be set by using an electronic fluid pump. In all situations, a record should be kept of the time the infusion was started to ensure that the desired volume is being delivered in the appropriate time.

The frequency of replacement of catheters and administration sets depends on local environmental conditions and the catheter material. Catheters made from polytetrafluoroethylene (Teflon) are associated with an increased incidence of thrombophlebitis and have a tendency to crack and kink.[984] These catheters should not be left in for longer than 72 hours. In contrast, soft catheters made from polyurethane or silicone rubber can often be safely left in place for at least 14 days when properly monitored.[984] These catheters should be replaced only when there is a suspected problem, and in a few horses they can be maintained for as long as 6 weeks. It is unclear how frequently administration sets should be replaced when used in a horse barn. The Centers for Disease Control and Prevention recommendation for human hospitals is not to replace administration sets more frequently than every 72 hours, except when used to administer blood or lipid-containing parenteral nutrition, in which case they should be changed every 24 hours.[985] Indwelling cecal catheters have been proposed for fluid therapy in horses, without the expense of sterile fluids. Unfortunately, although it is possible to deliver fluid by this technique, the high rate of serious complications precludes the use of cecal catheters.[986] For repeated administration of oral fluids, an indwelling nasogastric tube may be placed, which should be plugged with a syringe barrel between administrations to prevent excessive air influx. Some horses will not tolerate a large-bore nasogastric tube, and an adult feeding tube* sometimes can be used successfully in its place.

* 18Fr Equine Enteral Feeding Tube, Ross Laboratories, Columbus, OH.

32.96 RATES OF ADMINISTRATION AND VOLUME TO INFUSE

There are four overlapping phases to fluid therapy: resuscitation, rehydration, maintenance and ongoing loss provision, and electrolyte replacement. The resuscitation phase aims to rapidly restore circulating fluid deficits; the rehydration phase, to restore intracellular and interstitial fluid deficits; and the maintenance phase, to prevent occurrence of further fluid deficits. Electrolyte replacement usually takes place during the rehydration and early maintenance phases.

32.96.1 Resuscitation

Reversal of hypovolemia is the most important phase of fluid therapy. Although no specific experiments have been performed in the horse, there is plenty of evidence from human medicine that early reversal of hypovolemia dramatically improves outcome.[987,988] The clinical signs of hypovolemia are given in Table 32-7. There is no good evidence for choosing between balanced electrolyte solutions and colloids for treatment of hypovolemia. Therefore factors such as availability, speed of administration, ease of transport, and clinician preference will determine this choice.

The most common concept used to describe treatment of hypovolemia is the “shock dose.” This describes the maximum dose of fluids to be given acutely, as a bolus, to animals in shock. The shock dose for adult horses is 60 to 80 mL of crystalloids per kilogram. In practice, ¼ to ½ of the shock dose is given as a bolus. The animal is then quickly reassessed. If any evidence of continuing hypovolemia is present, a further ¼ of the shock dose is then given. This process is then repeated, with the animal being reassessed and given further boluses of ¼ of the shock dose as necessary, until hypovolemia has been reversed or a full shock dose has been given. It should be possible to deliver a full shock dose to a foal in 30 to 40 minutes and to an adult horse in 60 to 90 minutes. Delivering fluid this fast requires a large-gauge catheter and a wide-bore delivery system. In my practice, wide-

bore tubing designed for delivery of fluid during arthroscopy is used for reversal of hypovolemia in adult horses. Drip sets with inbuilt coils provide a much greater resistance to flow and are reserved for treatment of dehydration and ongoing losses and provision of maintenance needs. In adult horses with severe hypovolemia, both jugular veins may be catheterized with large-bore catheters (10 to 12 gauge) that allow approximately 35 L/hr to be administered by gravity if a wide-bore administration set is used. One of the jugular catheters should be removed immediately after the initial resuscitation phase is over, to reduce the risk of bilateral jugular vein thrombosis. A fluid pump may also be used to achieve high rates of fluid delivery, but the high pressures may cause damage to the intima of the vein and increase the risk of thrombosis. If colloid fluids are being used for initial resuscitation, 1 L should be used to replace each 3 to 4 L of crystalloid. The amount of hetastarch infused should not exceed 10 mL/kg.

In the neonatal foal, there is an alternative method to the shock dose method that is more practical. For this method, give a bolus of 1 L of crystalloids (i.e., approximately 20 mL/kg for a 50-kg foal) and reassess the foal to decide if hypovolemia has been reversed. Up to three further boluses may be given, reassessing the foal after each. Most obviously hypovolemic foals require at least two boluses. In foals in which the body weight is obviously different from 50 kg, the method needs to be adjusted so that the bolus is approximately 20 mL/kg. In pony foals and very premature thoroughbred foals, a bolus of 500 mL is usually appropriate. In large draft foals, the first bolus should be 2 L.

Deciding that hypovolemia has been reversed and that no further fluids are required is not always straightforward. In adult horses the clinical signs of hypovolemia should improve dramatically. Particularly useful to judge are the heart rate, jugular fill, and urination. Heart rate may not return to the normal range (particularly if other factors, such as pain, are also driving heart rate), but it should decrease. Jugular fill may be noticeably quicker. Adult horses often urinate once sufficient acute fluids have been given. In foals the clinical signs of hypovolemia may not have been present. Often there is an improvement in degree of consciousness with administration of fluids. As for adults, foals often urinate once hypovolemia has been reversed. There may also be a change in mean arterial blood pressure with fluid administration in foals, and a MAP that was reduced and now is consistently above 65 mm Hg probably indicates that sufficient acute fluids have been administered.

It is important to remember that reversal of hypovolemia represents the beginning of fluid therapy, and not the end. Almost all horses that have been hypovolemic will also be dehydrated, and this will need to be addressed over the next 12 to 24 hours. Furthermore, these horses may be sufficiently compromised to limit their fluid intake, or increase their losses, resulting in a continued need for fluid therapy.

32.96.2 Uncontrolled Hemorrhage

There is one important exception to aggressive fluid therapy for hypovolemia. This is in the case of uncontrolled hemorrhage (e.g., intraabdominal bleeds).[989,990] Fluids should be given at a rate of 2 to 3 mL/kg/hr until the hemorrhage has been controlled (usually by surgical intervention). When arterial blood pressure can be measured, therapy should be titrated to a moderate MAP (60 mm Hg).

32.96.3 Dehydration

Estimating the degree of dehydration and replacing it with fluid is not as straightforward as it sounds. Although tables relating clinical signs to estimated percent dehydration have been published,[991] it is unlikely that these are sufficiently accurate to be a useful clinical guide. Evidence from dogs and cats demonstrates that similar tables

772
773

are not accurate in those species,[992] and clinical experience suggests that the same is true of the tables designed for horses.

This therefore leaves the clinician without a set recipe to treat dehydration, and with a quandary. The key is monitoring. Once the hypovolemia has been treated, the horse should be examined for clinical and laboratory signs of dehydration. The horse should then be given fluids in excess of the ongoing losses plus the maintenance requirements, until the clinical and laboratory signs of dehydration are no longer present. The aim should be for dehydration to be reversed in 12 to 24 hours. In practical terms, dehydration is usually treated by giving fluids at twice the maintenance rate (see later) with the addition of fluids for ongoing losses. Therefore a dehydrated adult horse will receive 5 mL/kg/hr and ongoing losses, and a foal will receive 9 mL/kg/hr and ongoing losses, until dehydration is reversed. In horses with normal renal function, urine specific gravity is probably the most reliable indicator of when dehydration is reversed. Horses with urine specific gravities below 1.020, and foals with urine specific gravities of 1.010 or less, are unlikely to be dehydrated. Adult horses with normal renal function, frequent urination, and a urine specific gravity of 1.012 or below are probably receiving too much fluid. It is important, however, to check the other clinical signs of dehydration, as isosthenuria (urine specific gravity 1.008 to 1.012) can also occur in horses and foals with renal failure. These horses will usually have increased plasma creatinine concentrations. Horses with polyuric renal failure could become markedly dehydrated or hypovolemic, if fluid monitoring were based on urine specific gravity alone. Skin tent is a reasonably reliable clinical sign to use to judge dehydration in adult horses. It is less reliable in neonatal foals and geriatric horses. Tacky mucous membranes are also reasonably reliable indicators of ongoing dehydration, providing the animal is maintaining its mouth shut most of the time.

32.96.4 Ongoing Losses

Excessive fluid losses from horses with acute abdominal disease frequently do not stop when treatment is initiated, and these must be taken into account in the fluid plan. The most dramatic ongoing fluid losses are with severe diarrhea or nasogastric reflux, which may reach 200 mL/kg/day (100 L/day for a 500-kg horse).[993] Even without such obvious losses, horses may lose significant amounts of fluid through sweating, inadequate intake or, rarely, polyuric renal failure.

Treatment for ongoing losses is aimed to exactly replace the amount lost to maintain hydration. This is relatively simple when the amount of fluid lost can be measured, as in the case of nasogastric reflux. Reflux is collected in a graduated bucket, and the amount collected over a 4- to 12-hour period is compared with the amount of fluid administered. If the fluid lost is in excess of the amounts given, the fluid rates are adjusted both to replace this over the next 12 to 24 hours and to account for the higher level of ongoing losses than originally estimated. If the excessive losses have resulted in hypovolemia (on the basis of clinical and laboratory evidence), this must be treated acutely. It is much harder to estimate losses from diarrhea, sweating, and urination. In the case of diarrhea and urination, it is possible either to attempt to collect the feces or urine or to use absorbent bedding and measure the increase in weight. These are almost never done in clinical practice, except in the case of recumbent neonatal foals, for which feces or urine may be readily collected and weighed on incontinence pads or urine may be collected with an indwelling Foley catheter and closed collection system. When ongoing losses cannot be collected, they must be estimated. These estimates may be inaccurate, and the amount of ongoing loss can dramatically change; therefore it is important to frequently reassess the adequacy of fluid therapy through clinical examination and relevant laboratory investigations. Horses in which ongoing losses are not adequately replaced will become dehydrated initially, then hypovolemic. Urine specific gravity and the clinical signs of dehydration are the best methods of ensuring sufficient fluid delivery.

32.96.5 Maintenance

The mean daily water intake (including the water content of feed) of normal resting adult horses is 57 to 64 mL/kg/day at ambient temperatures of 41° F to 77° F (5° C to 25° C).[994,995] When mares were restricted to 40 mL/kg/day, they demonstrated significant dehydration.[996] A useful guideline for maintenance rate in adult horses is 60 mL/kg/day (2.5 mL/kg/hour). Thus, a 500-kg horse requires approximately 30 L/day for maintenance, in addition to any fluids to replace ongoing losses. The maintenance requirement of neonatal foals is significantly higher and is usually taken to be 4 to 5 mL/kg/hr,[997,998] although some authors use a lower estimate.[999] The fluid intake of nursing foals considerably exceeds this figure.[1000] However, clinical experience suggests that use of 4 to 5 mL/kg/hr is appropriate for maintenance in foals receiving no enteral fluids. It should be emphasized that it is important to take into account the fluid component of all infusions when calculating fluid rates to avoid inadvertent volume overload in neonatal foals receiving a number of intravenous infusions. For both horses and foals with normal enteral function, it is possible to meet maintenance requirements with nasogastric fluids, if this is clinically appropriate.

Monitoring of adequacy of fluid delivery is vital even when dehydration has been addressed and there are no major ongoing losses. The fluid requirements of the animal can change during treatment, and it is important to check that they are matched to requirements. Again, this is best done by monitoring urine specific gravity and assessing for the clinical signs of dehydration.

32.97 ELECTROLYTE REPLACEMENT AND TREATMENT OF ACID-BASE DISTURBANCES

Replacement of water losses is only part of developing a fluid therapy plan, albeit the most important one in acute resuscitation. The effect of the fluids on the electrolyte and acid-base status of the horse should also be considered, and fluids should be chosen to help correct physiologic disturbances. Unfortunately it is not possible to accurately predict electrolyte and acid-base disturbances based on clinical signs because seemingly similar clinical conditions may have quite different physiologic disturbances (Table 32-9).[1001] This limits the ability of the field veterinarian to monitor and treat these disturbances, although the recent availability of relatively inexpensive, portable blood gas and electrolyte measuring equipment has made determining the acid-base status a possibility in ambulatory equine practice. As stated earlier, in the absence of specific laboratory information, fluid therapy should probably be limited to isotonic polyionic crystalloid fluids, possibly with 10 to 20 mEq or potassium chloride per liter added in the maintenance phase.

773

When laboratory information is available within 4 to 6 hours, fluid therapy can be tailored to the individual horse, allowing correction of specific physiologic disturbances. Although calculations of whole body electrolyte or base deficits are possible, they are generally based on a simple “chemistry flask” model of the patient, in which addition of a known amount of electrolyte results in a predictable effect. Because this is clearly not the case, the relevance of these calculations to managing the clinical case with ongoing losses and renal responses to changes in plasma electrolyte concentrations is unclear.[1002] A safer and more physiologically relevant approach is to frequently monitor clinical and laboratory responses to therapy and adjust treatment accordingly, rather than relying on a calculated electrolyte dose to restore normality.

774

Table 32-9 Fluids of Choice for Specific Metabolic Disturbances

Metabolic Disturbance	Recommended Fluid	Dose
Lactic acidosis	Polyionic crystalloids (Normosol-R, lactated Ringer's solution) or	Up to 60 mL/kg/hr
	Hetastarch	Up to 10 mL/kg/hr
Hyponatremia		Sodium should be corrected no faster than 1 mEq/L/hr
With hypochloremia	Sodium chloride	
Without hypochloremia	Sodium bicarbonate	
Hypernatremia	5% Dextrose or 2.5% Dextrose/0.45% sodium chloride	To lower sodium no faster than 0.5 mEq/L/hr
Hypochloremia	Sodium chloride	0.9% or 7.5%, to effect
Hyperchloremia		
With hypernatremia	5% dextrose	To lower sodium no faster than 0.5 mEq/L/hr
Without hypernatremia	Sodium bicarbonate	5%, slowly, to effect
Hypokalemia	Potassium chloride	0.2 to 0.5 mEq/kg/hr, never to exceed 1 mEq/kg/hr
Hyperkalemia		
With clinical signs	Calcium gluconate	1 mL/kg IV over 10 min
Or >7 mEq/L	Sodium bicarbonate	1-2 mEq/L IV over 15 min
Without clinical signs	50% Dextrose solution polyionic crystalloid fluids	2 mL/kg IV over 5 min
Hypocalcemia	Calcium gluconate	Typically requires 100-300 mL of 23% solution
Hypercalcemia	Non—calcium-containing polyionic fluids Magnesium sulfate	4–16 mg/kg as an initial dose
Hypomagnesemia	Magnesium sulfate IV	4–16 mg/kg as an initial dose
	Magnesium oxide PO	8–32 mg/kg as an initial dose
Hypermagnesemia	Calcium gluconate	250–500 mL of 23% solution
Hypoalbuminemia	Fresh or fresh frozen equine plasma Hetastarch	To effect, not to exceed 10 mL/kg

IV, Intravenous; *PO*, by mouth.

Always take into account all disturbances present before commencing treatment.

32.97.1 Acid-Base Disturbances

The most common acid-base disturbance in horses with gastrointestinal disease is metabolic acidosis, caused by lactic acidosis (hypovolemia, endotoxemia), hyponatremia (colitis, peritonitis, intestinal torsion), or hyperchloremia (occasionally seen in colitis cases). Metabolic alkalosis, resulting from hypochloremia (high-volume gastric reflux) or hypoalbuminemia (severe enterocolitis, excessive fluid therapy), respiratory alkalosis (hyperventilation from pain), and respiratory acidosis (hypoventilation from extreme abdominal distention, central depression) can also occur.[952]

Although the predominant clinical signs in horses with acid-base disturbances are likely to result from the cause of the disturbance, clinical signs can arise from the physiologic consequences of the derangement. Metabolic acidosis can result in reduced cardiac contractility, constriction of the peripheral vasculature, inhibition of glycolysis, decrease in oxygen uptake by hemoglobin in the lungs, and CNS depression. Metabolic alkalosis can lead to overexcitability of nervous tissue, blunting of the hypoxic drive, compensatory hypoventilation, susceptibility to cardiac arrhythmias, and inhibition of oxygen release in the tissues.

Treatment of acid-base disturbances should be directed at the underlying cause and the specific plasma constituent imbalance. It is possible to determine the relative contributions of unidentified anions (principally lactate in horses with gastrointestinal disturbances), sodium, chloride, and protein to the measured acid-base status by the use of equations based on the calculated base excess.[952,1003] However, decisions for treatment can often be based on the absolute values of these blood constituents, and it is only in complex disturbances with changes in multiple blood constituents that the equations are usually necessary.

32.97.2 Lactate

As discussed earlier, increased blood or plasma lactate concentrations are usually a result of poor tissue perfusion in gastrointestinal diseases but may also be caused by inappropriate anaerobic metabolism in endotoxemia. The clinical signs of lactemia are those of the accompanying metabolic acidosis, but the signs of the cause of the lactic acidosis (those of shock) may predominate.

Although lactate can be directly measured, its plasma concentration can be accurately predicted by the anion gap in adult horses with normal plasma protein concentrations.[1004] The anion gap is calculated from the plasma concentrations of (sodium + potassium) minus the concentrations of (chloride + bicarbonate). The normal range is 7 to 15 mEq/L.[1004] At low and high protein concentrations, the equations based on base excess[952,1003] or the simplified strong ion gap ($2.24 \times$ total protein [g/dL]/$[1 + 10^{6.65-pH}]$ – Anion gap)[1004] should be used. Any of these calculations may easily be performed on a pocket calculator, but none was accurate in critically ill foals.[951]

774

775

Lactic acidosis should be treated with large volumes of polyionic crystalloid solutions. The use of sodium bicarbonate in lactic acidosis is highly controversial.[960,1005] It corrects the laboratory value (pH) without addressing the underlying pathophysiology (poor tissue perfusion) by imposing a hypernatremic alkalosis on an already deranged metabolic balance. Although increasing the pH may improve myocardial contractility, this effect may be negated by the myocardial depressant effects of an increased carbon dioxide tension.[1006] In endotoxic ponies, administration of sodium bicarbonate resulted in an increased blood lactate concentration, hypernatremia, hypokalemia, and hyperosmolality.[1007]

32.97.3 Sodium

Low plasma sodium concentrations are most commonly seen in acute colitis, such as salmonellosis, PHF, and clostridiosis. The hyponatremia is usually accompanied by hypochloremia because of an increased loss of electrolytes relative to water.[958] Other gastrointestinal conditions associated with hyponatremia are those that result in third spacing of sodium (peritonitis, torsion or volvulus of gut) and with sodium-wasting disorders (esophageal obstruction leading to loss of saliva). The clinical signs of hyponatremia are neurologic disturbances, including reduced or absent menace response, intention tremor, and hypermetric gait,[1008] but severe clinical signs do not usually occur until the sodium concentration is less than 110 mEq/L.[1009] Hyponatremia will also result in metabolic acidosis.[952]

The fluid choice for hyponatremia depends on whether there is concurrent hypochloremia. If the plasma chloride concentration is also low, sodium chloride should be used. If the chloride concentration is normal or increased (which is rare in gastrointestinal disease), then sodium bicarbonate should be administered. If the hyponatremia is severe, then hypertonic solutions may be administered initially (7% to 7.5% sodium chloride and 5% to 8.4% sodium bicarbonate, respectively). Rapid correction of sodium deficits in other species can cause central pontine myelinosis.[1009] It is unclear whether this is a risk in the horse and therefore whether it is necessary to follow the guidelines for sodium restoration in other species. These guidelines state that sodium should be corrected at a rate of 1 mEq/L/hr in acute hyponatremia and at less than 0.5 mEq/L/hr in chronic hyponatremia, in neither case to exceed 8 mEq/L during the first 24 hours.[1009]

Hypernatremia is rare in horses with gastrointestinal disease[958,1001,1010] and is usually caused by water loss in excess of electrolytes and accompanied by hyperchloremia. To correct hypernatremia, low-sodium fluids such as 5% dextrose or 2.5% dextrose and 0.45% sodium chloride should be administered. Again, in other species it is recommended not to correct hypernatremia too rapidly; sodium should be lowered by 0.5 mEq/L/hr, not to exceed 12 mEq/L over the first 24 hours.[1009]

Clinical signs associated with hyponatremia and hypernatremia are caused by changes in plasma osmolality. Sodium is the major cation in plasma, and sodium and glucose concentrations are the main determinants of plasma osmolality.[958] Changes in plasma osmolality can lead to CNS edema or dehydration, resulting in neurologic signs.[1011] Rapid changes in plasma sodium concentration may also cause CNS edema or dehydration, because the cerebrospinal fluid slowly equilibrates with the plasma, but will rapidly change if osmotic gradients are high.

32.97.4 Chloride

The loss of gastric hydrochloric acid in high-volume reflux (in proximal enteritis and grass sickness) and the secretion and/or lack of absorption of chloride in severe colitis often leads to hypochloremia in gastrointestinal disease.[1001,1010] Hypochloremia in the absence of hyponatremia results in metabolic alkalosis.[952] The alkalosis associated with hypochloremia may also result in increased cellular uptake of potassium, leading to hypokalemia.[1009]

Treatment of hypochloremia can usually be achieved with intravenous 0.9% sodium chloride, which contains more chloride relative to sodium than plasma. In horses with high-volume gastric reflux, administration of intravenous H_2-receptor antagonists (e.g., cimetidine at 6.6 mg/kg IV qid) reduces gastric hydrochloric acid

secretion and therefore should reduce chloride loss. In humans, intravenous hydrochloric acid has been used to treat severe hypochloremia,[1012] but carries substantial risks for the patient.[1013] Hyperchloremia is rare in horses with gastrointestinal disease but may occur in severe colitis because of water secretion in excess of electrolytes. It should be treated with 5% dextrose if accompanied by hypernatremia and with sodium bicarbonate if severe and accompanied by a low or normal plasma sodium concentration.[1009]

32.97.5 Potassium

Hypokalemia is commonly seen in horses after surgery for colic[1010] because of enhanced mineralocorticoid and glucocorticoid release and because of infusion of large amounts of sodium-containing fluids that increase distal tubular flow and renal potassium loss.[1011] Hypokalemia also occurs in colitis and metabolic alkalosis. The most relevant clinical sign of hypokalemia is reduced intestinal motility.[1009,1014] However, the association between hypokalemia and ileus remains undetermined in the horse. Other clinical signs include muscle weakness, lethargy, and inability to concentrate urine.[1009] Cardiac conduction abnormalities are rare except in severe hypokalemia and in preexisting cardiac dysfunction.[1014] The effect of potassium on acid-base status is small and need not be considered clinically.[952]

Potassium is primarily an intracellular ion, and therefore decreases in whole body potassium may not be detected by plasma measurements.[1015] Although erythrocyte potassium content has been used to estimate whole body potassium,[1015] its accuracy is unclear. Moreover, the extracellular potassium concentration (reflected in the plasma) is more relevant to neuromuscular transmission and therefore to the important clinical signs than whole body potassium stores.[1011] The intervention level for treatment of hypokalemia is unclear. In postoperative colic cases and proximal enteritis, the prevention of ileus is a primary goal, and it may be prudent to supplement the plasma potassium concentration below 3.5 mEq/L. In other patients, especially those being fed enterally, it may not be necessary to treat plasma potassium concentration above 3 mEq/L.

Hypokalemia is treated with intravenous potassium chloride solution. The rate of administration is more important than the amount. The rate should not normally exceed 0.5 mEq/kg/hr and should never exceed 1 mEq/ 775
kg/hr.[1009] The addition of 40 mEq of potassium chloride per liter of crystalloid fluids is safe at rates up to 10 776
mL/kg/hr (5 L/hr for a 500-kg horse). This amount is usually required only in severe hypokalemia (<2.7 mEq/L), and smaller disturbances can often be successfully treated with 20 mEq of fluid per liter. If hypokalemia does not respond to potassium chloride administration, magnesium should be supplemented.[1016] Hyperkalemia is not typical in horses with gastrointestinal disease, although it may occur with acidosis, colitis, secondary renal failure, and hyperkalemic periodic paralysis. Artifactual hyperkalemia may be seen in blood samples stored for longer than 2 hours before plasma separation, because of leaching of potassium from the erythrocytes. Clinical signs are due to disruption of neuromuscular transmission and are therefore similar to those of hypokalemia. In the absence of clinical signs, polyionic fluids should be administered. Possible treatments for symptomatic or severe (>7 mEq/L) hyperkalemia include calcium gluconate (1 mL/kg IV over 10 minutes), sodium bicarbonate (1 to 2 mEq/L IV over 15 minutes) and 50% dextrose solution (2 mL/kg IV over 5 minutes).[1009]

32.97.6 Calcium

Low plasma ionized calcium concentrations are common in horses with surgical colic[1017] and in colitis cases. Possible causes of this hypocalcemia include lactic acidosis,[1018] endotoxin-induced changes in calcium

homeostasis,[1019] and functional disturbances to the small intestine (the main site of calcium absorption in the horse[1020]). Clinical signs of hypocalcemia reported in the horse include synchronous diaphragmatic flutter, tetany, muscle spasm, and seizures.[1021] Of these, only diaphragmatic flutter is seen with any regularity in adult horses. Hypocalcemia has also been associated with POI in the horse,[1017,1022,1023] but a causal relationship has not been demonstrated.

Approximately 50% of the total calcium in plasma is bound to albumin or complexed with small ligands. The remaining ionized fraction is the biologically active form. Where possible, the plasma ionized calcium concentration should be measured, rather than the total concentration, because the plasma albumin concentration is often decreased in gastrointestinal diseases. If total plasma calcium measurements are used to guide therapy, the calcium concentration should be corrected for changes in albumin concentration. The intervention level for treatment of hypocalcemia is debatable. There is one report of exacerbation of endotoxemia with calcium administration in a rodent model.[1024] Although the relevance of this to the horse has not been determined, aggressive supplementation of calcium in endotoxemic horses may be inadvisable. Even in endotoxic horses, calcium should probably be supplemented if the ionized calcium concentration is less than 4.8 mg/dL (1.2 mmol/L).

Hypocalcemia is treated with intravenous 23% calcium gluconate or 20% to 40% calcium borogluconate solution. A typical volume required is 100 to 300 mL of the 20% to 23% solution,[1017] but the amount will depend on ongoing losses, and the ionized calcium concentration should be frequently checked during therapy. Calcium solutions are irritating to the veins and should be diluted in crystalloid fluids before administration. They are incompatible with sodium bicarbonate and whole blood. After calcium supplementation, the plasma calcium concentration should be checked after 4 to 8 hours because ongoing losses and redistribution into cells may result in further hypocalcemia. Hypocalcemia can be a sequela to magnesium deficiency, and therefore magnesium should be supplemented in horses with refractory hypocalcemia.

Hypercalcemia occurs in horses with chronic renal failure but is rare in gastrointestinal disease. Clinical signs are usually those of the underlying pathophysiology, but soft-tissue calcification may occur. Treatment for severe hypercalcemia (ionized calcium greater than 9 mg/dL [2.25 mmol/L]) should include non—calcium-containing intravenous fluids (sodium chloride or Normosol-R) and intravenous magnesium sulfate (see treatment of hypomagnesemia, later).

32.97.7 Magnesium

In one report, 44% of horses with gastrointestinal disease had low plasma magnesium concentrations.[1025] Causes of hypomagnesemia include decreased intake, gastrointestinal losses (prolonged nasogastric reflux, malabsorption), alterations in distribution (endotoxemia, parenteral nutrition administration), renal losses (prolonged administration of lactated Ringer's solution or other magnesium-free fluids, hypophosphatemia, acidemia, renal tubular acidosis),[1026,1027] and excessive sweating.[1028] Severe hypomagnesemia can result in ventricular arrhythmias and also muscle tremors, ataxia, seizures, and calcification of elastic tissue[1029] in the horse. Other clinical manifestations of hypomagnesemia reported in human patients include supraventricular tachycardia, atrial fibrillation, thrombosis, anemia, decreased muscle strength, increased nephrotoxicity of aminoglycoside drugs, increased pulmonary vascular resistance, and sudden death.[1026,1030–1032] Hypomagnesemia can also result in hypokalemia refractory to potassium supplementation.[1016]

Extracellular fluid contains approximately 1% of the total body magnesium, and therefore the serum magnesium concentration may not reflect the total body magnesium status,[1027] making diagnosis of hypomagnesemia difficult. Fortunately it is safe to administer moderate amounts of magnesium, irrespective of the magnesium status of the horse, providing the horse has normal renal function. Intravenous magnesium sulfate (at 2 mg/kg/min, not to exceed 50 mg/kg) is recommended for ventricular arrhythmias associated with hypomagnesemia.[1033] Higher doses should be avoided because they cause significant muscle weakness; 140 mg/kg of intravenous magnesium sulfate can induce recumbency in normal horses.[1034] For treatment of hypomagnesemia in the absence of cardiac signs, 2 to 8 mg/kg can be used as an initial dose in horses with normal renal function. Oral supplementation is possible with magnesium oxide, but oral magnesium sulfate should be avoided because of its laxative effects.

In the study by Costa and colleagues, 11% of horses with gastrointestinal disease were hypermagnesemic, but associated clinical signs were not reported.[1025] Severe clinical signs after nasogastric administration of magnesium sulfate were reported in two horses with large colon impactions. The doses given were between 1600 and 2000 mg/kg. Both horses recovered 1 to 6 hours after the onset of clinical signs, which included flaccid paralysis with recumbency, tachycardia, tachypnea, and nondetectable peripheral pulses. The horses were treated with 250 mL of 23% calcium gluconate solution IV, repeated after an hour, and polyionic intravenous fluids to promote diuresis.[1035] The phosphorylation of adenosine diphosphate (ADP) to form ATP is dependent on the intracellular magnesium concentration,[1036] and therefore hypomagnesemia can disrupt ATP-dependent cellular processes. The sodium-potassium ATPase pump, the major mechanism for controlling intracellular and extracellular sodium and potassium concentrations, is ATP dependent and thus magnesium dependent. This may explain the relationship of refractory hypokalemia to hypomagnesemia.[1016] The relationship between the sodium-potassium ATPase pump and magnesium may also explain the effect of magnesium on calcium flux, because sodium is exchanged down its concentration gradient (controlled by the sodium-potassium ATPase pump) for calcium by the sodium-calcium exchanger.[1037] Because of the interaction of the magnesium concentration with these other electrolytes, a main effect of hypomagnesium is to alter depolarization of nerve and muscle cells.[1031] Magnesium also directly competes with calcium for some of its binding sites, allowing greater binding of calcium to enzymes in hypomagnesemia. One such enzyme is phospholipase A_2; increased calcium binding results in greater activity of this enzyme, which leads to the increased formation of eicosanoids, particularly TXA_2,[1030] that may play a role in thrombophlebitis.[1038]

776

777

32.97.8 Phosphorus

Hypophosphatemia has been reported in horses with either strangulating intestinal lesions or intestinal ileus[1001] and is also a sequela to renal dysfunction.[949] Prolonged administration of lactate-containing fluids,[1039] metabolic or respiratory alkaloses, repeated gastric magnesium sulfate administration (because magnesium binds phosphate to form an insoluble complex), and prolonged administration of non—lipid-containing parenteral nutrition solutions[1040] may also result in hypophosphatemia. Reduced intestinal phosphate absorption, apparently without hypophosphatemia, is a sequela to large colon resection.[1041] Clinical signs reported in small animals and humans with hypophosphatemia include hemolysis, skeletal muscle weakness and rhabdomyolysis, leukocyte dysfunction, ventricular arrhythmias, and reduced cardiac output.[1040,1042]

Clinical manifestations and treatment of hypophosphatemia have not been reported in the horse, and in humans there is no good evidence for treatment in the absence of clinical signs.[1040] Treatment options reported in small

animals include intravenous potassium phosphate (0.01 to 0.03 mmol/kg/hr) and oral potassium phosphate (0.5 to 2 mmol/kg/day).[1042] The potential effects of potassium phosphate on the plasma potassium concentration must be considered before this treatment is commenced. Intravenous glucose-1-phosphate[1043] and intravenous sodium phosphate have also been reported in humans. The safety of these treatments has not been evaluated in the horse.

Hyperphosphatemia occurs in horses with strangulating intestinal lesions[1044] and severe colitis[1001] without specifically attributable clinical signs. Clinical findings reported in small animals include diarrhea, hypocalcemia, hypernatremia, and an increased propensity to metastatic soft-tissue calcification. Treatment recommended in small animals includes intravenous fluids, to correct any acidosis and promote renal phosphorus excretion, and dextrose-containing fluids, to promote translocation of phosphorus into cells.[1042]

The clinical signs of hypophosphatemia result from the wide range of physiologic functions of phosphate. These include storage of energy as ATP, which is used for many processes including muscle contraction, neuronal transmission, and electrolyte transport. Because phosphorus and magnesium deficiencies can both result in reduced availability of ATP, the clinical signs can be similar. Phosphate also acts as a buffer in plasma and is a component of many intracellular compounds including phospholipids, nucleic acids, enzymatic cofactors, and signaling molecules such as cyclic adenosine phosphate. It appears that increased plasma phosphate concentrations are not directly toxic.[1045] Hypocalcemia and metastatic soft-tissue calcification caused by hyperphosphatemia result from the calcium-phosphate product exceeding that required for precipitation of calcium phosphate in the tissues.[1042,1045]

32.97.9 Albumin

Hypoalbuminemia is common in horses with moderate to severe compromise of the colon. It may also occur with over-aggressive fluid therapy and parasitism. Clinical signs of hypoalbuminemia are peripheral edema (due to reduced plasma oncotic pressure) and tissue and organ edema, leading to reduced oxygen uptake by cells (increased perfusion distance), and in severe cases organ failure. Albumin is a weak acid, and severe hypoalbuminemia may contribute to metabolic alkalosis or mask concurrent metabolic acidosis.[952] A decrease in albumin concentration of 1 g/dL results in an increase in the base excess of +3.7 mEq/L.[1003]

Hypoalbuminemia should be treated when acute or if there are clinical signs. Although it is advisable to treat all horses with a plasma total solids concentration of less than 4 g/dL, a few horses with chronic hypoproteinemia can have plasma total solids concentrations of 3.5 to 4 g/dL with no apparent clinical signs. The treatment options for hypoalbuminemia include fresh or fresh frozen equine plasma, concentrated albumin solutions, and hetastarch. Plasma has the advantage of containing other factors, such as AT-III, that may be depleted in the disease process. Hetastarch has the advantage of large molecular size and long persistence in the circulation[971] but has questionable efficacy in human patients. Albumin solutions were shown to result in neither benefit nor harm in human critically ill patients when compared with saline.[1046] At the time of writing, equine albumin solutions are not available commercially, and their role in the treatment of horses is unclear.

32.98 COMPLICATIONS OF FLUID THERAPY

32.98.1 Thrombophlebitis

Thrombophlebitis is a common complication of intravenous fluid therapy.[962] It may be a nidus for infection and may cause mechanical blockage of venous drainage, resulting in local edema. Fatal edematous occlusion of the upper respiratory tract can result from bilateral jugular vein thrombosis. It is therefore advisable not to catheterize the contralateral jugular vein if one jugular vein shows any signs of thrombosis. Bacterial endocarditis, particularly of the tricuspid valve, can occur as a sequela to infectious thrombosis.

Thrombophlebitis can be identified by heat, swelling, or the presence of any exudate around the catheter insertion site or by palpation of a thrombus ("corded" feel) in the catheterized vein. Catheterized veins should be checked at least daily. Ultrasonography of the catheterized vein can help identify thrombus formation. It is prudent to continue to check the vein for 2 to 3 days after catheter removal because thrombophlebitis may develop or become apparent in this time period.

The risk factors for thrombophlebitis include administration of carboy fluids,[962] presence of diarrhea[962] or endotoxemia,[1038] polytetrafluoroethylene (Teflon) catheter material, and long duration of catheterization.[984] Several other risk factors for thrombophlebitis have been identified in humans but not studied in horses. These include inexperienced personnel placing the catheter,[1047] administration of total parenteral nutrition,[982] and larger-bore catheters.[1048] Treatment for thrombophlebitis should include topical nitroglycerin ointment[1049] and probably also hot-packing and topical DMSO ointment. Catheters from thrombosed veins should be removed aseptically and cultured (preferably by the roll-plate technique[1050]) to allow in vitro susceptibility directed antimicrobial therapy, if necessary. A fine-needle aspirate of the thrombus can also be used for bacterial culture. Fluid-filled pockets within the thrombus can often be identified by ultrasound[1051] and should undergo aspiration after surgical preparation of the skin over them. Empirical antimicrobial drugs should be broad spectrum with activity against *Streptococci* and *Staphylococci* species[1051] and have good tissue penetration. Such drugs include ceftiofur, gentamicin, and chloramphenicol.

777 778

32.98.2 Overhydration

Clinical signs of overhydration are rare in adult horses with normal cardiac and renal function. The most important clinical sign is pulmonary edema, manifested by dyspnea and a pink-white foamy nasal discharge. Treatment should include furosemide (0.5 to 1 mg/kg IV) and a reduction in the rate of fluid administration. Intranasal oxygen supplementation is indicated when there is significant hypoxemia (detected by arterial blood gas analysis). Further fluid therapy in such horses should be carefully monitored, ideally by means of CVP measurements.

32.99 INOTROPES, PRESSORS, AND VASODILATORS

Some horses with severe cardiovascular compromise will not respond to fluid therapy alone. A proportion of these patients can be successfully managed with inotropes, pressors or vasodilators. These drugs should be considered in cases with continued tachycardia, lactic acidosis, oliguria, and hypotension or hypertension despite appropriate fluid therapy. In general, horses with a jugular venous oxygen tension of less than 35 mm Hg are most likely to

require further cardiovascular support, and those with an oxygen tension over 60 mm Hg are least likely to respond.[1052,1053] The cause of the cardiovascular insufficiency should be considered before therapy is initiated. Horses with necrotic intestine that could not be resected are unlikely to respond to cardiovascular therapy unless the primary problem can be addressed.

The inotropes increase cardiac output by increasing myocardial contractility, resulting in a larger stroke volume. The most commonly used drugs in equine intensive care for this purpose are the β_1-adrenergic agonists. Inotropes that have some β_2-adrenergic activity, such as dobutamine, may also cause mild systemic vasodilation. The pressors cause arterial and venous vasoconstriction, mediated through α-adrenergic receptors, and the vasodilators, such as nitroprusside and fenoldopam, cause arterial or venous vasodilation mediated through the nitric oxide pathway.

The decision to use one of these drugs and the choice of drug should be based on as many cardiovascular parameters as can be measured.[1054] The minimum information required to select an appropriate drug includes heart rate, heart rhythm, indirect (tail cuff) arterial blood pressure, and response to fluid therapy. Direct measurements of CVP and arterial blood pressure, electrocardiogram, and cardiac output, if available, make these treatments safer and easier to titrate. All of these drugs should be carefully titrated to defined endpoints. For inotropes and pressors the goal should be to increase the arterial blood pressure sufficiently to decrease blood lactate concentration and increase urine output[1052] without inducing tachycardia or arrhythmias. For vasodilators the goal should be to reduce the MAP to less than 120 mm Hg without inducing hypotension, tachycardia, or acidosis. It is advisable to use an electronic pump to accurately deliver the diluted drug at the correct rate.

It is extremely important to frequently monitor the response to these drugs, as the underlying cardiovascular disturbances may change rapidly. Improvements in arterial blood pressure may not result in improved tissue perfusion. Heart rate and rhythm, the acid-base balance, venous oxygen tension, and urine output should be monitored in addition to arterial blood pressure. If indirect blood pressure is being used to monitor these drugs, it is important to bear in mind the limitations of the technique. All readings should be done in triplicate, and the cuff size should be matched to the patient. A small adult cuff designed for humans is appropriate for most adult horse tails.

Endotoxemia is the most common cause of severe cardiovascular disturbances in the adult. The initial cardiovascular response to experimental endotoxin administration is decreased MAP, systemic vasodilation, and increased cardiac output.[1055] However, this response varies markedly with the dose of endotoxin[1056,1057] and treatments given,[965,1055] and this pattern of disturbance cannot be assumed.

32.99.1 Dobutamine

In the absence of cardiac output measurements, dobutamine should be the first drug used in hypotensive horses (MAP <65 mm Hg) that have not responded to appropriate fluid therapy. Dobutamine is a β_1-adrenergic agonist and increases cardiac output.[1058] Dobutamine also has significant β_2 activity, which could cause vasodilation. Dobutamine should be diluted in isotonic saline, 5% dextrose, or lactated Ringer's solution. The dose should be carefully titrated from a starting dose of 1 to 3 μg/kg/min. The horse should be carefully monitored for tachycardia, which in some cases may indicate inadequate fluid resuscitation, and for dysrhythmias.

In horses with endotoxemia and increased cardiac output, dobutamine is unlikely to improve tissue oxygenation. Despite increasing cardiac output, dobutamine did not ameliorate experimental colon ischemia in the pig.[1059]

32.99.2 Norepinephrine

In hypotensive horses that either do not respond to dobutamine or have a measured increased cardiac output, norepinephrine (noradrenaline) administration should be considered. Norepinephrine is an α-adrenergic and moderate β_1-adrenergic agonist. It is a powerful vasoconstrictor in the horse.[1060] Norepinephrine should be diluted in 5% dextrose. A starting dose is 0.1 μg/kg/min, and effects may be seen in some patients at doses as low as 0.01 μg/kg/min. The highest reported doses are 1.5 μg/kg/min in the horse[1060] and 3.3 μg/kg/min in human patients.[1061] Concurrent infusion of dobutamine (5 μg/kg/min) with norepinephrine has been demonstrated in humans to result in improved tissue perfusion[1062] and might be prudent when cardiac output is not being directly monitored. It is important to carefully monitor urine output when using norepinephrine, as inappropriate doses may reduce renal blood flow.

32.99.3 Dopamine

Dopamine has β-adrenergic (inotropic), α-adrenergic (pressor), and dopaminergic effects. In other species the dopaminergic effects predominate at low doses (1-5 μg/kg/min), the β-adrenergic effects at moderate doses (5 to 10 μg/kg/min), and the α-adrenergic effects at high doses (above 10 μg/kg/min),[1063] but these distinctions may be blurred in the horse.[1064] In anesthetized horses a dopamine infusion started 5 minutes after endotoxin administration improved cardiovascular variables but did not prevent hypoxemia or metabolic acidosis.[1065] Dopamine causes significant vasoconstriction of equine colonic arteries at higher doses in vitro[1066] and is associated with reduced gastric mucosal perfusion in human septic patients in vivo.[1067] Furthermore, dopamine may disrupt normal equine gastrointestinal activity, even after the infusion is stopped.[1068] In normal horses low doses of dopamine (5 μg/kg/min) can cause cardiac arrhythmias.[1064]

778

779

Dopamine is not recommended for horses with gastrointestinal diseases because of the reported deleterious effects on the gastrointestinal system and because the predominant effects vary with the plasma concentration,[1064] which cannot be predicted from the infusion rate.[1069,1070] Low-dose dopamine has been demonstrated not to have any efficacy in preventing or treating acute renal failure in human patients,[1071] and dopamine infusion does not increase creatinine clearance in the normal horse.[1064]

32.99.4 Nitroprusside

In severely hypertensive horses, sodium nitroprusside administration should be considered.[1058] A diastolic blood pressure greater than 110 to 120 mm Hg is considered to be a hypertensive crisis in human medicine.[1072] Nitroprusside liberates nitric oxide by a nonenzymatic one-electron reduction that occurs on exposure to tissues such as vascular smooth muscle membranes.[1073] Hypertension, particularly pulmonary hypertension, has been reported in experimental horses and foals treated with a low dose of endotoxin.[965,1057,1074] Laminitis is also associated with hypertension (MAP up to 158 mm Hg).[1075] However, this increase in arterial pressure may be associated with increased cardiac output rather than a generalized increase in vascular tone (systemic vascular resistance).[1075] Nitroprusside induces relaxation of palmar digital arteries and veins isolated from carbohydrate-overloaded horses.[1076] Treatment of acute laminitis with glyceryl trinitrate applied topically to the pasterns results in some amelioration of clinical signs.[1077] Assuming that this response is due to nitric oxide, parenteral

nitroprusside administration would represent a method of delivering a more controlled source of nitric oxide. The potential beneficial role of nitroprusside administration in ameliorating laminitis remains to be investigated.

Sodium nitroprusside should be diluted in 5% dextrose solution and wrapped in foil to protect the solution from light. The dose should be carefully titrated from a starting dose of 0.1 to 0.3 µg/kg/min. It is imperative to monitor the blood pressure continuously during the initial titration phase and frequently thereafter. As with all nitric oxide donors, there is a reduced responsiveness with time that may necessitate increasing doses.[1073] Hepatic metabolism of nitroprusside produces thiocyanate and cyanide, which may result in altered neurologic status, acidosis, and death at high concentrations.[1078] In human patients, cyanide toxicity has not been reported at doses of less than 2 µg/kg/min.[1078] Fenoldopam, a selective dopamine-1 receptor agonist, is a possible alternative antihypertensive agent that has been used experimentally in the horse and foal.[1079,1080] However, the current cost of fenoldopam is likely to prohibit its use in adult horses.

32.100 RUMINANT ALIMENTARY DISEASE

Bradford P. Smith, Consulting Editor

32.101 DENTAL AND PERIODONTAL DISEASES

Guy St. Jean

32.102 ERUPTION OF TEETH

Determining an animal's age by examining the teeth is not an exact science, because the appearance of the teeth can be affected by inherited factors, nutrition, and geographic location.[1,2] At birth or within 2 weeks, four deciduous incisors usually are present. All eight deciduous incisors erupt within the first month.[3] The fourth incisor (corner) is a modified canine tooth. The incisors meet with the dental pad of the upper jaw for the purpose of gripping and cutting herbage. Usually all three pairs of deciduous premolars have erupted at birth or shortly afterward.[1,2] In cattle the formula for the deciduous teeth is as follows:

$$2(\text{incisors } 0/4,\ \text{premolars } 3/3) = 20$$

The age at which permanent teeth erupt often is the best criterion for determining the animal's age if a registration certificate is not available. However, systemic illnesses and malnutrition can retard dental development and cause retention of the deciduous teeth.[4] The first molars erupt at 8 months of age and are fully developed at 12 months. At 18 months the second molar is fully developed. The third molar erupts at 24 months and is fully developed at 30 months. The permanent premolar teeth start to replace the deciduous teeth at 24 months, and all three permanent premolars usually are present at 3 years of age.[1,2] The first pair of permanent incisors (centrals) erupts at 18 to 24 months of age, the second pair (medials) appears at 24 to 30 months, the third pair (laterals) erupts at 3 years of age, and the fourth pair (corners) erupts between 3½ and 4 years of age.[3,4] Cattle therefore have a complete set of permanent teeth at age 4 to 4½ years. The formula for the permanent teeth in cattle is as follows:

$$2(\text{incisors } 0/4,\ \text{premolars } 3/3,\ \text{molars } 3/3) = 32$$

The deciduous and permanent dental formulas of the sheep and goat are identical to those of cattle.[3] In sheep and goats the periods of eruption are as follows: The incisors are present at birth or within the first 4 weeks. The

premolars erupt 2 to 6 weeks after birth. The first pair of permanent incisors (centrals) replaces the deciduous teeth at 12 to 18 months of age. The second pair appears at 18 to 24 months. The third pair (laterals) erupts between 30 and 36 months, and the fourth pair (corners) appears at 3½ to 4 years. The three permanent premolars have erupted by 18 to 24 months of age; the first molar erupts at 3 months, the second molar between 9 and 12 months, and the last molar between 18 and 24 months.[3]

32.103 EXAMINATION OF TEETH

Dental disease in ruminants should be considered first on a flock or herd basis.[5,6] Determining dental health is particularly useful when unconventional feeds are incorporated into the herd nutritional program.[7,8] The clinical manifestations of dental diseases include inadequate food intake, inadequate calf development, weight loss, unthriftiness, low body condition score, quidding, low pregnancy rate in replacement heifers, and mandibular or maxillary swellings or draining tracts.[3,6–9] Examination of the herd should be followed by dental examination of individual animals. For examination of the premolars and molars, the tongue should be withdrawn from the mouth and held at the commissure of the mouth opposite the teeth being examined. A small dose of xylazine (0.03 to 0.04 mg/kg IV) and use of a mouth speculum allow for a much more thorough dental examination, including manual palpation in cattle.

The incisors have a sharp edge in front and are used for gripping and cutting herbage.[3,6] They should be aligned closely, with little space between them.[3,6] In sheep the periodontium of the incisor allows movement of up to 2 mm anteroposteriorly to accommodate rotating or turning forces during grazing.[9] This makes the sheep incisor very prone to loss with periodontal damage. The length of the premolar and molar teeth and their firm placement in the alveolar bone means that they are lost less often than the incisors.[1,2,6]

32.103.1 Dental Attrition and Erosion

Rapid wearing of teeth is seen most commonly in grazing sheep 5 years of age or older. Sheep and cattle grazing forage-deficient or sandy pastures and arid ranges in Africa, Australia, New Zealand, and the southwestern United States often show an accelerated rate of tooth wear.[6,10] In Rhodesia the incisors of Hereford cattle showed an increased rate of wear because of the softer enamel of this breed compared with that of indigenous cattle.[11]

Examination of an animal with dental attrition reveals worn incisor or molar teeth (or both); often only short stumps are seen. The teeth also may be loose, fractured, or missing. Dental attrition from excessive wear must be differentiated from periodontal disease that causes tooth loss.[6,12,13] The pathogenesis of excessive tooth wear relates to tooth hardness and diet quality. Ingestion and mastication of soil and sand with forage abrades and wears the incisor and molar teeth. In New Zealand dental attrition in sheep was attributed to the action of the acids and enzymes in the herbage on tooth dentin.[10] A calcium deficiency or calcium-phosphorus imbalance, which results in softness of the tooth enamel and dentin, may accelerate the rate of wear.

In the United States the feeding of fermented sweet potato cannery waste to cattle resulted in substantial increases in incisor erosion.[7,8] Cattle producers who fed the waste noticed a poor growth rate, inadequate calf development, low pregnancy rates in heifers, and worn, mottled, discolored incisors.[7,8] Sweet potato cannery waste is highly acidic (pH 3.2) and causes calcium loss and tooth erosion. Deciduous teeth are etched more rapidly, placing young cattle at higher risk for severe tooth wear and dental infection. In addition, the original

enamel surface and the pulp chamber are closer together in deciduous teeth than in permanent teeth, which also is more significant in younger cattle.[7,8] Mixing 10% broiler litter with sweet potato cannery waste raised the pH to 4, providing a palatable, high-quality feed and preventing the severe dental problems associated with feeding sweet potato cannery waste alone.[7]

A syndrome involving excessive wear of deciduous incisor teeth, maleruption of permanent incisors, and an increased prevalence of dentigerous cysts in sheep has been reported from New Zealand.[14] Excessive wear of the incisor teeth of cattle was recorded on the same farms. Ingestion of soil during winter because of the inclement weather, overgrazing of pastures, and low blood levels of copper were the main causes of the syndrome.[14] Dental attrition can be prevented by providing supplemental feed to avoid overgrazing of pastures. Adding 1% ground limestone to the feed in calcium-deficient areas is recommended.[15]

32.103.2 Periodontal Disease

Periodontal disease is a disease condition of the supporting tissue that surrounds the teeth.[16,17] Periodontal disease of sheep is endemic in parts of New Zealand. A periodontal disease known as *cara inchada*, or swollen face, has caused losses of cattle in Brazil.[9,18]

Periodontal disease is characterized by protruding, loose incisors.[2,6] With time, incisors, premolars, and molars may be missing. Why periodontal disease is prevalent in sheep but less common in cattle is unknown. Periodontal disease causes pain on mastication, leading to poor maceration of food and reduction in food digestibility.

Periodontal disease has been associated with bacterial plaque-induced gingivitis.[16,19–21] The acute gingivitis is replaced progressively by a chronic inflammation in the gingival sulcus. The periodontal ligament is destroyed by plaque-forming oral microorganisms and host enzymes. At this stage, periodontal pockets are formed and lead to loosening of teeth. This process may take months or years. With time the infection extends to the apical area. The gum margin begins to recede over the lesion, food accumulates in the pocket, and the entire alveolus becomes infected. At this point the tooth becomes a sequestrum. The alveolar pyorrhea causes a periostitis of the external surface of the alveolar process, and swelling is observed. Once a tooth has been lost from an affected alveolus, granulation tissue fills the alveolus. Deep to the granulation tissue, alveolar bone is redeposited.

Bacteria such as *Bacteroides* species, *Actinomyces* species, and spirochetes, metabolic or immune disorders in the host, and mechanical or chemical agents have been implicated in the pathogenesis of periodontal diseases in sheep.[6,20,22,23] Bacterial invasion in the gingival pockets has been associated with a defect of host immune competence.[24] Hypomagnesemia has been a common finding in sheep with periodontal disease, but this may be a secondary development.[23] Gingival trauma may be important in the etiology.[25] Dissolution of the enamel at the attachment of the gingival epithelium by organic acids from microorganisms of the soil may be a predisposing factor.[26] The serum values for calcium, albumin, and alkaline phosphatase (AP) were lower for sheep with periodontal disease than for sheep unaffected by dental disease.[27]

A postmortem examination of Scottish hill sheep revealed that 60% of 478 aged sheep had either loose or missing teeth. Gingival pockets were present in 87% of the population and were correlated with tooth looseness.[28] In the United States a 25% mortality rate caused by dental disease in a herd of 300 ewes was reported.[29] The clinical signs were depression, anorexia, ataxia, and emaciation.[29] Necropsy revealed dental disease of the

mandibular teeth with plaque, plant fibers in periodontal pockets, and osteomyelitis of the mandibular bone. Initial trauma to the gingivae from cheatgrass awns in the hayfield was implicated.[29]

A particular type of periodontal disease in cattle has been reported from Brazil.[18,19] This condition involves an inflammatory process of the periodontium of calves and older Zebu cattle that results in alveolar periostitis of the maxilla or, less often, the mandible.[18,19] Examination reveals deep periodontal pockets and loss of or loosened teeth. Affected animals suffer from malnutrition, diarrhea, and loss of condition and often die. *Bacteroides* and *Actinomyces* organisms often are found in the lesion and are suspected of causing the disease.[18] This disorder is seen only in certain areas of Brazil, and the cattle improve if moved to unaffected areas. In one trial the development of periodontal disease in calves was avoided by administration of the antimicrobial drug spiramycin.[19]

780

781

The assumption that incisor condition is a good indicator of future productivity is not well founded. Little scientific evidence exists on which to base the practice of culling sheep with periodontal disease. Three farms with a high prevalence of periodontal disease were selected, and the body condition and weight of affected sheep were compared with those of sheep with no signs of periodontal disease. On only one farm was a significant association noted between periodontal disease and body condition or weight. It was concluded that periodontal disease in sheep may impair productivity on some farms but not others.[30,31]

Treating periodontal disease on a flock basis often may prove impractical. Dental treatment, drug therapy, and management change have been tried in sheep. One form of dental treatment, tooth grinding, consists of trimming the incisors to the levels of the lower dental pad.[12] Two trials of the productivity effects of tooth grinding have been conducted, and neither showed any benefit from the procedure.[30] An attempt to influence the development of periodontal disease in sheep through long-term treatment with tetracycline and metronidazole has proved ineffective.[21] In commercial sheep surgical treatment could improve conditions such as periapical and gingival abscesses, but such treatment is not economically feasible.

Sheep can live without incisors provided they do not have to graze too closely. Supplementary feeding or improved pasture usage for sheep that have lost incisors should provide a net gain to the owner. However, this approach is unlikely to be effective when premolar and molar teeth are involved, because of the inability to chew and ruminate efficiently.

32.103.3 Dentigerous Cysts

Dentigerous cysts have been described in ruminants, particularly sheep.[14,31] These are odontogenic cysts of unknown cause that manifest as localized, bony swellings. Radiographs demonstrate the cystic nature of the swelling and reveal one or more teeth in the cyst.[14,31] For valuable individuals, treatment is surgical.

32.103.4 Developmental Anomalies and Retention of Deciduous Teeth

Developmental anomalies have been reported in cattle.[5] Occasionally tooth buds fail to develop, and the fourth pair of permanent incisors is the set most often absent. The first mandibular premolar on one or both sides also occasionally fails to form. The permanent incisor teeth have been observed to be rotated up to 180 degrees in the alveolus. Rotation of the first permanent mandibular premolar also has been seen; the rotation was 90 degrees, and no cause could be detected. Retention of a deciduous premolar is common in 12- to 18-month-old cattle.

This results in difficulty in masticating and excessive salivation. Treatment consists of removing the deciduous premolar with forceps.

32.103.5 Overgrown or Loose Molar Teeth

Overgrown molar teeth are found most commonly in old ruminants. The opposite tooth often is missing. Food accumulates between the affected tooth and the cheek, causing obvious swelling of the face. Interference with mastication often is noted. The offending tooth should be rasped regularly or removed. A power tool to grind cheek teeth works well. Premolar or molar teeth can become loose in advanced cases of actinomycosis, affecting the jaw. It may be difficult to determine whether the loose tooth is a cause or a result of the bony abnormalities. One cow with maxillary lymphosarcoma and loose teeth has been reported.[32]

32.103.6 Broken Teeth

Broken incisors are not common because of the loose alveolar attachment of these teeth. Broken premolars and molars are more common because these teeth are more solidly attached in their alveoli; breakage usually results from attempts to masticate hard objects. Most fractures usually involve only a portion of the tooth, do not involve the root, and are asymptomatic. A sagittal tooth fracture that includes the root causes pain and may result in reduced feed intake and loss of condition. Treatment is described later, in the section Tooth Root Abscess.

32.103.7 Dental Caries

Dental caries, or decay, creates areas of decalcification of the tooth.[3] Dental caries is rare in ruminants,[3] but it sometimes can be found in both temporary and permanent teeth and in both dentin and enamel.[5] Interference with prehension usually is not seen. On oral examination an orange or black pigment is seen in the defective enamel or exposed dentin; these areas should be probed with a fine dental pick or needle. Caries may be filled or the tooth extracted. In rare cases the caries can reach down the pulp cavity to the root apex, causing periodontal abscesses. (See Tooth Root Abscess, later.)

32.103.8 Osteodystrophia Fibrosa

Osteodystrophia fibrosa is caused by resorption of calcium from bone and its replacement with connective tissue.[33] It is seen most commonly in the goat. Osteodystrophia fibrosa can result from calcium, phosphorus, or vitamin D deficiency or from hyperparathyroidism. The affected individual usually is a growing animal with a bilateral, soft, painless swelling of the maxilla or mandible or both.[33] The diagnosis is based on radiographic evidence of poorly mineralized bone and inward rotation of the premolar and molar teeth. Treatment consists of supplementing the ration with adequate mineral levels while maintaining a ratio of calcium to phosphorus of 2:1.

32.103.9 Tooth Root Abscess

Dental repulsion is done preferably using general anesthesia with the affected tooth uppermost. A straight incision is made directly over the longitudinal axis of the tooth, or a trephine hole over the base of the root can be made. Only the bone lateral to the tooth is removed. If necessary, a chisel is used to free the tooth of bone at its rostral and caudal surface, taking care not to disturb the neighboring teeth. A dental punch is placed on the tooth root, and dental repulsion is performed. The ventral aspect of the incision can be left open for drainage, or

the alveolus can be packed with dental wax, gauze, or dental material, such as Optisil. Abscessed maxillary cheek teeth often cause maxillary sinusitis. The sinus must be curetted at the time of surgery and flushed daily for 1 to 2 weeks after surgery. The alveolus must be packed until granulation tissue fills the hole. Antibiotics are administered for 1 week according to culture and antimicrobial sensitivity results. After removal of the affected tooth, the abscess and clinical signs usually resolve, but chronic sinusitis may require a bone flap and extensive curettage.

781

782

32.104 SALIVARY GLAND DISEASES

Guy St. Jean

The parotid, mandibular, and sublingual glands are the three largest salivary glands in ruminants.[34] In cattle the mandibular gland is larger than the parotid gland. The adult bovine produces 50 L or more of saliva in 24 hours. Saliva is secreted continuously, but the rate of secretion is increased by feeding, rumination, and the presence of coarse feed in the rumen.[34] The saliva provides a fluid medium for transport of ingesta during deglutition and regurgitation. It also maintains adequate phosphate for bacterial digestion of cellulose in the rumen and contains bicarbonate, which acts as a buffer to maintain ruminal pH above 5.5. Ruminant saliva contains approximately 80 mEq of bicarbonate per liter.

32.104.1 Excessive Salivation

Excessive salivation (ptyalism) is a sign of many pathologic conditions. The volume of saliva may be normal, but if it is not being swallowed, salivation can appear excessive. Gloves should be worn to examine the mouth of any animal that is salivating excessively as a precaution against exposure to rabies. Excessive salivation may be seen with dental disease, stomatitis, foreign objects in the mouth or pharynx, or esophageal obstruction. It also has been seen with ruminal disorders, in cows that have eaten spoiled silage, and with impaction of the abomasum. Ptyalism may be a clinical sign in rabies, pseudorabies, meningoencephalitis, and slaframine toxicity.[34,35] Mercury, iodine, lead, copper, and arsenic also can stimulate secretion by the salivary glands. Treatment depends on the underlying causes.

32.104.2 Sialocele

A sialocele develops when saliva escapes from a duct or salivary gland and enters the surrounding tissue. The saliva contains enzymes that irritate the tissue. The accumulation of saliva is surrounded by inflamed tissue, which gives the lesion a cystic appearance. A soft, fluctuant swelling usually is seen. Signs of pain may be observed during mastication. Trauma or foreign body usually is the cause of a sialocele. The diagnosis is based on the history, palpation, paracentesis, and sialography. Needle aspiration may yield mucoid saliva. Two treatments have been described.[36,37] The first involves removal of both the mandibular and sublingual glands and ducts.[36] Surgical extirpation of the mandibular salivary gland in the caudal area of the mandibular spaces has been performed successfully in cows, sheep, goats, and buffaloes.[34] Exposure of the tissue by opening the capsule of the gland facilitates the process of extirpation and prevents trauma of the surrounding nerves and blood vessels.[36] In the second treatment option the sialocele is opened, drained, and chemically debrided using copper sulfate.[37]

32.104.3 Parotid Gland Carcinomas

Three cows at slaughter had parotid gland carcinomas.[38] The neoplastic cells appeared to originate from ductal and acinar epithelium.[38] Ocular squamous cell carcinoma may spread locally to the parotid or mandibular lymph nodes.[39]

32.104.4 Sialoadenitis

Inflammation of the salivary glands usually is caused by nonspecific infections, penetrating wounds, or plant awns. Diffuse swelling of the salivary glands may be observed, and the swelling may be hot and painful on palpation. Abscess formation is a common complication. Treatment consists of systemic antibiotics and antiinflammatory and analgesic drugs. Abscesses should be drained when they localize. Salivary fistulas can be sequelae to salivary abscesses.

32.105 ACTINOBACILLOSIS (WOODY TONGUE, WOODEN TONGUE)

Bradford P. Smith

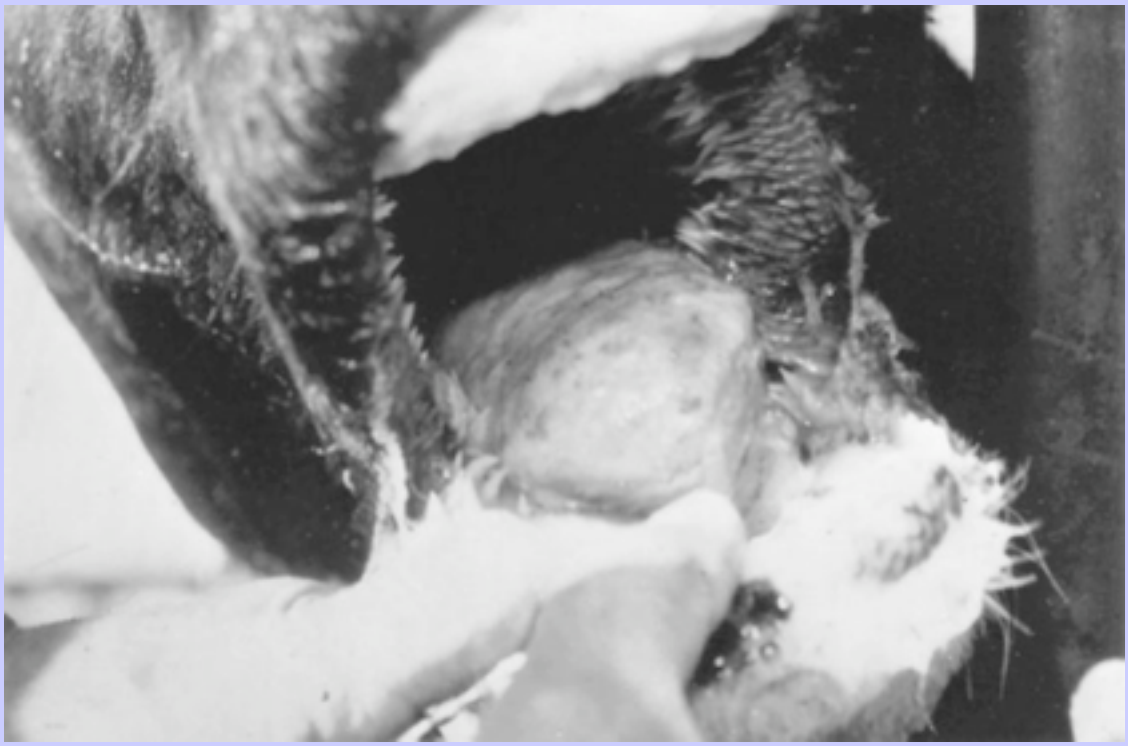
32.105.1 Definition and Etiology

Actinobacillus lignieresii, a gram-negative rod, is a normal inhabitant of the rumen and mouth of many cattle and sheep and probably goats. When the organism enters the soft tissues through a lesion, actinobacillosis results in a granulomatous abscessation. Ruminants of all ages can be affected, and the disease appears to have a worldwide distribution. The classic site of infection is the bovine tongue; because the condition causes a very hard, diffuse nodular swelling, it has been given the name “woody tongue” or “wooden tongue.” The prevalence of woody tongue in bovines at slaughter is 0.7% to 3.6%.[40] Atypical actinobacillosis lesions of cattle can occur in the lips, nose, or lymph nodes of the head or neck or at other sites.[41–43] Although the lesions normally occur sporadically, herd outbreaks with up to 73% morbidity have been reported.[44,45] Sheep are most commonly affected by hard swellings of the lips, often with fistulous tracts.[46] Actinobacillosis has also been reported to cause tongue lesions in sheep[46,47] and horses.[48] These lesions appear to be rare in goats.

32.105.2 Clinical Signs and Differential Diagnosis

Actinobacillosis lesions usually involve soft tissues. When the tongue is affected, the major clinical signs are inability to prehend food normally, excessive salivation, and sometimes a visibly enlarged tongue that protrudes from the mouth. The submandibular area often is enlarged and firm. On palpation the tongue is firm to very hard, painful, and nodular (Fig. 32-62). Nodular lesions often are slightly ulcerated. The base of the tongue is most frequently affected, but the shaft may also be involved. An ulceration filled with plant awns or stems often is seen in the sulcus lingualis at the junction of the base and shaft of the tongue. Because cattle use the tongue to prehend food, anorexia results when the tongue is painful and inflexible. Actinobacillosis must be differentiated from dental disease, oral foreign bodies, pharyngeal trauma, and other diseases that cause oral pain.

Fig. 32-62 Firm, enlarged bovine tongue typical of woody tongue caused by *Actinobacillus lignieresii*. Partly ulcerated areas of mucosa overlie hard nodules.



Atypical lesions in cattle involve sites other than the tongue. Lymph nodes of the head and cranial cervical area are most frequently affected, but where any abrasion is present, granulomas or abscesses may develop, followed by licking or contact with pus draining from a lesion on another animal. Because plant awns and stems create entry sites for the organism in the mouth, most lesions are in the head. Granulomas in the nose and eyelids and needle puncture wounds over the left jugular vein have been reported.[41] These granulomas may be confused with tumors, polyps, or cysts. Granulomas have been reported in the esophagus, pharynx, palate, flank,[42] internal iliac lymph nodes,[43] and testes[43]; multiple subcutaneous lesions with regional lymph node involvement also have been reported.[45] Three cases involving cutaneous lesions of the facial tissues were described as extensive swollen plaques under alopecic areas.[49] Most granulomatous abscesses in a herd outbreak of actinobacillosis involved the tongue, muzzle, and lips and the submandibular, parotid, and cranial cervical areas.[44] Generalized involvement or granuloma formation in internal organs may also occur.

Lesions in sheep typically involve the lips and face or parotid and submaxillary regions.[47] The nasal cavity and internal organs occasionally may be involved. Soft tissues of the head may be infected through fight wounds.[47] Lesions of the lips must be differentiated from those of contagious ecthyma (CE), and granulomatous abscesses in other sites must be differentiated from caseous lymphadenitis lesions. Lesions of the tongue of sheep,

essentially identical to those found in cattle, have been reported as a cause of green staining of the lips and "cud-dropping" in sheep.[46]

32.105.3 Clinical Pathology

Diagnosis of actinobacillosis requires biopsy and culture of the lesion. The pus usually is not malodorous. Pus crushed between two glass slides shows "sulfur granules," "clublike rosettes," or "club colonies." Similar colonies may be found in actinomycosis and some staphylococcal infections.[47] *A. lignieresii* are small, gram-negative rods. Definitive diagnosis relies on culture. No reliable serologic test is available for actinobacillosis, and the hematologic and clinical chemical findings may be normal or typical of a response to chronic infection.

32.105.4 Pathophysiology

A. lignieresii is a normal inhabitant of the mouth of ruminants and can be found in many plant awns. When mucosal lesions occur as a result of plant awns (e.g., foxtails), thistles, or particularly stemmy coarse feed, actinobacillosis may occur. Cattle often have a small ulcer in the sulcus lingualis at the junction of the base and shaft of the tongue. Plant fibers are sometimes found in the granulomatous lesions of actinobacillosis.[44] Once inoculated into tissues the organism may cause a local lesion, lesions in draining lymph nodes, or both. Lesions elsewhere on the body may be contaminated by saliva or by pus from other draining lesions or directly by plant awns on which *A. lignieresii* resides.

32.105.5 Epidemiology

Most cases of actinobacillosis are sporadic. Herd outbreaks may be associated with abrasive feedstuffs and crowded conditions in which the organism is spread rapidly to wounds on other animals by way of saliva. In one herd outbreak, 73% of a group of heifers (4 to 24 months of age) were affected 1 month after feeding of a coarse, stemmy haylage had begun.[44] Atypical lesions often are associated with a previous wound at the site, such as a nose lead wound,[41] multiple needle punctures,[41] or a head butting wound.[47] Outbreaks of actinobacillosis in wounds of the head, neck, body, and limbs have been reported.[49,50]

32.105.6 Necropsy and Biopsy Findings

Actinobacillosis lesions typically are firm, pale, gritty, granulomatous abscesses. Grossly they are similar to exuberant granulation tissue and connective tissue, often appearing to have a yellowish granular (1 to 3 mm) surface. Masses contain multifocal necrotic foci, often filled with nonodorous, thick, yellow-white pus. Histologically the lesion is a granulomatous abscess.[41] An outer capsular region of connective and granulation tissue surrounds an area of leukocytes and rosettes ("club colonies"). Mononuclear cells, plasma cells, and eosinophils predominate. Many neutrophils are seen at the center of the lesion. Multinucleated giant cells or plant fibers, or both, may be seen.

32.105.7 Treatment and Prognosis

Treatment usually is successful, and the condition has an excellent prognosis when only the tongue is involved. The prognosis may be only slightly less optimistic when internal organs and atypical sites are involved. Sodium iodide (70 mg/kg given IV as a 10% to 20% solution) is the treatment of choice. Intravenous treatment is given

once and repeated at least one more time at a 7- to 10-day interval. In refractory cases intravenous therapy may be repeated more often (2- to 3-day intervals). In severe cases daily organic iodides can be administered orally at a rate of 60 mg/kg/day[41] in addition to the intravenous iodide. If signs of iodinism develop (excessive tearing, coughing, inappetence, diarrhea, and/or dandruff), iodine administration should be halted; the adverse signs normally disappear shortly thereafter.

The onset of therapeutic benefit of sodium iodide is remarkably rapid. Within 48 hours after treatment, the tongue is flexible enough to allow the animal to eat. Although the mode by which iodides exert their beneficial therapeutic effect in actinobacillosis is not well understood, it seems most likely that they exert some antiinflammatory effect on the granulomatous inflammation. Iodides have little in vitro bacteriostatic or bactericidal effect at the concentrations given,[51] yet the onset of action is very rapid. They probably act in some way other than by direct antimicrobial effect. The old belief that iodides cause abortion at the recommended dose has been cast into doubt by my clinical experience and by reports of others,[52] who gave one and one-half to two times the recommended intravenous dose without inducing abortion. Nevertheless, there are anecdotal reports of the association, and when products are labeled with a contraindication for use in pregnant cattle, due caution should be exercised. Iodides should be given slowly and with caution to horses because of the possibility of severe generalized adverse reactions to intravenous sodium iodide.

Most strains of *A. lignieresii* are sensitive in vitro to a number of antimicrobial drugs, including ceftiofur, ampicillin, penicillin, florfenicol, sulfas, aminoglycosides, and tetracyclines. Each isolate should be tested for antimicrobial sensitivity. Therapy with an antimicrobial drug to which the isolate is sensitive is recommended in severe, generalized, or refractory cases of actinobacillosis. Therapy should also include iodides.

Surgical debulking of lesions, particularly if they interfere with airflow, is also possible for atypical cases in which a large granulomatous mass is present and the mass has proved refractory to medical therapy. Hemostasis may be a problem after surgical debulking. 783 784

32.105.8 Prevention and Control

Prevention relies mainly on avoidance of coarse, stemmy, scabrous feeds and pastures full of hard, penetrating plant awns (e.g., foxtails) or thistles. If an outbreak occurs, immediate change to a softer feed is advised, and affected animals should be treated individually. Rapid resolution of the outbreak can be expected once these steps have been taken. If atypical lesions occur, a cause of skin wounds in the area should be sought and resolved.

32.106 ACTINOMYCOSIS (LUMPY JAW)

Bradford P. Smith

32.106.1 Definition and Etiology

Actinomycosis is caused by *Actinomyces bovis*, a gram-positive, nonencapsulated, branching, filamentous bacterium that is a normal inhabitant of the ruminant mouth. The disease occurs mainly in cattle but on rare occasions may affect sheep or goats. It enters the tissues and bone through oral abrasions, openings, and punctures associated with dental or gingival disease, hard plant awns (e.g., foxtails), thorns, stickers, or dry, coarse, stemmy feeds. Lesions may begin as cavities (caries) in the dentin or dental pulp.[53] Lesions are sporadic and occur mainly in the mandible[54–56] and less commonly in the maxilla. The preponderance of mandibular

lesions, with the development of periosteal new bone and fibrosis, gives the disease its common name of "lumpy jaw." Lesions occasionally occur in soft tissues of the head, esophagus, forestomachs, and trachea.[57–60] Occasionally *A. bovis* may cause granulomatous abscesses in other soft tissues. Most of the early reports of esophageal groove and forestomach involvement incriminate actinobacillosis rather than actinomycosis.[61]

Osteomyelitis of the mandible in a horse associated with nocardiosis has been reported,[61] but no cases of mandibular actinomycosis in horses have been reported.

32.106.2 Clinical Signs and Differential Diagnosis

Bovine actinomycosis typically causes a hard, immovable, painless, bony mass on the mandible (Fig. 32-63). The lesion is most common on the horizontal ramus. Initially it is nondraining (has no fistulous tracts), but it may develop fistulous tracts and involve tooth roots as the condition progresses. When teeth become involved, evidence of pain when chewing may be seen, and weight loss may result. A careful examination of the mouth is required to detect loose teeth, plant awns, or severe gingivitis and to rule out a pathologic fracture. If a fistula is present, it is useful to flush the tract with organic iodine and perform contrast radiographs to determine if it communicates with the mouth. The differential diagnosis includes tooth root abscess, fracture, tumors, and osteomyelitis caused by other organisms. A mandibular swelling that continues to enlarge despite therapy should be radiographed for evidence of a fracture or sequestrum. Atypical actinomycosis with lesions in soft tissue causes a variety of clinical signs, depending on the location.

32.106.3 Clinical Pathology and Diagnosis

Hematologic and clinical chemistry findings may be normal or may reflect a chronic infection. Radiographs of the lesion are helpful in determining if there is dental involvement or a pathologic fracture. The radiographic lesion consists of multiple central radiolucent areas of osteomyelitis surrounded by periosteal new bone and fibrous tissue. If a fistulous tract is present, a contrast study done while flushing into the tract may help determine the extent of the fistula. Before flushing, material from the core of the lesion should be aspirated or biopsied. A Gram stain and culture of pus should be performed. The organism is gram-positive, filamentous, and branching. "Sulfur granules" similar to those described for actinobacillosis may be seen. Many authors report that they were unsuccessful at culturing the organism.

Fig. 32-63 Hard swelling on the distal mandible of a cow, typical of lumpy jaw caused by *Actinomyces bovis*. Loss of teeth and bone destruction, along with fibrosis and callus formation, are seen in this advanced case. The oral mucosa is secondarily ulcerated by trauma.

32.106.4 Pathophysiology and Epidemiology

A. bovis appears to enter the bone through mucous membrane punctures caused by foreign bodies, plant awns, or coarse, stemmy feeds or through a diseased tooth or areas of gingivitis that allow oral bacteria access to the bone. Cases usually are sporadic.

32.106.5 Necropsy and Biopsy Findings

Actinomycosis causes a granulomatous abscess.[59] Scattered through the mass of tissue are basophilic clumps of bacteria surrounded by eosinophilic clublike projections. The bacteria are long, filamentous, branching rods. Surrounding them is cellular reaction composed of neutrophils, epithelioid cells, macrophages, and occasional multinucleated giant cells. In the outer fibrous tissue are plasma cells.

32.106.6 Treatment and Prognosis

Treatment of actinomycotic bone lesions usually results in arrest of the lesion, but seldom does the size of the hard mass regress significantly. The prognosis for arrest of the lesion with vigorous treatment is good. If the mass does not have any fistulous tracts and no affected teeth are loose, medical therapy alone may be sufficient. If the mass has fistulous tracts, it should also be vigorously curetted and flushed with povidone-iodine or other organic iodine. The lesion has a rich blood supply, and curettage can result in severe hemorrhage. If the cavity is large, it may be necessary to flush and pack with iodine-soaked gauze daily for several days, then less frequently as healing progresses. One paper reports on the successful treatment of three cases of actinomycosis by using repeat treatments consisting of curettage followed by cryotherapy with liquid nitrogen poured into the lesion. The authors repeated the treatment on day 2, day 9, and day 16.[62] If there is an open fistula into the mouth (as judged by vigorous flushing) or if teeth are involved, the affected tooth or teeth should be carefully removed or repaired endodontically.[53] Care must be taken to prevent mandibular fracture, and the animal must be sedated or anesthetized to allow for proper intraoral manipulation. The empty alveolus should be carefully packed with gauze or a dental acrylic to which a wire or umbilical tape is attached and pulled through the fistula. The wire is tied externally to a small gauze roll to keep the alveolar packing firmly in place. The wire should be untied daily and the tract flushed thoroughly with povidone-iodine until the wound is completely granulated. Once granulation begins, it may not be necessary to check and flush the lesion more than once a week. The alveolus will take several weeks to close, pushing the gauze or acrylic out as it does so.

784
785

Medical treatment of actinomycosis involves the use of sodium iodide, isoniazid, and penicillin or another antimicrobial drug to which the organism is sensitive. Sodium iodide is given IV at a dose of 70 mg/kg as a 10% to 20% solution. It can be given every 7 to 10 days or more often until signs of iodinism occur (i.e., lacrimation, cough, inappetence, diarrhea, and dandruff). If repeated intravenous treatments are difficult, oral organic iodides can be given at the rate of 60 mg/kg/day for 3 weeks. As with actinobacillosis, the beneficial therapeutic effects of iodides appear to lie in their ability to reduce granulomatous inflammation rather than in direct antimicrobial effects.[63] Iodides do not appear to cause abortion and can be safely given to pregnant cows,[64] although care should be used because there are anecdotal reports to the contrary, and products are labeled with a contraindication for pregnant cattle.

Isoniazid (10 mg/kg/day given PO for 1 month) is effective at arresting actinomycosis of the mandible in cattle.[54] It is inexpensive and readily consumed in a small amount of grain. A prolonged withdrawal period before

slaughter for human consumption is required. The drug appears to be nontoxic at this dosage, but it may cause abortion and should not be used in pregnant cattle.

Penicillin (10,000 U/kg IM twice daily) or another antimicrobial drug such as florfenicol or ampicillin can be added to the treatment regimen in cases involving valuable animals or when twice-daily treatment for 7 to 14 days is possible. Streptomycin was found effective in one study,[56] but because of the prolonged persistence of tissue residues, aminoglycosides generally are considered unacceptable in food animals.

32.106.7 Prevention and Control

A. bovis is a normal mouth inhabitant of ruminants; therefore the only possible means of prevention is to avoid feeding coarse, stemmy feeds, feeds with hard, penetrating plant awns, or feeds with other sharp materials. The recommendations in this regard are similar to those for actinobacillosis.

32.107 PHARYNGEAL TRAUMA AND ABSCESS

Bradford P. Smith

32.107.1 Definition and Etiology

Pharyngeal trauma occurs relatively frequently in cattle, resulting in cellulitis,[65] abscessation,[65] or hematoma formation.[66] One case resulted in megaesophagus.[67] Pharyngeal trauma is almost always associated with use of a balling gun,[65,68] long dose syringe, speculum, paste wormer gun, rigid probe of calf esophageal feeder, or rigid stomach tube.[65] Occasionally a foreign body such as a sharp stick or wire can perforate the pharynx. Hematomas may result from unidentified blunt trauma.[66] The puncture or laceration may be very small and usually is located in the area near the origin of the esophagus. The result is that feed and saliva enter the retropharyngeal area, and eventually inflammation develops (also see Chapter 31, Retropharyngeal Abscess).

32.107.2 Clinical Signs and Differential Diagnosis

The clinical signs include anorexia, drooling of saliva, malodorous breath, extended head and neck, localized or diffuse pharyngeal pain, feed coming from the external nares, and forestomach stasis or bloat.[65] Severe cases may involve obvious pharyngeal swelling, fever, easily elicited cough on laryngeal palpation, dyspnea, and aspiration pneumonia. Intraluminal submucosal pharyngeal abscesses with similar clinical signs have been reported.[69] Differential diagnosis in cattle must include retropharyngeal abscesses (also see Chapter 31, Retropharyngeal Abscess), pharyngeal foreign body, actinobacillosis, and lymphosarcoma or other tumor that involves the pharyngeal lymph nodes.

If megaesophagus occurs, it must be differentiated from diaphragmatic hernia with herniation of the reticulum into the thorax; other outflow obstructions involving the reticulum can result in frequent regurgitation and vomiting, as can a number of other diseases, including esophageal foreign body and esophageal diverticulum. Several toxins also cause vomiting (see Chapter 7). Rabies is easily differentiated, because the only clinical signs common to both are anorexia and salivation. Careful digital palpation of the pharynx often is diagnostic, although restraint is difficult because the area is painful and swollen, causing dyspnea and struggling. A well-lubricated stomach tube should be gently passed to relieve bloat and ascertain that no esophageal obstruction is

present. Pharyngeal trauma is rare in sheep and goats, and retropharyngeal abscesses caused by *Corynebacterium pseudotuberculosis* (caseous lymphadenitis) are the most common cause of pharyngeal swelling.

32.107.3 Clinical Pathology and Laboratory Aids

Endoscopy and radiography may be of great help in diagnosing the site of the lesion, the extent of cellulitis, and the presence of a foreign body. Endoscopy reveals a swollen, collapsed pharyngeal air space. The wound may be visible, and it may have exudate at its origin. Endoscopy can help rule out intraluminal masses and foreign bodies. Retropharyngeal cellulitis, abscess, or hematoma often can be visualized radiographically, and radiopaque foreign bodies can be seen (Fig. 32-64). Gas in the soft tissues or a discrete mass can be seen with cellulitis and abscess, respectively. Gas often can be seen in the lumen of the esophagus as well. Radiographs of the lung may be helpful if aspiration pneumonia is suspected. The results of hematologic analysis may reflect an infectious inflammatory process.

32.107.4 Pathophysiology

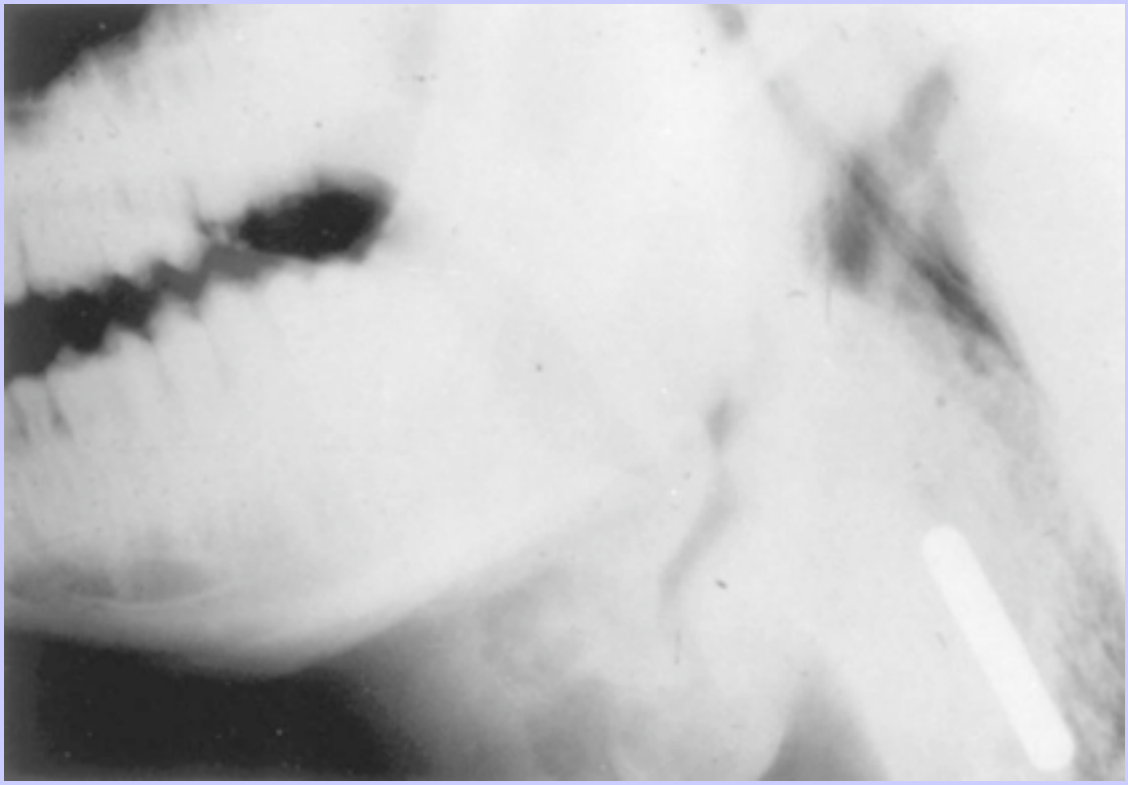
Inflammation, swelling, and necrosis in the retropharyngeal tissues interfere with normal swallowing by causing pain when swallowing is attempted, physical interference with passage of a bolus, and neurologic involvement. The resultant dysphagia may predispose the animal to inhalation of feed and saliva.

785

If the retropharyngeal inflammation affects the pharyngeal branch of the vagus nerve on the dorsolateral surface of the pharynx, the esophageal and pharyngeal phases of swallowing and eructation are disturbed.[65,70] The resultant pharyngeal paresis may lead to reflux of feed through the nares. Involvement of the adjacent cranial laryngeal nerve makes the laryngeal mucosa less sensitive to foreign material and thus diminishes the cough reflex.[65] Severe inflammation may involve the vagus nerve itself and cause forestomach stasis with bloat and laryngeal motor dysfunction.[65,71] Eructation also involves pharyngeal muscular activity, and the maneuver is likely to be quite painful when cellulitis is present in the area.

786

Fig. 32-64 Pharyngeal trauma in a 2-year-old bull caused by a magnet that was given forcefully with a balling gun 24 hours previously. The magnet is visible in the retropharyngeal tissues surrounded by cellulitis, with swelling and gas in the tissues. The area is swollen and painful.



32.107.5 Treatment and Prognosis

In spite of the fact that affected animals often are completely anorectic and febrile and look very ill, most cases of pharyngeal puncture or laceration resolve successfully if the animal can be vigorously treated with broad-spectrum antimicrobial drugs for 7 to 14 days, if aspiration pneumonia can be controlled by limiting access to feed, and if adequate supportive care can be given. Tetracyclines, sulfas, ampicillin, ceftiofur, TMS, and florfenicol or penicillin plus an aminoglycoside have been used successfully. NSAIDs should be given for analgesia and for their ability to reduce inflammation. Oral administration of boluses should be avoided.

The animal should have access to water; if it cannot drink, a soft stomach tube should be used several times daily to gently administer a total of 30 to 50 L (8 to 13 gallons) of water plus electrolytes daily. The most important electrolyte to administer is potassium: 60 to 100 g of potassium chloride should be given daily with the water. Once the animal can drink without coughing or nasal reflux, soft green grass or a soft mash should be offered. If this is well tolerated, it should be continued for 2 weeks, after which green pasture or soft, green, leafy alfalfa hay or other equally palatable feed should be gradually and carefully introduced into the diet.

If a discrete retropharyngeal abscess forms, it is best first to attempt drainage into the pharynx through the original laceration by pushing a finger into the healing wound until pus escapes. If this fails, a surgical approach to the area may be necessary. Surgery is rarely required in cases of pharyngeal trauma or laceration with cellulitis.

32.107.6 Prevention and Control

Careful use of balling guns, paste wormer guns, and other equipment that can damage the pharynx is the best prevention. Adequate restraint of the head of any animal that is to be orally treated also helps prevent pharyngeal trauma.

32.108 BLUETONGUE

Paul G.E. Michelsen

Bradford P. Smith

32.108.1 Definition and Etiology

Bluetongue is an arthropod-borne noncontagious viral disease of domestic and wild ruminants with complex interactions with the host, the host's immune system, the vector or vectors, other similar viruses, and the biopolitical environment. Clinical disease is largely restricted to sheep, but other ruminants may show disease in some circumstances. Cattle and other ruminants are considered amplifying reservoir hosts.[72] Epizootics of bluetongue disease such as one on the Iberian peninsula in 1956 that killed 179,000 sheep in 4 months led to the idea of bluetongue as an emerging exotic disease that threatened livestock industries. Since 1999 there have been reports of bluetongue from Greece, Italy, France, Spain, Portugal, Turkey, and the Balkans.[73] It occurs in the United States, South Africa, and parts of Asia. Bluetongue virus (BTV) has now been isolated from ruminants and insect vectors from all continents except Antarctica, yet the international movement of ruminants is often severely restricted for fear of importing BTV.[72] Epidemic disease outbreaks, the wide host range, the potential for establishment of endemic disease, and the similarity of some signs of bluetongue to those of vesicular diseases have made bluetongue infection the subject of intense regulatory interest worldwide. Import regulations promulgated in reaction to the disease have been more of a threat than the disease itself to the livestock industries of some countries.[74]

BTV is the prototypic orbivirus, a genus (or subfamily) within the family Reoviridae. It is inactivated by iodophores and phenols but stable in the presence of protein. Other viruses in the genus, some of which cross-react serologically with BTV, include Palyam virus, the epizootic hemorrhagic disease of deer virus and the agent of African horse sickness. The virus has a segmented genome of 10 double-stranded RNA pieces, each of which codes for one or two polypeptides. The genome of BTV was recently determined down to atomic resolution using crystallography, the largest molecule known in such detail to date.[75] The serologic classification is based on the protein product of one or two genomic segments, but virulence and other characteristics may not be related to this protein, and genetic reassortment of the pieces occurs in infections of cells with more than one serotype.[76] BTV reproduces in both arthropod and mammalian hosts and must evolve quickly to maintain itself in these imperfectly overlapping realms. Reassortment of the segmented genome contributes to the prodigious genetic diversity and rapid evolution of BTV.[77]

Strains of the virus with the same serotype may have markedly different virulence.[78,79] The discovery of BTV in Australia in 1975 originally was a cause of great concern, because the continent had been thought to be free of the virus. Subsequent investigation showed the presence of antibody in stored sera, and the Australian strains of serotypes that are pathogenic elsewhere proved to have almost no pathogenic capability. Twenty-five serotypes are recognized worldwide, five (2, 10, 11, 13, and 17) in the United States. Recently BTV-1 was isolated from an ill white-tailed deer fawn in Louisiana.[80]

32.108.2 Clinical Signs and Differential Diagnosis

786

787

Clinical bluetongue disease is manifested in two ways: reproductive syndromes and bluetongue per se, a vasculitic disease of several organ systems. Cattle and goats rarely manifest clinical disease; infected sheep commonly do.

In sheep the first clinical signs appear after an incubation period of 3 to 20 days. These signs include a transient fever (up to 41.1° C [106° F] or higher); edema of the face, lips, muzzle, and ears; excessive salivation; and hyperemia of the oral mucosa. Affected sheep usually produce a profuse serous nasal discharge that becomes mucopurulent after a few days, leaving crusts around the nostrils and muzzle. The tongue may be cyanotic (hence the name), but this is an infrequent sign. The oral lesions progress to petechial hemorrhages, erosions, and ulcers, which are especially prominent on the dental pad and the commissures of the mouth. Pulmonary edema is often marked, and some cases appear to owners to be pneumonia. Secondary bacterial bronchopneumonia frequently complicates bluetongue. Lameness and stiffness caused by coronitis and myopathy are later signs, occurring 7 to 12 days after exposure, and the coronary band shows petechial hemorrhages and hyperemia. Cardiac myopathy may result in sudden death at any time, even in an animal that appears to be recovering. Lameness may progress to “knee walking” or recumbency. The hooves may slough, and breaks in the wool are common. Diarrhea, with or without blood, is frequently seen. Many sheep become depressed, are unable to rise, and die, but some severely affected sheep make a full recovery. The differential diagnosis for sheep showing some of these signs includes sore mouth (CE), foot-and-mouth disease (FMD), peste des petits ruminants (PPR), and sheeppox.

The reproductive and teratogenic effects of BTV in sheep and cattle appear to vary greatly depending on the strain, the host, and the ecologic factors. Reproductive effects, including abortions, stillbirths, and weak, live “dummy lamb” births, were prominent when live attenuated vaccine was given to pregnant ewes in California. In South Africa, which has been recognized as bluetongue-endemic since the first descriptions of the disease before 1900, teratogenic effects have not been firmly linked to the virus despite the use of polyvalent attenuated live vaccines and near-continuous exposure to the virus.[78]

The virus has been shown to be both abortigenic and teratogenic in cattle under experimental conditions,[81] but despite evidence of high seroprevalence in cattle, abortion and teratogenesis are very uncommon under field conditions.[82] Early embryonic wastage and decreased reproductive efficiency may be more important in cattle than teratogenesis and abortion; bluetongue-seropositive cows had more services per conception, longer calving-to-conception intervals, and a greater number of total services compared with age-matched bluetongue-negative cows on the same large California dairy.[83] Experimental early gestation infections in cattle produce severe deformities that preclude live birth; later infections can cause premature delivery of low-birthweight, weak, viremic calves.[79]

Clinical disease in cattle is rare, but it can show many of the same signs as in sheep. Excessive salivation may be the first clinical sign. Hyperemia and necrosis of the muzzle ("burnt muzzle") and a patchy dermatitis may also be seen. In cattle, depending on which signs are exhibited, the differential diagnosis should include mucosal disease (BVD), malignant catarrhal fever (MCF), vesicular diseases, rinderpest (RP), photosensitization, bovine papular stomatitis (BPS), and infectious bovine rhinotracheitis. Clinical disease in cattle can be difficult to distinguish from FMD and vesicular stomatitis (VS), and appropriate regulatory officials should be notified in such outbreaks.

"White eye calf" syndrome has been described in Harney County, Oregon. The problem has a low incidence on affected ranches (0.5% to 8%). The calves are full-term stillbirths or weak, recumbent animals that rarely survive, even with good nursing care. Most affected calves have congenital cataracts, often bilaterally, which clear at 3 weeks to 3 months in the few that survive. Hydranencephaly and arthrogryposis are seen in a few calves, together with the lens opacity. The calves test negative for BTV antibody on agar gel immunodiffusion (AGID) tests, but BTV or epizootic hemorrhagic disease virus, or both, can be isolated from the spleen or bone marrow.[84] Lenticular, other ocular, and brain abnormalities may also be caused by bovine virus diarrhea (BVD) virus, and that cause should be considered in the differential diagnosis of suspected bluetongue teratogenesis in cattle.

32.108.3 Laboratory Diagnosis and Immunology

Two types of viral antigen are involved in bluetongue diagnosis by serologic testing. All BTVs have one of the types, the group antigen, which is a protein called *P7*. The other type of antigen, the P2 protein, determines the serotype (1 through 25) of the virus in question. The serum commonly is tested with complement fixation (CF), AGID, or one of several ELISAs for P7, which indicates bluetongue infection. Antibodies detected by AGID persist for years in normal animals exposed to BTV. CF tests detect shorter-lived antibodies and can be difficult to perform but are still used to determine BTV exposure status for export. The AGID test cross-reacts with related orbiviruses and can also produce a rather high number of false-negative results. The competitive ELISA (C-ELISA) has proved to be the best serologic test for detecting group antibodies to BTV.[85,86] Because of the wide pathogenic variability among BTVs (aided, no doubt, by reassortment of the segmented genome) and the fact that some other nonpathogenic orbiviruses have antigenic similarities to BTV, a positive result on the bluetongue group test does not prove that an animal's clinical disease was caused by BTV.

Virus isolation from blood obtained during the viremic, febrile stage is the most definitive means of bluetongue diagnosis. Splenic tissues or, in the case of aborted fetuses, brain tissues also can be a source of virus for isolation. Virus isolation is done by inoculation of samples into a variety of test animals and culture systems, but it is being at least partly replaced by detection of viral RNA using PCR technology. PCR-based tests for bluetongue are extremely sensitive and specific for BTV RNA and currently are being performed on clinical samples at several diagnostic laboratories. A positive PCR result is not synonymous with infection, however, because viral RNA can be detected for some time after viremia (as detected by standard virus isolation methods) has waned.[87]

Other laboratory aids to diagnosis include the presence of leukopenia during the early febrile stage of the disease and an often marked increase in serum creatinine kinase that corresponds to the latter phase of reluctance to move and stiffness.

The development of immune tolerance to BTV (in utero infection producing antibody-negative, virus-positive individuals), as happens in BVD infections, now is regarded by many as rarely if ever occurring under natural conditions,[86,88] but some controversy remains.[89]

32.108.4 Pathophysiology

BTV is capable of reproducing in a variety of mammalian cells. In clinical cases the disease appears to be a vasculitis caused by infection of vascular endothelial cells. Vasculitis results in edema and necrosis of epithelial and mucosal surfaces. In bulls the virus can cause inflammation and degeneration of the seminiferous tubules. 787
Teratogenic effects appear to be caused by general disruptions of organogenesis by viral infection of the 788
developing fetus. The development of clinical disease in cattle may require previous sensitization to the virus, operating through an IgE-mediated hypersensitivity reaction.[84] The disease in sheep also appears to be most severe when previous exposure has occurred.[90] Late-term in utero infections produce elevated fetal cortisol in calves, which could be the mechanism for the induction of premature delivery.[81]

32.108.5 Epidemiology

The development of clinical disease is the product of a complex interaction among host, strain, vector, and environmental characteristics. Bluetongue disease provides a model of host-vector-pathogen coevolution; the pathogenicity of endemic virus to endemic livestock breeds usually is low.[91] Epizootics occur when new virus, new animals, or new vectors are introduced into the stable prevailing system.

BTV infects both wild and domestic ruminants and camelids, primarily through the bite of the vector midge of the genus *Culicoides*. There are over 1400 *Culicoides* species; however, only a few have been identified as BTV-competent vectors. This midge is most prevalent in midsummer to early fall, and natural bluetongue in animals usually is limited to this time as well. The virus also can be transmitted sexually in infected semen and transplacentally from dam to offspring but apparently not through embryo transfer if the embryo is washed 10 times.[86,89] Vector transmission is by far the most important method of transmission in endemic areas. In the United States, bluetongue prevalence closely mirrors *Culicoides* prevalence, with lower rates in northern climates inhospitable to the midge and higher prevalence in California and southern regions. *Culicoides sonorensis* (formerly called *Culicoides variipennis)* is the principal vector of BTV in North America, but not all *C. sonorensis* populations are competent vectors of the virus.[92,93] In the absence of competent vector populations, animal-to-animal transmission is incapable of maintaining the endemic state. The overall seroprevalence in cattle in the United States exceeds 18%.[94]

The location of “overwintering” virus or the reservoir for infection in endemic areas is unclear. After infection the BTV virus can be isolated for over 9 weeks from ovine skin biopsies.[95] Cattle have been suspected because of the high seroprevalence in cattle and the longer course of viremia possible in some cattle compared with sheep, but a recent paper demonstrated that BTV survived for only 1 to 5 weeks after infection in cattle skin biopsy samples.[96] In the Iberian epidemic of bluetongue in 1956 that killed 179,000 sheep in 4 months and caused clinical disease in cattle, the disease failed to become established despite the presence of vectors, suggesting that cattle were not an effective reservoir in this instance. White-tailed deer showed a high BTV seroprevalence (81%) in a survey in northeastern Mexico.[97] The virus reproduces in *C. sonorensis*, and the vector may be the overwintering site in some situations. Another intriguing possibility that needs more

investigation involves the prolonged presence of viral RNA in blood as detected by PCR; the vector may be able to recover BTV infectivity from PCR-positive but virus isolation—negative blood.[98]

The severity of clinical signs varies by breed. Early in the history of the bluetongue investigation, it was noted that African Landrace breeds showed few if any signs of infection, whereas imported European breeds showed fulminant disease.[99] More recently, breed differences in immunologic response to a bluetongue vaccine have been reported.[100]

32.108.6 Necropsy Findings

No one gross or histologic lesion points with certainty toward bluetongue. Some animals that die appear surprisingly normal at necropsy. Most show unusual hemorrhage in some organ, particularly the heart. Some experts consider subendocardial hemorrhage at the base of the pulmonary artery to be pathognomonic. Petechial and ecchymotic hemorrhages are also seen under the tongue, on the hard palate, and in the esophagus, forestomachs (especially on the ruminal folds), lymph nodes, bladder, and spleen. Gross hemorrhage may be seen in skeletal muscles (often alternating with linear areas of pallor, indicating Zenker's necrosis) and in the pulmonary artery. Erosions and ulcers are seen on any surface of the oral mucosa, prominently on the dental pad and tongue, and less often in other digestive organs. Gelatinous subcutaneous edema of the head, neck, forelimbs, and trunk is commonly encountered. Pulmonary congestion and edema probably are caused by vasculitis and occur secondary to heart failure.[101] Microscopically, lesions show evidence of inflammatory cell infiltration, cellular vacuolation, blood stasis, hypertrophy of small vessel endothelial cells, and fragmentation of small vessels. Cattle, but not sheep, show eosinophilic infiltrates histologically, suggesting the role of hypersensitivity in the rare clinical cases in cattle.

32.108.7 Treatment, Prevention, and Control

Treatment is nonspecific and aimed at supportive and nursing care. Animals with severe oral lesions are reluctant to eat. Valuable animals can be fed gruels of alfalfa pellets by stomach tube and can be encouraged to eat soft feeds or green grass. Muscle and coronary band pain may limit mobility; therefore water and shade must be close at hand. Sulfas or other relatively broad-spectrum antimicrobial drugs should be administered in an attempt to prevent or treat secondary bacterial pneumonia. NSAIDs, including aspirin and flunixin, are commonly used.

Elimination of *C. sonorensis* from the environment usually is not practical, but housing sheep indoors during the peak of activity (dusk, early evening) to avoid the house-shy midge may be beneficial. Grazing wet areas such as irrigated pasture only during the heat of the day also may help. Midges that feed on ivermectin-treated cattle are killed, but the exchange of virus may be made before the insect's demise. *C. sonorensis* larvae develop in fine-grained mud with high organic matter content, such as around farm reservoirs, overflowing watering troughs, and shallow septic systems. Elimination of these breeding grounds combined with larvicidal treatments may help in some situations.

Modified live vaccines are available in some parts of the world and should be based on the local strains and serotypes. Some cross-protection between some serotypes does occur. A modified live virus containing serotypes 10, 11, and 17 is available in California from the California Woolgrowers' Association. The vaccine should be given at least 2 weeks before breeding season to avoid teratogenic effects. In the face of an outbreak, lambs and breeding rams should be vaccinated; pregnant ewes in late gestation may be vaccinated, but there is some risk of inducing abortion. Vaccinated breeding rams may have a slight risk of decreased fertility. Pregnant animals cannot be vaccinated with modified live vaccines with impunity, because the teratogenic effects may manifest.

Genetic engineering techniques may produce effective killed vaccines, perhaps as subunits, but both cellular and humoral immunity appear necessary for complete protection. The capability of the virus to reassort the genome in mixed infections makes some aspects of modified live vaccines problematic. For example, a host-adapted, low-virulence vaccine strain could gain virulence from wild-type virus and be serologically indistinguishable in its pathogenic form from the mild vaccine virus.

32.109 CONTAGIOUS ECTHYMA (SORE MOUTH, ORF, CONTAGIOUS PUSTULAR DERMATITIS, SCABBY MOUTH)

Paul G.E. Michelsen

Bradford P. Smith

32.109.1 Definition and Etiology

CE (sore mouth, orf, contagious pustular dermatitis, scabby mouth) is a common disease of sheep and goats that is transmissible to humans and has a worldwide distribution. A good review of human lesions was published in 2005.[103] The colloquial name *sore mouth* describes the most common presentation of the disease in sheep and goats; the name orf (possibly from the old Norse term *hrufa*, meaning a crust or scab) is more commonly used for the disease in all species in England and for human disease in the United States. The agent is a DNA poxvirus of the parapoxvirus subgroup, which includes the closely related viruses pseudocowpox (the cause of orflike “milker's nodules” in humans), the agent of BPS, parapoxvirus of red deer in New Zealand, squirrel parapoxvirus, and parapoxvirus of grey seals. Biologic and genetic differences exist among strains of CE virus, but these differences are not expressed antigenically; only one serotype of orf (CE) is recognized. A study demonstrated that the sheep orf virus does not cause lesions in camels, and vice versa,[104] so it is likely that no infection is transmitted between camels and sheep or goats. Wild ruminants (reindeer, musk ox, and others) and camels are also affected.[105] The virus is epitheliotropic, usually creating proliferative lesions in the skin of the lips, nostrils, oral mucosa, teats, and occasionally the vulva.

32.109.2 Clinical Signs and Differential Diagnosis

The most common presentation is of a young animal with crusting, proliferative lesions of the mucocutaneous junctions of the mouth and nose (Fig. 32-65). Proliferative lesions may be seen on the gums (Fig. 32-66). Older immunologically naive animals may be affected, and lesions may occur at the coronary band, on the tongue, interdigitally, on the conjunctiva of the eye, on the external genitalia, or on the udder or teats, with the last site affected especially in does or ewes nursing affected kids. The disease progresses through papular, vesicular, and pustular stages, which are rarely seen, before the characteristic presentation of proliferative, coalescing, scabbed lesions appears. One recent report described the characteristic proliferative scabs on the margins of healing burn wounds.[106] Affected animals may be reluctant to nurse, eat, walk, or be nursed, depending on the location of lesions. Secondary bacterial infection or myiasis of affected parts may occur. The disease usually runs its course in 3 to 6 weeks, but chronic cases have been reported.[107] Complete healing without scarring is the norm as scabs fall off. Severe infections may result in stunting of growth. Overwhelming infection has been noted on rare occasions, with extension of lesions into the deeper respiratory or gastrointestinal tracts. Does and ewes with severe udder infection may develop mastitis from secondary bacterial infection. Sheeppox and goatpox may occasionally produce lesions similar to those of CE, but they are virulent diseases with systemic signs, including conjunctivitis, pyrexia, anorexia, and rhinitis. Animals with bluetongue may have a crusted mouth and nose and

eye lesions in the convalescent phase, but bluetongue is a disease with more evidence of oral erosive rather than proliferative lesions and systemic signs, including pyrexia, reluctance to move, lesions on the tongue, and conjunctivitis. Bluetongue has a seasonal incidence (late summer, early fall) that coincides with the activity of its insect vector. CE may be seen at any time but typically occurs in spring in the lamb or kid crop. Ulcerative dermatosis (lip and leg ulcer) is an uncommon disease caused by a virus similar to that of CE, but the lesions are crusted ulcers, to be distinguished from the crusted proliferations of CE. I have seen a series of cases of what appeared to be mild CE of long duration (several years in one individual) in a family of Nubian goats; this was confirmed by an immunofluorescence assay. Smith and co-workers reported on five sheep, 4 months to 3 years of age, that developed severe refractory distal limb lesions resembling warts. Two also had lesions on the head. The sheep were from three different flocks; one was a Hampshire and four were Suffolk. Lesions were confirmed as orf by electron microscopy and immunohistochemistry.[108] A report from Texas describes severe multifocal persistent orf lesions in 16 Boer or Boer cross-bred goat kids 2 to 5 months of age, from two different farms. Some of the kids had been vaccinated with live-virus vaccine at 1 day of age, others at 2 weeks of age. Lesions were found on lips, nose, ears, body, legs, and feet.[109]

Fig. 32-65 Typical scabby lesions of contagious ecthyma (sore mouth, orf) on the lips of a young goat. Lesions tend to be proliferative rather than ulcerative.

Fig. 32-66 Typical proliferative lesions of contagious ecthyma (sore mouth, orf) on the gums of a young sheep.

32.109.3 Laboratory Diagnosis

The diagnosis usually is made in the field by recognition of the typical lesions in a naive flock or in a naive group (young lambs or kids) in a disease-endemic flock. Definitive diagnosis usually involves identifying the distinctive cross-hatched virus particles in early lesions with electron microscopy, PCR,[110] immunohistochemistry, or inoculation into known protected or susceptible animals. Vesicular fluid or minced biopsy tissues have been used as a source of virus that is identified by fluorescent antibodies after it has been growing in embryonic ovine kidney cell cultures.[111] CF tests to detect antibodies (using patient serum) or antigen (using vesicular fluid or a suspension of scabs) have also been used.

32.109.4 Pathophysiology

The disease follows a similar time course in animals and human beings-approximately 6 weeks. Six stages have been described,[112] which begin after an incubation period of 3 to 14 days. Each stage lasts approximately 1 week.

1 *Maculopapular stage:* An erythematous spot becomes elevated. Histologically this stage shows vacuolization of cells in the upper one third of the epidermis with intracytoplasmic eosinophilic inclusions in the affected cells.

2 *Target stage:* A red halo of dilated blood vessels and inflammatory cell infiltrates surrounds a white ring of vacuolated epidermal cells with intracytoplasmic and intranuclear inclusions, which surrounds a red center of pyknotic epidermal cells.

3 *Acute stage:* The lesion is a red, weeping nodule. Microscopically there is reticular degeneration of the epidermis with vesicles. The dermis is infiltrated with macrophages and lymphocytes and is denuded of epidermis in places. The hair follicles are distended with pyknotic epidermal cells.

4 *Regenerative stage:* The nodule is now dry with small black dots (the pyknotic follicle cells, now extruded to the surface) in a thin yellow surface.

5 *Papillomatous stage:* The surface of the nodule is roughened with papillomas, which microscopically prove to be fingerlike, downward projections of epidermis through a full thickness of dermis.

6 *Regressive stage:* The lesion decreases in size and elevation above the surface, the papillomas regress, and several crusts may come off. Microscopically the papillomas and infiltrates regress, leaving normal architecture.

Orf virus encodes for a protein that is apparently homologous to mammalian vascular endothelial growth factors. This family of molecules mediates vascular permeability, angiogenesis, and endothelial cell proliferation, which may account for the swollen, proliferative nature of orf lesions.[113] Transient fever and lymphadenopathy are occasionally seen in humans. Lesions in humans that are not biopsied or excised heal without a scar.

Orf virus encodes a range of immunomodulatory genes that interfere with host antivirus immune and inflammatory effector mechanisms, allowing time for virus replication in epidermal cells.[114]

32.109.5 Epidemiology

The naturally occurring disease is primarily one of sheep, goats, and human beings, but it has also been reported in a variety of wild ruminants.[115] Experimental transmission has been achieved in cattle, rabbits, horses, and monkeys. No clinical cases in these species have been reported. All ages and classes of sheep and goats are affected, and clinically normal sheep can infect naive individuals.[116] In herds and flocks in which the disease is endemic, it usually is seen in the lamb crop and on the udders and teats of some of the nursing mothers. Animals that have had a bout of disease are solidly immune for 1 to several years, but morbidity is high (often 80%) among naive individuals. Humans are infected through contact with affected animals or fomites that have contacted affected animals (including one report of transmission by a pickup truck that had been used to haul sheep).[112] Human-to-human transmission can occur.[115] Mortality is low among animals except when young individuals are severely affected and quit nursing or have mothers with severe udder lesions. Overwhelming infections are rare, but some outbreaks are more severe than others.

The virus is quite resistant to many environmental conditions and persists from year to year on infected premises. Dried scabs allow the virus to persist for years, but wet conditions are less hospitable to it.[117] Reports of persistently infected sheep[118] point to another possible source of infection in wet climates.[117]

32.109.6 Treatment, Prevention, and Control

The infection usually is self-limiting and of minor consequence. Young individuals may need to be tube-fed if the lesions are severe enough to preclude suckling. Secondary infections, myiasis, or mastitis may be treated with topical disinfectants, antibiotics, or insecticides as appropriate.[118] The hard crusts should not be removed, because doing so may delay healing and promote scarring. Also, humans should limit contact with affected animals and should wear gloves when handling them is necessary. Anecdotal reports, each consisting of one case, have claimed good results for treatment of human orf with intralesional corticosteroids,[119] IFN,[120] idoxuridine in DMSO,[121] or diethyl ether[122] or cryotherapy.[123] An immunosuppressed human with a huge orf lesion on the finger was successfully treated with topical cidofovir antiviral cream.[124] Similar good results were obtained in a group of 12 severely affected, bottle-fed lambs with painful intraoral lesions. The proliferative tissues were debrided and cauterized with a portable diathermy unit. The exposed submucosa was then frozen twice with liquid nitrogen spray. Healing occurred by second intention, with rapid recovery of affected lambs.[125]

The infection is prevented by maintaining a virus-free herd or flock by not introducing or contacting infected individuals. Lesions often are not apparent on carriers.[116] Once established, the disease is persistent on the premises because of virus in scabs. Vaccination should be undertaken only if the infection is persistent, because the vaccine consists of virulent live virus. Vaccination can also be achieved with dried scabs from the previous year's outbreak; the scab material is rubbed into scarified skin in an inconspicuous location (inner thigh, under the tail, in the axilla). A localized inflammatory reaction at the site 1 week after vaccination indicates a successful inoculation. Infected or vaccinated animals should not contact unexposed animals (as at shows) until the lesions have healed. Lambs born to immunized ewes may not be protected by colostral antibodies even though their levels of antibody postsuckling are high,[126] pointing to the importance of cell-mediated immunity in protection from the disease. Lambs should be vaccinated at 6 to 8 weeks of age and are immune 3 weeks later.[118] Yearly vaccination of the new lamb crop and new additions to the herd should prevent devastating outbreaks on infected farms. Vaccine failures may be related to virulence of the disease-causing strain rather than to serologic differences between vaccine and field strains.[127]

32.110 BOVINE PAPULAR STOMATITIS (PROLIFERATIVE STOMATITIS)

Bradford P. Smith

BPS is a disease principally of young cattle caused by a parapoxvirus closely related to CE and pseudocowpox. There are many similarities among BPS, CE, and pseudocowpox, and they may indicate a single virus adapted to different species.[128] There are as many antigenic differences among strains of BPS as among BPS, CE, and pseudocowpox.[128] Local strains therefore are recommended for vaccination. Infection usually is asymptomatic,[129] but lesions consisting of raised papules may be noted on the muzzle, nose, oral mucosa (particularly the hard palate), or esophagus, where they are important differential diagnoses for lesions caused by VS, FMD, and BVD.[129] In young feedlot cattle, 2- to 10-mm lesions of BPS are common for the first 4 weeks after arrival.[130] Morbidity may approach 100%.[129] BPS may also occur as a chronic disease in young cattle.[131] It may be the same disease as proliferative stomatitis, muzzle disease, mycotic stomatitis, erosive stomatitis, ulcerative stomatitis, and necrotic stomatitis.

Ulcerative esophagitis caused by BPS virus in a 5-month-old, unthrifty calf was associated with a 20% morbidity rate in a group of 25 calves.[132] Outbreaks of severe disease associated with BPS with a mortality rate over 50% have been reported.[132–134] Weight loss and diarrhea accompanied by papular lesions are commonly associated with the severe syndrome. Many lesions are erosions or shallow ulcers with elevated borders,[134] whereas others are obvious raised papules. Lesions are found in the mouth, esophagus, and rumen.[134] There are no lesions on the feet. BPS is commonly seen in calves 1 to 12 months of age and is rare in adult cattle. The disease is spread by animal contact and appears to be worldwide in distribution.[134]

The first evidence of the disease is the appearance of 2- to 4-mm hyperemic foci, most commonly in the ventral margins of the nares. Similar lesions next appear in the mouth. Within 18 hours they become raised papules. Some lesions enlarge to form raised plaques over 1 cm in diameter. Lesions regress in 1 day to 3 weeks, leaving a yellow, red, or brown spot that persists for several weeks more.[129] Secondary lesions come and go, with some calves being visibly infected for 4 months.[129] Most animals have no fever or obvious clinical signs, and they continue to eat normally. Leukopenia was not seen in experimentally infected calves.[129] Secondary lesions appear to be spread through the blood; intravenous inoculation results in similar upper alimentary tract lesions.[135]

Histologic lesions consist of hydropic degeneration of the epithelial cells of the oral mucosa, hyperplasia of the papillae of the lamina propria, and eosinophilic inclusions in the cytoplasm of the degenerating epithelial cells.[134] Lesions reaching the ulcerative stage show secondary necrosis, bacterial invasion, and sloughing of epithelium.

BPS has been associated with the “rat tail” syndrome of feedlot cattle.[136] Thirty-six of 84 Texas feedlots reported the problem, with a morbidity rate of 1% to 10%. The syndrome consists of diarrhea, salivation, poor weight gain, and loss of hair from the end of the tail.[136] Sarcocystosis has also been mentioned in association with “rat tail” syndrome. BPS is capable of causing painful proliferative lesions in human beings.[137] The lesions resemble those caused by CE or pseudocowpox. Most often the affected individual has a recent history of examining the mouths of cattle, often with cuts or abrasions on the hands. Lesions in humans apparently are limited to the primary site of inoculation on the hands.

Although ovine ecthyma vaccines are commercially available, no vaccine is marketed for protection against BPS. Local strains of parapoxviruses would be most likely to be more protective than commercial vaccine strains.

32.111 DISEASES CAUSED BY BOVINE VIRUS DIARRHEA VIRUS

Daniel L. Grooms

John C. Baker

Trevor R. Ames

32.111.1 Definition and Etiology

Disease in cattle resulting from infection with BVD virus (BVDV) is responsible for economic losses throughout the world. These economic losses are realized through decreased performance, loss of milk production, reproductive wastage, and increased rates of morbidity and mortality. More than 50 years ago an enteric disease of cattle was described in North America that was characterized by outbreaks of diarrhea and erosive lesions of

the digestive tract.[138,139] The virus was named *bovine virus diarrhea virus*. Subsequently the virus was associated with a sporadically occurring, highly fatal disease referred to as *mucosal disease*. Mucosal disease occurs only in cattle that are born persistently infected (PI) with BVDV. Persistent infection occurs as a result of in utero exposure of the fetus to BVDV at less than 125 days of gestation.[140]

BVDV is a member of the family Flaviviridae,[141] which consists of three genera: Pestivirus, Flavivirus, and Hepacivirus. BVDV is the prototypic member of the genus Pestivirus, which includes two other viruses of veterinary importance: classical swine fever virus (hog cholera virus) and border disease virus of sheep. Isolates of BVDV can be classified in vitro as cytopathic (CP) or noncytopathic (NCP); this classification is referred to as the *biotype*.[142] The NCP biotype predominates in the cattle population and is associated with persistent infection. It has been established that mucosal disease occurs when cattle born immunotolerant to and persistently infected with an NCP-BVDV become superinfected with a CP-BVDV. There also is genetic and antigenic variation among isolates of BVDV.[143] BVDV has been divided into two groups based on genotype: BVDV type 1 and BVDV type 2.[144] BVDV type 2 infections have been associated with a severe acute disease and a hemorrhagic syndrome characterized by thrombocytopenia and death.[145] BVDV genotypes can be further divided into subgenotypes (e.g., BVDV type 1a). The significant genetic and antigenic variations among BVDV isolates may be factors in achieving complete control of BVDV infections through vaccination.

The virus is unstable at low or high pH and at high temperatures. On the basis of research with the related classical swine fever virus, BVDV probably does not persist in the environment longer than 2 weeks.[146] This same work with the classical swine fever virus also suggests that BVDV is susceptible to common disinfectants such as chlorhexidine, phenols, iodophors, aldehydes, and hypochlorites.[146]

32.111.2 Epidemiology

32.111.2.1 PREVALENCE

Evidence of BVDV has been documented in many countries throughout the world. Serologic surveys have demonstrated considerable differences in the prevalence of antibody-positive cattle, ranging from 20% to 90%.[147–152] Cattle density, management practices, and vaccine use are likely to account for these differences. Several studies have shown the prevalence of persistently infected cattle to be less than 2% of the general cattle population.[153–155] In individual herds the prevalence of persistently infected cattle may be substantially higher. No significant differences have been noted between dairy and beef breeds. The prevalence of U.S. herds containing at least one persistently infected animal has been estimated to be 4% to 15%.[154,155] Economic losses attributable to BVDV are difficult to assess. Losses in individual herds have been documented and range from a few thousand to $100,000 per herd.[156,157] National-level losses are estimated to range from $10 to $40 (U.S. dollars) per calving.[157–159]

791

792

32.111.2.2 TRANSMISSION

Cattle persistently infected with BVDV shed large amounts of virus their entire life and are the major source of BVDV transmission both within and among herds. Acutely infected cattle are also an important source of BVDV transmission, but the level of virus shed is considerably lower and the length of shedding is limited. Inhalation or ingestion of virus is the most common mode of infection. The most efficient mode of

transmission is direct contact with body fluids from persistently infected cattle.[148] Virus has been isolated from nasal swabs, aerosols, saliva, urine, feces, and uterine fluids.[160] Indirect transmission can occur through blood-feeding insects[161] or contaminated mechanical vectors such as common needles, nose tongs, and animal caretakers.[162] Horizontal transmission has also occurred with frozen semen collected from BVDV-infected bulls and inseminated into susceptible cows.[163] Vertical transmission results with transplacental infection of the fetus in cows acutely or persistently infected with BVDV. The role of other species of animals in the transmission of BVDV is unclear. Transmission of BVDV between cattle and sheep has been demonstrated.[164] In addition, BVDV has been isolated from many captive and free-living ruminants as well as pigs.[165] Recently, camelid species have been identified as being susceptible to BVDV and have emerged as a potential source of transmission to cattle.[166]

The rate of transmission of BVDV within a herd varies depending on the source of the virus. Introduction of a persistently infected animal into a herd can result in rapid dissemination of the virus among the majority of susceptible cattle in less than 6 months.[148] Conversely, if acutely infected cattle are the source of the virus, the spread of BVDV may require an extended period.[148]

Spread of BVDV between farms most commonly occurs by the acquisition of new cattle that are persistently infected or pregnant and carrying a persistently infected fetus. Cattle operations that have purchased cattle within the past 5 years are at highest risk for having persistently infected animals.[167] The purchase of new cattle incubating an acute infection is also an important source of virus introduction into a herd. Exposure to other cattle through fence line contact, communal pastures, and animal exhibitions may all be important modes of herd-to-herd transmission.

32.111.3 Clinical Disease, Differential Diagnosis, and Patho-genesis

Infection with BVDV can result in a wide assortment of clinical manifestations ranging from subclinical conditions to death. The clinical outcome after infection is complex and depends on a number of factors. Host factors that influence the clinical outcome include whether the host is immunotolerant or immunocompetent to BVDV, pregnancy status, gestational age of the fetus at the time of infection, immune status (passive or active from exposure or vaccination), and concurrent level of environmental stress at the time of infection. In addition, genetic diversity, antigenic variation, and differences in virulence among BVDV isolates may account for variations in the clinical response to infection.

32.111.4 Subclinical Bovine Virus Diarrhea Virus Infection

Most animals infected with BVDV have subclinical infections that result in mild fever, leukopenia, and the development of serum neutralizing (SN) antibodies. These infections often go undetected. Subclinical infections explain the positive serum neutralization titers to BVDV found in most unvaccinated cattle. It has been estimated that 70% to 90% of BVDV infections occur without manifestation of clinical signs.[168]

32.111.5 Acute Bovine Virus Diarrhea Virus Infection

Acute BVDV infection often is defined as clinical disease that occurs in immunocompetent cattle that are not persistently infected. Acute BVDV infection has also been referred to as “primary BVDV” or “transient BVDV” infection. This disease syndrome usually occurs in cattle 6 to 24 months of age and traditionally has been

thought of as primarily causing disease in cattle that are seronegative (i.e., passive immunity has waned but active immunity has not yet been acquired). The acute BVDV incubation period is 5 to 7 days, with clinical signs of fever, leukopenia, depression, anorexia, oculonasal discharge, oral erosions and ulcerations, diarrhea, and decreased milk production in lactating cows after infection. A rapid respiratory rate may be observed, which may be interpreted incorrectly as pneumonia. Viremia typically lasts 2 to 5 days and starts around day 3 postinfection but may last for up to 15 days. Viral shedding is in low amounts when compared with the amount of virus shed by cattle persistently infected with BVDV. This form of the disease, as it was initially described, has been traditionally referred to as *bovine virus diarrhea*.

Neonatal infection with BVDV may result in enteritis or pneumonia, occurring most often when failure of passive transfer has occurred. Passively derived humoral immunity in calves is thought to be protective unless sufficient antigenic diversity exists between the challenge strain and the strain against which the colostral immunity was developed. Viral infection in young calves without suitable or sufficient passive immunity may result in secondary disease because of the disease's immunosuppressive effects.

The differential diagnosis for acute BVDV infection for the neonatal period includes other causes of diarrhea in young calves such as rotavirus or coronavirus infection, cryptosporidiosis, *E. coli* infection, salmonellosis, and coccidiosis. Other causes of calf pneumonia such as bovine respiratory syncytial virus, pasteurellosis, hemophilosis, or mycoplasma infection should also be considered. Diarrheal diseases considered as differential diagnoses for acute BVDV infection in adults include salmonellosis, winter dysentery, Johne's disease, intestinal parasites, MCF, arsenic poisoning, and copper deficiency. Differential diagnoses for diseases that cause oral lesions in cattle include MCF, VS, papular stomatitis, foot-and-mouth disease, and bluetongue.

Acute BVDV causes disease in infected cattle by damaging the epithelial tissue of the gastrointestinal, integumentary, and respiratory systems.[169] Viral antigen has been demonstrated in the epithelium of the tongue, esophagus, intestinal crypts and villi, bronchi, and basal layer of the skin of cattle clinically affected with acute BVD or mucosal disease.[169] In infected animals the viral antigens may also be detected in the phagocytic cells of the thymus, lymph nodes, Peyer's patches, tonsils, and spleen. In vitro studies support the theory that phagocytic cells become infected.[170] These phagocytic cells probably represent the antigen-trapping cells of lymphoid structures such as the thymus, lymph nodes, Peyer's patches, tonsils, and spleen. As demonstrated by the presence of viral antigen, the first tissues to be infected are in the respiratory tract and tonsils.[169] From there, BVDV is disseminated to the epithelial surfaces and lymphoid tissue. Mononuclear phagocytic cells in the lymphoid tissue retain the virus.

792

793

32.111.6 Severe Acute Bovine Virus Diarrhea Virus Infection

Before 1993 it was believed that most BVDV infections in immunocompetent adult cattle resulted in subclinical or mild disease as described earlier. Beginning in 1993, however, an atypical form of BVDV infection was recognized in Canada and the United States.[145,171] The disease had a peracute course, caused high morbidity, and resulted in a substantial number of deaths in all age groups. This new form of BVDV infection killed approximately 25% of veal calves in Quebec.[145] Clinical disease in the Ontario outbreaks was characterized by fever, pneumonia, and sudden death in all age groups of cattle.[171] Abortions in cattle also were a common occurrence. The severity of the disease varied among herds, with some herds experiencing 10% to 20% mortality rates. The gross lesions were similar in appearance to those of mucosal disease, which is the primary differential diagnosis (see the section on Acute Mucosal Disease later in this chapter).

Viral isolates obtained from these severe acute outbreaks were obviously of enhanced virulence. Nucleotide sequencing of the 5′ untranslated end of the RNA of these isolates followed by comparison with classic BVDV isolates revealed a distinct group, designated BVDV type 2.[144,145] Classical BVDV isolates are now referred to as BVDV type 1.

A further observation from the Ontario outbreaks was that cattle properly vaccinated with BVDV type 1 vaccines appeared to be protected from clinical disease.[171] It should be emphasized that outbreaks of severe acute BVDV infection should not always be assumed to be caused by BVDV type 2. Not all BVDV type 2 isolates cause severe disease, and it is likely that some type 1 isolates are capable of causing severe disease.

32.111.7 Hemorrhagic Syndrome

Acute BVDV infections in cattle can cause a hemorrhagic syndrome.[172] These infections are characterized by marked thrombocytopenia, bloody diarrhea, epistaxis, hemorrhages on mucosal surfaces, hyphema, bleeding from injection sites, pyrexia, leukopenia, and death.[172] Hemorrhagic syndrome appears to be associated with noncytopathic isolates of BVDV,[172] and thus far only BVDV type 2 has been associated with the syndrome.[144,145] Thrombocytopenic BVDV infections have been experimentally reproduced in calves.[173] Diseases that can mimic hemorrhagic syndrome include septicemia with subsequent development of disseminated intravascular coagulation, sweet clover poisoning, and bracken fern poisoning.

Virus-induced thrombocytopenia is the major pathogenic mechanism responsible for the BVDV-induced hemorrhagic syndrome. The mechanism by which BVDV infection induces thrombocytopenia has not been clarified. BVDV does appear to be associated with platelets; a recent study demonstrated that in addition to thrombocytopenia, platelet function is altered.[173] Also, BVDV antigen has been demonstrated in megakaryocytes that are undergoing necrosis.[173]

32.111.8 Acute Bovine Virus Diarrhea Virus Infections and Bovine Respiratory Disease

Bovine respiratory disease (BRD) is the most common cause of morbidity and mortality in North American feedlots.[174,175] (For a more complete description of BRD, see Chapter 31, Ruminant Respiratory Disease.) BVDV has been implicated in BRD complex since its first descriptions. Although this theory has been the subject of controversy, both circumstantial and experimental evidence suggests a role for BVDV in ruminant respiratory disease.[176,177] In the United States BVDV has been reported as the virus most often isolated in outbreaks of BRD. Experimentally it has been difficult to reproduce respiratory disease with BVDV alone, but synergistic effects have been documented between BVDV and *Mannheimia haemolytica*,[178] bovine herpesvirus type 1,[179] and bovine respiratory syncytial virus.[180] Recent evidence also supports a role of BVDV in the development of *Mycoplasma* species pneumonia and arthritis in feedlot cattle.[181,182] Differences in pneumopathogenicity have been reported for isolates of BVDV.[183] The results of epidemiologic studies attempting to define the role of BVDV in BRD have been equivocal. Studies have both implicated and shown no evidence of BVDV involvement in outbreaks of respiratory disease.[177] Taken together, the majority of evidence supports the theory that BVDV plays a role in BRD, and the contribution of BVDV to respiratory disease is likely from the immunosuppressive effects of BVDV infection (see next section).

32.111.9 Acute Bovine Virus Diarrhea Virus Infections and Immunosuppression

It has been well established that acute BVDV infection can result in immunosuppression.[184] The importance of BVDV-induced immunosuppression is that it increases the host's susceptibility to other pathogens and may enhance the pathogenicity of co-infecting organisms. Stress on the host at the time of BVDV infection undoubtedly adds to the viral-induced immunosuppression. As previously described, synergistic effects of BVDV infection have been demonstrated with *M. haemolytica*, bovine herpesvirus type 1, and bovine respiratory syncytial virus. BVDV infections have also been associated with concurrent salmonellosis, *E. coli* infection, BPS, and rotavirus and coronavirus infections.[176] The ability of BVDV to cause immunosuppression contributes to the broad range of clinical disease associated with this virus.

The pathogenesis of BVDV-induced immunosuppression involves several aspects of the immune system, and more mechanisms continue to be uncovered. BVDV is known to target lymphocytes and macrophages.[185] Acute BVDV infection may result in transient leukopenia with lymphoid depletion.[186] Also, a decrease in CD 4^+ and CD 8^+ T lymphocytes, as well as B lymphocytes and neutrophils, can occur.[187] In vitro studies have demonstrated different causes of immunosuppression, including decreased responsiveness of infected lymphocytes to mitogen stimulation[188]; decreased production of IFN,[189] IL-1,[190] IL-2,[191] and TNF-α[192]; and diminished chemotactic response by monocytes.[170] In addition, neutrophil-mediated, antibody-dependent, cell-mediated cytotoxicity can be impaired by BVDV.[193] Neutrophils from BVDV-infected cattle have reduced bactericidal activity.[194] It should be noted that the degree of immunosuppression and the mechanisms by which immunosuppression is induced are strain dependent.[195]

32.111.10 Reproductive Consequences of Acute Bovine Virus Diarrhea Virus Infection

Reproductive losses may be the most economically important consequence of BVDV infection. Reproductive losses associated with BVDV infection were documented in the first clinical description of BVDV.[139] Since that time it has become evident that BVDV can cause a wide array of reproductive losses that are largely dependent on the stage of gestation at which infection occurs and the virus strain (Fig. 32-67).

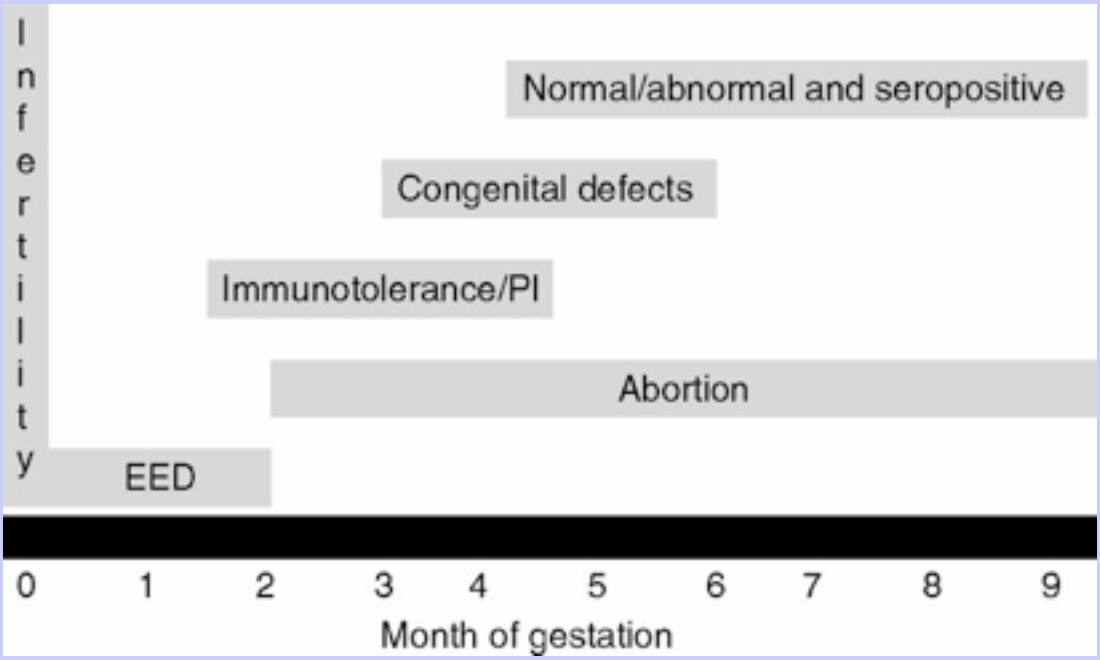
32.111.10.1 VENEREAL INFECTIONS

793

Semen from bulls with acute infection or that are persistently infected with BVDV contains virus and may serve as a source of infection.[163] In acutely infected bulls, shedding of virus in the semen may extend beyond the period of viremia because of local replication in the genital tract. Although it occurs rarely, bulls that are immunocompetent to BVDV and that lack evidence of systemic virus persistence have been found to be persistently shedding virus in semen.[196] It is hypothesized that acute BVDV infection around the time of puberty may become localized in the testes and protected from the systemic immune response by the blood-testes barrier.

794

Fig. 32-67 Potential reproductive outcome after infection with BVDV during different stages of gestation.



32.111.10.2

INFERTILITY AND EARLY EMBRYONIC DEATHS

Field and epidemiologic studies provide evidence that BVDV can have a significant impact on early reproductive performance.[197,198] The mechanism for decreased conception rates is not clear but may depend on the time of infection with respect to the stage of early reproductive events. Virus and pathologic changes have been localized in ovarian tissue for prolonged periods of time after acute infection with cytopathic BVDV and noncytopathic virus.[199,200] Acute infection with BVDV has also been shown to affect ovarian function.[201–204] During the early embryonic stages, BVDV has been shown to have detrimental effects, especially after the embryo has hatched from the zona pellucida.[205]

32.111.10.3

ABORTIONS

Transplacental infection by BVDV virus is a common event and occurs with high efficiency. BVDV has been shown to be detrimental to early embryonic development and a cause of embryonic death.[206] Transplacental infection of the fetus at 50 to 100 days of gestation may result in fetal death.[207] Expulsion of the fetus may occur days to months after infection. In general, late-term fetal infections do not result in abortion, but late-term abortions in association with BVDV have been reported. It should be remembered that BVDV infection can cause abortion during any stage of gestation. Although the incidence of abortion is generally low in immune herds, it can increase dramatically in nonimmune herds.

32.111.10.4

CONGENITAL DEFECTS

Infection of the fetus at 100 to 150 days' gestation may result in a number of congenital anomalies. This period of fetal development corresponds to the final stages of organogenesis of the nervous system and the development of the fetal immune system, which can result in the generation of an inflammatory response to BVDV infection. At this stage of gestation, BVDV infection may inhibit cell growth or cell differentiation or cause direct cellular lyses. The more common congenital defects induced by BVDV infection include hydrocephalus, cerebella hypoplasia, hypomyelinogenesis, microphthalmia, cataracts, retinal atrophy or dysplasia, hypotrichosis, brachygnathia and other skeletal abnormalities, growth restriction, and pulmonary hypoplasia.

32.111.10.5

BOVINE VIRUS DIARRHEA VIRUS INFECTION DURING THE LATER STAGES OF GESTATION

In the later stages of gestation, immunocompetence and organogenesis are usually complete. Although abortions and the birth of weak calves have been attributed to infection with BVDV late in gestation, fetuses infected during this time period are normally able to mount an effective immune response to BVDV and effectively clear the virus. These calves are usually normal at birth and have precolostral neutralizing antibodies to BVDV.[208] Congenital infection may contribute to neonatal calf loss during a herd outbreak of BVDV, with weak undersized calves being born. In addition, calves congenitally infected with BVDV may be at greater risk for experiencing a serious postnatal health event.[209,210]

32.111.10.6

PERSISTENT INFECTION

Infection of the fetus with NCP-BVDV isolates before the development of fetal immunocompetence may result in the birth of calves that are immunotolerant to and persistently infected with BVDV. The development of immunotolerance to BVDV is rare after 100 days' gestation but has been reported to occur as late as 125 days' gestation.[140] Cattle persistently infected with BVDV are viremic, continuously shed virus, and may appear healthy. Persistently infected cattle are immunocompetent with respect to other antigens. The immunotolerance is specific to the infecting NCP-BVDV; therefore persistently infected cattle can respond immunologically to heterologous isolates of BVDV.[211] For this reason, persistently infected cattle can be seropositive for BVDV. Persistently infected females produce persistently infected offspring,[212] which may result in the production of persistently infected family lines. It appears likely that persistently infected cattle are the main mechanism by which BVDV is maintained in the cattle population.

Persistently infected cattle are at risk for developing mucosal disease and appear to be at risk for other diseases and have decreased survivorship.[213] Persistently infected calves have death rates of 50% in the first 12 months of life,[146] and it is believed that fewer than 10% of persistently infected dairy replacement heifers reach the lactating herd. Persistently infected calves may be born undersized and have slower growth rates. Some persistently infected calves appear to be predisposed to infections; this often results in pneumonia and enteritis,[214] which tend to become chronic and unresponsive to treatment. An alteration in immune response, such as suppression of neutrophil and lymphocyte function, also has been reported in persistently infected cattle.[215] Subclinical disease that eventually becomes clinical or immunosuppression that allows secondary

bacterial infections may explain unthriftiness and mortality in persistently infected cattle. Postmortem findings such as glomerulitis and encephalitis have been reported in persistently infected animals.[216]

32.111.11 Disease Occurring in Persistently Infected Cattle

32.111.11.1 MUCOSAL DISEASE

Mucosal disease occurs when cattle that are immunotolerant to and persistently infected with an NCP biotype of BVDV become infected with a CP biotype of BVDV that shares close antigenic homology with the persistently infecting noncytopathic virus.[217] Thus not every combination of NCP and CP virus results in mucosal disease. The origin of the CP virus can be external, as demonstrated by the documented occurrence of mucosal disease after the use of modified live BVDV vaccines and in experimental studies in which mucosal disease was produced by superinfection with CP-BVDV. It is more commonly believed that the CP-BVDV arises de novo from the NCP, persistently infecting BVDV by molecular rearrangement.

794

795

Mucosal disease takes different clinical forms. The differences in the relatedness of NCP-BVDV and CP-BVDV may be responsible for the variations in clinical response. One extreme is acute mucosal disease, in which the CP virus shares close homology with the persistently infecting NCP virus. The other extreme is no clinical disease but seroconversion, in which the CP virus is heterologous to the NCP virus. Between these extremes lie other clinical forms of mucosal disease (chronic mucosal disease and possibly mucosal disease with recovery), which are determined by the antigenic relationship of the NCP and CP viruses. A delayed onset form of mucosal disease recently was described.[218] As the name implies, delayed onset mucosal disease occurs after the expected time frame for acute mucosal disease after exposure of a persistently infected animal to an exogenous CP virus. Although the CP virus is heterologous to the persistently infecting NCP virus, a genetic recombination of the two viruses results in a CP virus that is antigenically identical to the resident NCP, and mucosal disease results.

32.111.11.2 ACUTE MUCOSAL DISEASE

The occurrence of acute mucosal disease is sporadic, with less than 5% of the herd being affected. Often the animals affected in a herd are grouped by age and represent calves that were all persistently infected with the same NCP-BVDV. In rare cases, up to 25% of the herd may be involved, but a high number of persistently infected animals would be necessary for this to occur. The case fatality rate for acute mucosal disease approaches 100%.

Acute mucosal disease is characterized by an incubation period of 10 to 14 days after exposure. Clinical signs of mucosal disease include a biphasic fever, anorexia, tachycardia, polypnea, decreased milk production, and profuse, watery diarrhea (occasionally with frank blood, fibrinous casts, and a foul odor). The oral papillae may be blunted, and the epithelium of the tongue, palate, buccal surfaces, and pharynx may have erosions. Erosive lesions also may be present in the interdigital regions and on the teats and vulva. All erosive lesions may be ulcerative to diphtheric, depending on their duration. Other clinical signs may include nasal and corneal discharge, corneal opacity, excessive salivation, decreased rumination, and bloat. Cattle may have inflammation of the coronary band and, in some cases, laminitis. Acutely infected animals often are neutropenic (without a left shift) and thrombocytopenic. Animals with mucosal disease commonly have secondary bacterial infections, resulting in pneumonia, mastitis, and metritis. Cattle with mucosal disease

become progressively dehydrated and debilitated and usually die within 3 to 10 days. Some animals survive the acute phase but experience the chronic form of the disease.

The differential diagnosis for bovine diseases with oral lesions and diarrhea includes severe acute BVDV infection, RP, bovine MCF, and mucosal disease. Diseases characterized by oral lesions but no diarrhea include FMD, VS, and BPS. Diseases involving diarrhea but no oral lesions include winter dysentery, salmonellosis, Johne's disease, parasitism, and copper deficiency.

32.111.11.3 CHRONIC MUCOSAL DISEASE

Some cattle that develop mucosal disease do not die in the expected time frame but rather become chronically affected. Cattle with chronic mucosal disease are unthrifty and may have persistently loose feces or intermittent diarrhea, chronic bloat, decreased appetite, weight loss, interdigital erosions, or nonhealing erosive skin lesions. Nasal discharge and persistent ocular discharge are common findings. Areas of alopecia and hyperkeratinization of the skin may develop, typically in the neck area. Chronic lameness may develop because of laminitis, interdigital necrosis, or hoof deformities. These animals may be persistently anemic, neutropenic, and thrombocytopenic. Cattle with chronic mucosal disease rarely survive beyond 18 months and ultimately die of severe debilitation. Chronic mucosal disease should be distinguished from calves born persistently infected with BVDV that are poor doers from birth.

32.111.11.4 MUCOSAL DISEASE WITH RECOVERY

A single report exists of several persistently infected calves that showed transient signs of mucosal disease and subsequently recovered.[219] These calves remained healthy until slaughtered. The observation is interesting, and mucosal disease with recovery is a possibility based on the current understanding of the pathogenesis of mucosal disease.

32.111.12 Necropsy Findings

The postmortem examination findings for animals that died from BVDV vary depending on the form of the disease.

32.111.12.1 MUCOSAL DISEASE

Animals that die of mucosal disease usually have severe, necrotizing erosive or ulcerative lesions involving the mouth, tongue, esophagus, ruminal pillars, omasum, abomasum, intestines, and cecum. Erosive lesions may extend onto the external nares and into the nasal cavity. Ulcers involving the esophagus typically are elongated. The Peyer's patches in the small intestine often are necrotic and hemorrhagic. Bowel contents are watery, hemorrhagic, and foul smelling. Pathologic gastrointestinal conditions may be absent or very mild in cattle with chronic mucosal disease, although histopathologic lesions usually are present. Skin lesions are often found and include patchy hyperkeratosis around the neck, shoulder, and perineal areas. Erosive lesions involving the perineal area, the prepuce, and the interdigital cleft and coronary band of the hoof may be present. Skin lesions are most apparent in cattle suffering from chronic mucosal disease.

32.111.12.2 ACUTE DISEASE

Animals that die of acute BVDV infection have less severe lesions, but some or all of those mentioned for mucosal disease may be present. Often, secondary bacterial infections such as pneumonia or mastitis are present and have contributed to the animal's death. Animals that die of hemorrhagic syndrome may have evidence of hemorrhage in many organ systems, including the gastrointestinal, cardiovascular, respiratory, and urinary systems. Petechial or ecchymotic hemorrhages are often apparent on mucosal surfaces, and significant hemorrhage in the gastrointestinal submucosa and Peyer's patches may also be present.

32.111.12.3 ABORTIONS AND CONGENITAL DEFECTS

Fetuses aborted as a result of in utero BVDV infection often are autolytic when expelled. Lesions found in aborted fetuses and the accompanying placentas are nonspecific for BVDV. Under experimental conditions or when aborted fetuses are expelled soon after death, lesions observed include conjunctivitis, peribronchiolar and interalveolar pneumonia, and nonspecific myocarditis. A significant decrease in cerebellar mass may be evident in calves affected by cerebella hypoplasia as a result of in utero infection with BVDV during the second trimester of gestation. Other common congenital defects associated with BVDV infection that may be noted at necropsy include cataracts and thymic hypoplasia.

32.111.13 Diagnosis

A diagnosis of BVDV infection can be made by serologic evaluation, virus isolation, viral antigen detection, and viral RNA detection using amplification methods such as the PCR technique.

795

796

32.111.13.1 VIRUS ISOLATION

Virus isolation is commonly used for identifying cattle infected with BVDV. Serum is most often used to isolate virus from cattle persistently infected with BVDV, whereas buffy coats or nasal swabs are most appropriate for attempting to detect acute infections. Antemortem differentiation of persistently infected cattle from those acutely infected with BVDV requires serial isolation of virus at least 2 weeks apart. At postmortem examination, BVDV is best isolated from lymphoid tissues such as Peyer's patches, lymph nodes, thymus, and spleen.

BVDV is isolated by inoculating appropriate samples onto bovine cells in culture. Isolates can be characterized as cytopathic or noncytopathic biotypes by the presence or absence of characteristic cytopathic effects in cell culture. Noncytopathic isolates are identified in cell culture using immunoenzymes or immunofluorescence. The immunoperoxidase monolayer assay (IPMA) is a common adaptation of virus isolation and immunoenzymatic antigen detection used for rapid BVDV screening.[220]

32.111.13.2 ANTIGEN DETECTION

Virus can be identified in tissue samples by using fluorescent antibodies or immunohistochemistry. Immunohistochemistry has been reported to be more accurate than virus isolation and immunofluorescent methods in diagnosing BVDV in cases of abortion and perinatal death.[221] BVDV can also be identified in blood and tissue samples by using an antigen-capture ELISA. Antigen-capture ELISAs are equal in sensitivity

to virus isolation for detection of persistently infected cattle but less sensitive for identification of acute infections with BVDV.[222] Skin and "ear notches" are common samples to use for both immunohistochemistry and antigen capture ELISAs for detecting cattle persistently infected with BVDV.

32.111.13.3 VIRAL RNA DETECTION

Nucleic acid detection assays involve the direct identification of BVDV viral genomic RNA or a synthesized copy of the RNA called *cDNA*. The PCR test is the most commonly used nucleic acid detection assay. The advantage of PCR assays are that they can be very sensitive and specific. It is estimated that PCR is 10 to 1000 times more sensitive than virus isolation. Detection of BVDV by PCR requires that genomic RNA be extracted from the sample of interest. This can be problematic because RNA is rapidly degraded if exposed to RNases, which are ubiquitous in nature. Careful sample handling is necessary to reduce this pitfall. Samples in which BVDV RNA has been detected include serum, WBC preparations, nasal swabs, homogenized tissues, semen, and milk. Specific PCR primers have been designed to differentiate among the reported genotypes of BVDV. This may be useful in epidemiologic investigations and when designing vaccine programs aimed at controlling different genotypes of BVDV.

Because of its ability to detect low levels of virus in samples, a PCR-positive sample does not allow the differentiation of viremia due to an acute or transient infection from viremia due to being persistently infected. Similarly, interpretation of PCR results must consider timing of vaccination with modified live virus products, as PCR is able to detect a transient viremia present 3 to 10 days after vaccination with a modified live virus BVDV vaccine.[223]

PCR can be used to screen pooled samples of blood, milk, or tissues (skin) in herd surveillance programs. This strategy takes advantage of the high sensitivity of the assay while reducing the cost per animal tested.

32.111.13.4 SEROLOGIC EVALUATION

Serologic detection of BVDV exposure is most commonly done by serum neutralization assays. It is important to realize that serum neutralization titers can vary significantly from laboratory to laboratory.[224] In most situations, evaluation of paired acute and convalescent titers must be used. Single point titers are very difficult to interpret, especially if vaccination programs are used in the herd. Demonstration of a fourfold increase in SN antibodies in association with appropriate clinical signs is considered significant. Use of paired serologic evaluation for diagnosis of abortion may be difficult because seroconversion may already have occurred by the time the event is noticed. Persistently infected cattle generally have no or very low serum neutralization titers. However, persistently infected cattle may seroconvert to field virus or vaccination, especially if the vaccine or field virus is antigenically distinct from the virus with which the animal is persistently infected.[225] As a result, the identification of seronegative cattle cannot be used as a sole criterion for determining persistently infected status. Serologic evaluation may be useful in determining the infection status of a herd. The presence of high serum neutralization titers in unvaccinated heifers older than 6 months of age indicates that BVDV is currently or has recently been circulating and is correlated with the presence of persistently infected cattle in dairy herds.[155,226] This strategy has been less successful when used in beef herds.[227]

Table 32-10 summarizes diagnostic testing that can be used for specific forms of the disease.

32.111.14

Treatment and Prognosis

No specific treatment is available for animals showing clinical signs of BVDV infection. Owners should be informed that severely ill animals may have mucosal disease, which normally is fatal. The goals of therapy for cattle suspected of having acute BVDV infection are supportive care and prevention of secondary bacterial infection. Broad-spectrum antimicrobial agents, fluids, electrolytes, and vitamins may be indicated.

32.111.15

Prevention and Control

Practices aimed at preventing the introduction of BVDV to a farm are primarily applicable only for closed breeding operations (dairy farms or beef cow and calf operations) and cannot be used for feedlot or veal operations. Strict biosecurity systems with isolation and testing of all cattle entering the farm are necessary to ensure that no virus enters the farm; this may be difficult for most dairy and cow and calf operations to achieve. A reasonable compromise is to limit movement of cattle on and off the farm to the essential traffic, to avoid moving pregnant animals, and to purchase replacement animals (including bred heifers) from herds for which accurate records of disease history and vaccination programs are kept. Isolation of new additions for 3 weeks should prevent transmission of virus from acutely infected (non-persistently infected) cattle. Purchased cattle should be tested for BVDV before entering the resident herd. If pregnant cattle are purchased, their offspring should be tested to ensure that they are free of BVDV. Semen used for artificial insemination should be from bulls that have been tested for BVDV infection. It is important to test embryo transplantation recipients before their use to ensure that they are not persistently infected. Exposure of cattle to small and wild ruminants should be limited through separate housing for sheep and goats and well-maintained fences to reduce contact with deer.

In stocker or backgrounder and feedlot operations, immunity to BVDV has been shown to be protective against BRD complex.[228] Vaccination against BVDV before the expected occurrence of respiratory disease (as is done in preconditioning programs for beef calves) may minimize the consequences that accompany infection with field strains of BVDV. This, in turn, reduces the severity of infection by other pathogens involved in the respiratory disease complex. Although strict biosecurity measures designed to keep BVDV off the farm may not be possible in the feedlot, large feedlots have found economic advantage in screening incoming calves to ensure no persistently infected animals are present in feedlot pens. Presence of persistently infected calves can result in increased disease, treatment costs, and death in the persistently infected calves as well as increased disease and treatment costs for the pen as a whole.[153]

Table 32-10 Diagnostic Testing for Bovine Virus Diarrhea Virus (BVDV)

Clinical Form	Specimen	Diagnostic Test	Comments
Subclinical or acute BVD disease	Serum	Serum virus neutralization	Pair sera 3–4 weeks apart Serology for both types 1 and 2 BVDV should be performed
	Serum or whole blood	Virus isolation PCR	Whole blood preferred Viremia may be too transient for successful virus isolation
	Nasal swabs	Virus isolation PCR	Useful for establishing role of BVDV in bovine respiratory disease complex
	Postmortem tissues	Fluorescent antibody Immunohistochemistry Virus isolation PCR	Tissues of choice include ileum, Peyer's patches, mesenteric lymph nodes, spleen, thymus (calves), lung (BRD)
Infertility	Serum	Serum virus neutralization	May need to establish serum bank on at risk animals as seroconversion complete when reproductive problem noticed or compare titers of affected to unaffected cattle Serology for both types 1 and 2 BVDV should be performed
Abortion	Serum	Serum virus neutralization	Pair sera 3–4 weeks apart Serology for both types 1 and 2 BVDV should be performed
	Fetal fluid	Serum virus neutralization	Presence of antibodies or BVDV suggestive but not definitive for BVDV-induced abortion Serology for both types 1 and 2 BVDV should be performed
	Fetal tissues	Fluorescent antibody Immunohistochemistry Virus isolation PCR	Tissues of choice include ileum, mesenteric lymph nodes, spleen, thymus, liver, lung

Persistent infection	Serum or whole blood	Virus isolation (IPMA) Antigen capture ELISA PCR	Should be repeated in 2–4 wk to confirm persistent infection For virus isolation, buffy coats should be used on calves less than 6 months of age
	Skin biopsy	Antigen capture ELISA Immunohistochemistry Fluorescent antibody PCR	Should be retested in 3–4 wk with blood sample to confirm persistent infection Pools of skin or blood may be tested initially by PCR
Mucosal disease	Serum or whole blood	Virus isolation PCR	Isolation of both CP and NCP-BVDV
	Postmortem tissues	Fluorescent antibody Immunohistochemistry Virus isolation PCR	
Herd Screening	Bulk milk tank	PCR	Screens only lactating cows; 300 cows per milk pool
	Serum from sentinel cattle	Serum virus neutralization	Unvaccinated cattle 6–12 months of age Serology for both types 1 and 2 BVDV should be performed

BRD, Bovine respiratory disease; *BVD*, bovine virus diarrhea; *BVDV*, bovine virus diarrhea virus; *CP*, cytopathic biotype; *ELISA*, enzyme-linked immunosorbent assay; *IPMA*, immunoperoxidase monolayer assay; *NCP*, noncytopathic biotype; *PCR*, polymerase chain reaction.

Vaccination programs are routinely used to limit disease from BVDV infection. The goal of a BVDV vaccination program is to induce immunity that will limit viral replication after infection and thereby prevent the subsequent effects of viral infection. On dairy farms or in beef cow-calf operations, ensuring adequate immunity in breeding females is aimed at preventing in utero infections and harmful sequelae (infertility, abortion, congenital malformation, birth of weak calves, and persistent infection). An additional benefit of vaccination of breeding stock is enhancement of the level of colostral immunity passed to the offspring. 797 798

Many practitioners have concerns about commercial BVDV vaccines. Concerns over vaccine safety with modified live BVDV vaccines have traditionally centered on “vaccine breaks,” transmission of vaccine strains, and vaccine-induced immunosuppression, abortion, and congenital anomalies. New technologies and better quality control of vaccine reagents has greatly reduced the occurrence of vaccine contamination. Immunosuppression has been demonstrated experimentally after the use of modified live BVDV vaccines.[229] Vaccinal strains of modified live BVDV are reported to cross the placenta and induce the same detrimental outcomes as seen in fetal infection with field strains of BVDV except persistent infections. This is of greatest concern during the first and second trimesters. Modified live vaccines may or may not induce mucosal disease in persistently infected cattle. The possible induction of mucosal disease in persistently infected cattle should not be a deterrent to using modified live vaccines.

Killed BVDV vaccines are safe for use in pregnant cows and do not result in vaccine breaks or cause immunosuppression unless improperly attenuated. When using a killed virus vaccine in cattle that have never been vaccinated against BVDV, a booster dose must be administered 2 to 4 weeks after the initial vaccination to ensure proper vaccination.

Concerns about the efficacy of BVDV vaccines have centered on the ability of vaccines to stimulate an immune response capable of protecting against the broad antigenic spectrum represented by BVDV types 1 and 2. Current BVDV vaccines appear to be capable of preventing severe disease in cattle infected with heterologous field viruses.[230,231] However, the ability of vaccines to protect against fetal infection is not clear. The majority of fetal challenge studies have demonstrated that vaccines reduce the risk of fetal infection with BVDV but do not eliminate it.[232–236] BVDV vaccines should be used strategically to optimize immunity during gestation, especially during the first two trimesters when the fetus is most susceptible to the detrimental effects of the virus. This would include vaccination of all breeding stock before the animals are bred. Replacement heifers should be vaccinated at 5 to 6 months of age when colostral immunity declines and again before breeding. When possible, modified live vaccines should be used to ensure broader and longer protection. In calves, vaccination before the decline in colostral antibodies occurs is of questionable value, although some studies indicate that it is beneficial in protecting against calf hood disease associated with BVDV.[230] Vaccination against BVDV should be part of any preconditioning program for beef calves before entry into a commingled environment.

In herds experiencing problems with BVDV infections, screening for persistently infected cattle may be warranted. In breeding herds, persistently infected animals serve as a continuous source of infection to susceptible cattle. In addition, because persistently infected females may produce persistently infected offspring, it is desirable to cull these females before they spread virus to their offspring or before they have disease themselves, resulting in economic loss. Before instituting a herd-screening program, several points should be emphasized. First, there should be a definitive diagnosis of BVDV infection in the herd before the expense of testing is undertaken; second, the herd should be experiencing a disease syndrome that is associated with BVDV infection; third, the owner must be willing to implement biosecurity measures aimed at reducing the risk of reintroducing BVDV into the herd. Herd screening involves testing strategic subsets or all cattle on the farm for BVDV. This includes in utero calves that are tested after birth.

Cattle that are determined to be persistently infected with BVDV will remain so for their entire life and will continually serve as a virus reservoir for susceptible animals. Once detected, persistently infected animals should be removed from the herd immediately and appropriate actions taken so that they do not come in contact with other susceptible animals.

32.112 MALIGNANT CATARRHAL FEVER (BOVINE MALIGNANT CATARRH, MALIGNANT HEAD CATARRH)

Bradford P. Smith

32.112.1 Definition and Etiology

Acute MCF is a highly fatal disease of cattle, deer, bison, buffalo, some other ruminants (33 species to date), and pigs caused by a herpesvirus. It has worldwide distribution and has also been a major problem in zoos and game parks. The African strain, identified as alcelaphine herpesvirus type 1 (AlHV-1), is a wildebeest-associated gammaherpesvirus[237] carried by the blue or white-bearded wildebeest *(Connochaetes taurinus)* AlHV type 2 is a

closely related but nonpathogenic gammaherpesvirus from other species of African antelope. The name *ovine herpesvirus type 2* (OvHV-2) has been proposed for the sheep isolate. OvHV-2 is carried by numerous species of domestic and wild sheep and goats worldwide. OvHV-2, AlHV-1, and AlHV-2 are closely related antigenically to bovine cytomegalovirus (bovine herpesvirus type 3), which offers some cross-protection.[238] Goats may carry caprine herpesvirus type 2 (CpHV-2), which can be transmitted to Sitka deer[239] and perhaps other species.

The sheep-associated form of MCF can be acute or chronic, and animals may recover. European, Australian, Asian, and American sheep-associated viruses have been isolated. These herpesviruses appear to represent species-adapted variants of the same virus.[240] The disease usually occurs sporadically, with only one animal affected, but many large outbreaks have been reported. Cattle are considered dead-end hosts and usually do not spread the infection by contact transmission because there is no cell-free virus in secretions.[241] The virus is fragile and unlikely to survive outside a host for more than a day or even hours.

The African and North American forms of the disease are similar except for the reservoir host and the fact that the African herpesvirus appears to be more contagious and is more easily transmitted experimentally. The incubation period for American MCF is more than twice as long as that for African MCF, but the course of clinical disease is one third as long. A higher percentage of cattle develop acute disease with severe diarrhea with the American form.[242]

Some African hoofed ungulates may have clinical signs, and infected animals in wild animal parks may pose a danger to domestic livestock. Bison, Dall sheep, muskox, elk, moose, deer, and other species can also be infected. Acute outbreaks in bison have been reported.[243] In one report exposure of bison to sheep for less than a day at an auction resulted in heavy mortality.[244] Pigs were infected and developed clinical disease in Norway.[245] Both the African and North American viruses can be transmitted to rabbits, in which infection causes an acute, fatal lymphoproliferative disorder.

798

799

Sheep are usually asymptomatic, but a heavy experimental intranasal inoculation of OvHV-2 resulted in illness and lesions in three sheep.[246]

32.112.2 Clinical Signs and Differential Diagnosis

Cattle from 4 weeks of age to adulthood can be infected and develop clinical illness. After an incubation period of 3 to 10 weeks, the disease attacks vascular endothelium (vasculitis), and all epithelial surfaces are affected. The incubation period can be prolonged, and in at least one case the incubation period was 200 days. Oral erosions, diarrhea, dysentery, severe keratoconjunctivitis, mucopurulent nasal discharge, thickened cracking skin, encephalitis, lymphadenopathy with very enlarged nodes, and high fever may be seen (Fig. 32-68). Generalized weakness and dyspnea occur. Ropy saliva may be dropped from the painful mouth, and scabs may develop on the muzzle. The hoof or horns may be shed, and lameness may be pronounced. Hematuria often is present. When particular signs predominate, the condition may be labeled the alimentary form, the encephalitic form, the head and eye form, or the skin form. One strain of virus can cause all forms, and animals with most of these signs can be seen in a given outbreak. Clinical signs in any single animal may progress rapidly or over a course of weeks. In California a pygmy goat had vasculitis, sloughing skin, keratitis, neurologic signs, fever, and a positive titer to MCF before dying (Smith BP, unpublished data). Disease in Sitka deer (and perhaps other species) may consist primarily of dermatitis and alopecia.[247]

The course of the acute disease usually is 3 to 7 days; some animals survive longer. The mortality rate is very high. In some outbreaks an acute form has predominated, with affected cattle dying 1 to 3 days after developing

a high fever, severe diarrhea, and conjunctivitis.[248,249] Peracute deaths without any visible symptoms also were recorded. A mild form, with transient fever and mild oral and nasal mucosal erosions followed by recovery, has been seen in experimentally infected cattle. In a natural outbreak in the United States, three of the animals survived longer than 3 months with clinical signs, and evidence indicated that some animals seroconverted and remained infected for years. The main lesion in chronic or recovered cases is obliterative arteriopathy.[250] Cattle with chronic MCF and cattle that have recovered from sheep-associated MCF have been described.[251,252] The authors concluded that sheep-associated MCF can manifest with a full range of clinical signs. Some animals recovered after treatment with corticosteroids, but there is also a report of recrudescence of MCF in a deer given corticosteroids.

Fig. 32-68 Yearling steer with malignant catarrhal fever. Note the corneal opacity, lacrimation, and mucopurulent nasal discharge.

MCF must be differentiated from BVD-mucosal disease (BVD-MD), RP, bluetongue, VS, and FMD. The last two diseases are not usually associated with diarrhea, and VS and FMD tend to have high morbidity and low mortality rates. Clinical bluetongue is rare in cattle and not usually associated with dysentery. Arsenic toxicity and chlorinated naphthalene toxicity have some clinical similarities to the intestinal forms of MCF. Ocular signs, including corneal opacity, conjunctivitis, and discharges, must be differentiated from bovine pinkeye, in which the lesion starts at the center of the cornea. The corneal opacity of MCF starts at the limbus and is caused by edema secondary to the loss of the internal endothelial layer of the cornea.[253]

32.112.3 Clinical Pathology and Serology

Some affected animals show leukopenia caused by neutropenia if sampled early in the course of disease, but this is a very inconsistent finding in natural outbreaks.[248] Joint fluid is cloudy and may contain increased protein and mononuclear cell numbers. Cerebrospinal fluid has elevated protein concentrations (up to 584 mg/dL) and elevated WBC counts (up to 945/mm^3), mainly because of an increase in mononuclear cells.[254] Serologic tests include ELISA, indirect immunofluorescence,[250,255] CF, and virus neutralization. Virus isolation can be attempted. PCR[256–258] tests have been developed for AlHV-1 and recently for OvHV-2. The wildebeest-associated and sheep-associated viruses appear to be closely related antigenically, cross-react serologically, and offer some cross-protection.[259]

Diagnosis is based on a history of exposure, clinical signs, and gross and histologic lesions. PCR and competitive inhibition ELISA are definitive.[260] Rabbit inoculations can also be used. Nasal swabs and 500 mL of blood, as well as spleen and lymph node samples, should be collected for viral isolation (these should not be frozen). A cytopathic effect on thyroid cell cultures may be observed 4 to 20 days after inoculation.[261]

32.112.4 Pathophysiology

Although the incubation period has been described as 3 to 10 weeks, a period of 150 days has been documented between the first and last cases in an outbreak.[248] Persistent asymptomatic infection for 5 months after inoculation with MCF virus followed by 4 weeks of viremia and death was documented in a steer.[262] The MCF virus appears to cause proliferation of cytotoxic T lymphocytes. The evidence suggests that the vasculitis observed with MCF is mediated by lymphoid cell infiltration rather than by virus or immune complexes.[263] Lymphocytes and lymphoblasts are found in all affected tissues, whereas neutrophils and plasma cells are rare. No visible viral particles are involved in the arteritis. Large granular lymphocytes are a subpopulation of T cells that act as NK cells and also as T lymphocyte suppressor cells. If these cells are malfunctioning, suppressor dysfunction can result in exuberant T cell proliferation, whereas NK cell dysfunction can result in indiscriminant killing of normal cells.[264] Major histocompatibility complex restriction and macrophages also appear to play a role in the pathogenesis. AlHV-1 has similarities to other oncogenic lymphotrophic herpesviruses such as the Marek's disease virus and the Epstein-Barr virus.[237] The molecular structure of the MCF virus genome supports this view.

32.112.5 Epidemiology

The African form of MCF is spread to cattle and other susceptible species by wildebeests, especially during the wildebeests' calving season.[265] AHV-1 has been isolated from asymptomatic wildebeests, from the nasal and lacrimal secretions of wildebeest calves,[241] and from a wildebeest fetus.[242] The virus does not survive more than a few hours in the environment. In South Africa, however, MCF occurs in cattle without wildebeest contact (except at a distance) and when wildebeest calves are usually 8 to 10 months old.[266] The exact mode of transmission is thus incompletely understood at present. Hartebeests and topis are also reservoir hosts for the virus.

The sheep-associated form of MCF is spread to cattle by contact or housing in nearby fields, even without direct contact between sheep and cattle.[248] There is evidence of aerosol transmission for over 70 meters.[253] Lambing is associated with many outbreaks as ewes shed more virus in the periparturient period. A high proportion of sheep sera yields positive findings for antibody to AlHV-1 by indirect immunofluorescence, including some from cesarean-derived lambs, which may indicate transplacental virus transmission,[267] and 99% of North American domestic sheep are infected.[268]

Although the disease usually occurs sporadically in a single individual, many severe outbreaks involving large numbers of cattle[248,259,269] and bison[244] have been reported. The dairy cow outbreaks[248,259] that occurred in the late 1970s in California and Minnesota were sheep associated, whereas recurrent North American feedlot outbreaks may not be.

Asymptomatic carrier cattle,[262] bison,[253] or deer[237] may be sources of the virus, which would explain how outbreaks can occur without apparent contact with wildebeests, hartebeests, topis, or sheep. OvHV-2 infection of cattle can occur without concurrent development of clinical MCF.[260] A steer inoculated with MCF virus was asymptomatic for 5 months before becoming viremic for 4 weeks[262] and having clinical MCF. A deer that had previously had MCF as a fawn but had been asymptomatic for 4 months recrudesced (shed virus and had clinical MCF) when given dexamethasone.[237] Cattle (and bison) traditionally have been considered dead-end hosts for MCF virus because isolated individuals usually are affected, but this may not always be the case if an asymptomatic or symptomatic bovine were to shed cell-free virus in secretions. Vertical transmission in cattle and bison through in utero infection has been documented.

32.112.6 Necropsy Findings

The nasal mucosa is hyperemic to hemorrhagic. The oral mucosa has necrotic papillae and large areas of necrosis and ulceration. Multiple focal ulcerations are seen in the esophagus. Parts of the forestomachs and intestines are thickened, edematous, and occasionally ulcerated and hemorrhagic. The lymph nodes, tonsils, and Peyer's patches are enlarged, moist, and friable. Splenic lymphoid follicles are prominent, and the liver is swollen. The adrenal glands are hemorrhagic. The mucosal surface of the bladder has focal areas of hemorrhage. The eyes are hyperemic and ulcerated and show severe corneal edema. The brain has intersulcal cloudiness and meningeal petechiation. Joints have swollen and reddened synovium with an increased quantity of cloudy fluid.[254]

Microscopic lesions involve blood vessels and epithelial surfaces. There is a marked lymphoid accumulation around vessels, as well as necrosis of the tunica media and intima. There is generalized lymphoid hyperplasia and lymphoid infiltrates in subepithelial and intraepithelial locations, associated with epithelial necrosis and sloughing. Similar changes occur in all epithelial tissues.[254] Chronic cases develop chronic obliterative arteriopathy.[250]

32.112.7 Treatment and Prognosis

Treatment of full-blown cases does not appear to be successful, but fluid therapy and good nursing care may allow some animals to survive. The morbidity rate may be quite high, running to 37% in one outbreak. Although some animals that exhibit mild disease may survive, close to 100% of those with severe clinical signs die.

32.112.8 Prevention and Control

There is evidence that cattle-to-cattle and bison-to-bison transmission may occur in endemically infected herds; thus carriers should be identified by PCR and competitive inhibition ELISA (CI-ELISA) and isolated or culled. Incoming animals in bison herds should be tested.[253] During an epidemic animals that are exposed or that show clinical signs should be separated from unexposed animals, and no across-the-fence contact should be allowed. Exposed or recovered cattle may serve as a reservoir for the virus for months. Sheep should be kept well away from cattle, and cattle should not be exposed to African wildlife, especially wildebeests, hartebeests, and topis, which may be infected carriers of the MCF virus. Vaccination with live or killed MCF virus has not proved consistently protective against challenge[270] and generally is not used.

32.113 VESICULAR STOMATITIS

Bradford P. Smith

32.113.1 Definition and Etiology

Vesicular stomatitis (VS) is a rhabdoviral disease of the genus *Vesiculovirus* that causes sporadic (cyclic) outbreaks in cattle, horses, donkeys, mules, and pigs and typically has a high morbidity but a low mortality rate. Cattle under 1 year of age rarely show clinical signs. VS is seen in the United States, Mexico, and Central and South America. Human beings have sometimes been infected with an influenza-like disease. Two distinct antigenic strains have been designated, the New Jersey (NJ) and Indiana (I) serotypes. Vesicles occur in the mouth, on the teats, and in interdigital areas. Lesions may occur only on the teats or only in the mouth.[271,272] The vesicles rapidly turn to painful ulcerations that cause dysphagia and reluctance to eat, frothing at the mouth, drooling, agalactia, weight loss, mastitis, and lameness. Death is rare. Epizootic waves of VS have tended to occur at about 10-year intervals, usually in the summer or fall, but since the major epizootic in 1982 and 1983 in the western United States, the NJ serotype has been identified in the United States each year.[271] An outbreak occurred in 1995 in the western United States, in New Mexico, and Colorado.[273] More cases occurred in 1997 and 1998. Although the NJ serotype has at least 14 distinct genotypes, only a few of these have been found in recent outbreaks in the United States. The NJ serotype should be considered a collection of serologically related but genetically variant viruses.[271] The I serotype has three subtypes; I-1 occurs in the United States. State and federal regulatory veterinarians should be contacted immediately when VS is suspected so that quarantine and disease identification measures can be used quickly to contain an outbreak.

Numerous outbreaks occur yearly from southern Mexico to northern South America.

32.113.2 Clinical Signs and Differential Diagnosis

After a mean incubation period of 9 days (the range is 3 to 21 days), there is onset of fever and oral lesions that cause excess salivation and reluctance to eat.[274,275] From 5% to 60% of cattle on a farm may show clinical signs. 800
Vesicles are only occasionally visible, because the epithelium rapidly necroses and many lesions quickly turn to ulcers. Lesions on the gums and tongue may coalesce to form large eroded areas (Fig. 32-69). Milk yield falls quickly. Teat lesions are common in dairy cattle, and small ulcers in the interdigital area and on the coronary band are occasionally seen. Recovery varies from 2 to 21 days, depending on the severity of the lesions and 801

management factors such as the type of feed and milking sanitation.[274] Actual healing of the lesions may take 34 to 59 days.[275]

Fig. 32-69 Severe ulceration of the tongue of a dairy cow caused by vesicular stomatitis. A plaque of dying mucosa covered by fibrin is visible at the tip of the tongue, and excessive salivation is obvious. Photo courtesy of Dr. Mark Thurmond.

The major differential diagnostic consideration is FMD, which causes almost identical clinical signs. Other diseases of cattle that result in oral lesions (BVD, BPS, bluetongue) do not usually appear as epidemics but rather in one or a few animals (although BPS may have a high morbidity). Other causes of oral lesions such as bristle grass irritation and toxins should be ruled out.

32.113.3 Clinical Pathology and Laboratory Diagnosis

The VS virus is difficult to isolate from blood, urine, feces, and oral swabs but has been isolated from tongue epithelium.[275] A CF test and a fluorescent antibody test are available for virus identification. Serum neutralizing (SN) titer rises rapidly after exposure and then gradually falls over the first year. SN titers that follow natural exposure may persist for years. Vaccination with inactivated virus results in a rapid rise in titer followed by a gradual decline for a year.[276] The presence of an SN antibody titer does not prevent reinfection or development of clinical signs.[277] ELISAs are also available.[278] Hematologic and clinical chemistry findings generally reflect an acute to chronic inflammatory disease and are nonspecific in helping to make a diagnosis.

32.113.4 Pathophysiology

After a short incubation period of 24 hours, fever and viral invasion of the germinative layer of oral epithelial cells occur. Oral abrasions or trauma may increase susceptibility.[274] Contact of virus with teats or feet can result in lesions in these areas, especially if the teats are chapped or cracked[274] or the feet are traumatized. The lesions progress rapidly from blanched macules to vesicles and soon rupture, leaving sloughed epithelium and ulcerated areas. Healing occurs quite rapidly if feed is soft and nontraumatic.

32.113.5 Epidemiology

Older, higher-producing dairy cows that have been in milk longer are more susceptible than herdmates to clinical disease caused by VS.[274] Because the virus cannot penetrate intact mucosa, cattle fed coarse feeds or hard pellets that traumatize the oral mucosa are at higher risk.[274] Cows with chapped or cracked teats and those on farms with poor milking hygiene are more likely to get teat lesions.[274] Cow-to-cow contact is a major mode of transmission in outbreaks, and increased interpen movement of cattle, as well as shared feed and water troughs, unless cleaned frequently, increases the risk of development of VS.[274] The virus is transmitted by milking machines and human hands during outbreaks. Insect vectors also contribute to the mechanical spread.

Outbreaks are often associated with the movement of animals from another area, but disease epidemics not associated with new animals do occur. The infection tends to be seasonal (occurring in the summer and fall in temperate areas and at the end of the rainy season in the tropics) and behaves like an arthropod-borne virus.[279] The midge *C. sonorensis* was found in 2005 to be an efficient vector of VS virus.[280] Other vectors include black flies (*Simulium* species).[281] Antibodies have been found in a number of wild species of animals (deer, raccoon, bobcat, monkey), which may provide a virus reservoir.[279] Active cases of VS occur in Mexico between U.S. epidemics, giving rise to the possibility that cattle from Mexico arriving in the United Sates may also act as sources of VS virus.[271] Sheep and goats in contact often seroconvert, although clinical signs in these species are rare. The virus survives several weeks in cool soils and is very resistant to pH changes. Cattle generally show a high morbidity rate and a low mortality rate (1% to 5%). Although many in-contact cattle do not show obvious clinical signs of disease, many more have oral lesions if closely examined, and most animals in the herd seroconvert.[275]

The economic losses associated with an outbreak of VS can be severe, especially in dairy cattle. In the 1982 epizootic in California, losses on two dairies (principally decreased milk production and culling for mastitis) totaled $225,000 during 2 months.[282]

32.113.6 Necropsy Findings

Deaths are rare and usually are attributed to secondary bacterial diseases, including environmental mastitis and pneumonia. Cattle become gaunt and weak as a result of dysphagia and resultant reduced food intake. Erosive and ulcerative lesions are usually confined to the mouth. The teats frequently are involved in lactating cows, and lesions on the coronary band and interdigital area occasionally may be seen.

Histologically, intracellular and extracellular edema, ballooning and degeneration of epithelial cells, and vesicle formation accompanied by neutrophilic infiltration are present. There are no inclusion bodies. The characteristic

bullet-shaped structure of the VS virus sometimes can be seen with electron microscope examination of fresh lesions or vesicular fluid.[279]

32.113.7 Treatment and Prognosis

Mortality can be almost completely prevented if ill cattle are offered shade, fresh water, clean bedding, and soft feed. Offering soft feed hastens recovery and reduces the anorectic period. Debilitated cattle should be given broad-spectrum antibiotics in an effort to control secondary bacterial pneumonia. Cattle with teat lesions are at high risk for developing mastitis and should be carefully milked last and monitored closely for mastitis. The prognosis for survival is very good, but agalactia and mastitis may result in culling of a large number of animals.

32.113.8 Prevention and Control

The reader should use websites such as the World Organisation for Animal Health (OIE) and the U.S. Department of Agriculture (USDA) for the latest information on contagious illnesses. During an outbreak of VS, quarantine of the premises and isolation of sick animals are required. Regulatory officials will help organize and maintain a quarantine. Feed should be soft and fine, because coarse or hard-pelleted feeds increase the spread of the virus and prolong the recovery time.[274] Leftover feed should be removed from feed bunks twice daily, and the bunks disinfected. Water troughs should be cleaned and disinfected daily. Disinfection can be accomplished by using 1% formalin, organic iodines, hexachlorophene, or phenyl-phenolic preparations. Two hours of exposure to lye (2% NaOH) will *not* deactivate the virus.

801

802

Vaccination using killed[283] or live virus vaccines[284] is rarely practiced preventively because the disease occurs as rare epidemics in small areas and because vaccination interferes with serologic testing and monitoring. Vaccination with a killed virus vaccine may be used by regulatory veterinarians in at-risk animals during an epidemic, as it has been shown to be an effective vaccine.[283] Owners and managers should consult state and federal veterinarians before considering VS vaccination.

32.114 FOOT-AND-MOUTH DISEASE (AFTOSA, APHTHOUS FEVER)

Bradford P. Smith

32.114.1 Definition and Etiology

FMD is an acute, highly contagious viral disease of cloven-hoofed livestock characterized by vesicular lesions, erosions, and ulcers in the mouth and interdigital areas and on the muzzle, teats, and coronary band.[285] Natural hosts include cattle, sheep, goats, swine, water buffalo, bison, deer, elk, antelope (all wild ruminants), bears, llamas, camels, giraffes, elephants, rats, yaks, capybaras, and hedgehogs.[286] Of these, cattle and swine are the most susceptible, and camelids have low susceptibility. Mature sheep and goats usually have mild signs. Livestock of all ages are susceptible, but the mortality rate is higher in young animals because cardiac lesions occur. The horse is resistant to infection. In rare cases, humans have contracted the disease. It is endemic in Asia, Africa, parts of Europe, and most of South America, where losses involve not only those caused by the disease itself but also the monetary losses that result because fewer animal products are available for export as a result of loss of foreign markets. Great Britain experienced a major epidemic in 2001.

The FMD virus is a picornavirus of the genus Aphthovirus. At least seven immunologically distinct types of FMDV have been identified: A; O; C; SAT 1, 2, and 3; and Asia 1. Within the seven types at least 60 subtypes have been recognized. Vaccination against one subtype may not protect against another.[287] This fact, together with the fact that immunity is generally short term, means that effective vaccination programs are difficult. The virus is rapidly inactivated by high or low pH, sunlight, and very high temperatures but is very resistant to normal environmental conditions and drying.[285] Sodium hydroxide, sodium carbonate, iodophors, chlorine dioxide, and acetic acid are effective disinfectants, but many common disinfectants are ineffective, and the virus is resistant to iodophors, quaternary ammonium, hypochlorite, and phenol.

32.114.2 Clinical Signs and Differential Diagnosis

FMD is clinically indistinguishable from VS except that VS also affects horses. Clinical signs of FMD include fever, depression, anorexia, listlessness, occasional shivering, excess salivation, lip smacking, nasal discharge, and lameness.[287] Agalactia may occur. In addition to VS the differential diagnosis includes BPS, bluetongue, RP, MCF, and severe cases of infectious bovine rhinotracheitis. Teat lesions can be confused with those caused by bovine herpes mammillitis or parapoxviruses.

Vesicular lesions (blisters) 0.5 to 10 cm in diameter rupture within 48 hours, followed by a mucosal slough and large erosion.[287] These lesions appear to be very painful, and affected animals are reluctant to eat or move. The morbidity rate is high, but the mortality rate is low. The disease is economically devastating because it spreads rapidly and causes weight loss, mastitis, loss of milk production,[288] and frequent abortion. An outbreak of FMD in a country previously free of the disease can cost billions of dollars in trade losses over ensuing years. Deaths may occur in young calves, mainly from myocardial necrosis, and secondary bacterial pneumonia and foot infections are common.

32.114.3 Laboratory Diagnosis

Because FMD is clinically indistinguishable from VS and other viral mucosal diseases, laboratory confirmation of the diagnosis is obtained through CF, virus neutralization, agar gel precipitation, ELISA, or fluorescent antibody tests.[287] ELISA appears to be more sensitive and type specific than CF[289] and virus neutralization.[290] When VS or FMD is suspected, state and federal authorities should be contacted immediately. In FMD-free countries, quarantine is practical to control spread. Slaughtered animals are burned. All animals within 3 km may be destroyed during efforts to halt the disease.

32.114.4 Pathophysiology

The usual incubation period is 2 to 14 days. The usual primary sites of infection and replication by the FMD virus are the pharyngeal and digestive mucosa[287] and alveolar epithelium of the udder.[291] The virus replicates in the cells of the stratum spinosum.[292] It spreads locally and also enters the circulation and is carried to other susceptible tissues. Within 2 to 21 days a fever begins, and some vesicles appear.[293] Vesicles develop in the mouth and on the ruminal pillars, and myocardial and skeletal muscle degeneration characterized by Zenker's necrosis may occur in young cattle. The mucosal cell disruption results in separation of superficial epithelium from basal epithelium, which fills with tissue fluids. When these epithelial layers slough, erosions are left behind that take days to weeks to heal, depending on their size.[287]

32.114.5 Epidemiology

Transmission occurs primarily by means of aerosols,[287,294,295] animal contact, and fomites such as shoes, tires, and equipment. The virus may be spread to farms 50 miles distant. Human beings can carry (and subsequently transmit) the virus on their shoes or clothing or in respiratory tract tissues for longer than 24 hours. Recovered cattle usually stop shedding the virus by 2 weeks, but some harbor it for 6 to 24 months and may act as sources of the virus at the start of an epidemic.[293] The virus has been isolated from semen,[296] and the possibility exists of sexual transmission from the African buffalo to cattle.[297] African Cape buffaloes can be lifelong carriers.

The virus exists in milk, and it may survive pasteurization. Uncooked or partly cooked meat products or garbage scraps, hides, or other tissues contaminated with the FMD virus from an endemic area of the world may transmit the disease long distances. The virus can persist in frozen meat for years. Besides actively infected animals, sources of infection include bedding, feed, milk, shoes and hands of humans, and equipment.[287]

802

803

32.114.6 Necropsy Findings

In addition to oral erosions and ulcerations, ulcers may be seen on the ruminal pillars. In young cattle myocardial and skeletal muscle degeneration and necrosis may be noted. Histologically the vesicles are characterized by ballooning, cellular degeneration, intracellular and extracellular edema, and separation of the basal epithelium.[292] There are no inclusion bodies. Muscle lesions (skeletal and cardiac) are characterized by necrosis (Zenker's degeneration).

32.114.7 Treatment and Prognosis

Where FMD is endemic, quarantine, local eradication, virus typing, and revaccination of contact and at-risk cattle with the appropriate virus subtype should be considered. Good nursing care and administration of systemic antimicrobial drugs to limit secondary bacterial pneumonia and mastitis are recommended. Soft feeds such as chopped green grass are much more palatable than hay to sore-mouthed animals. The prognosis is good for survival, although many animals abort, lose weight, stop lactating, or have severe bacterial mastitis secondary to viral teat lesions and must be culled. The virus destroys mammary alveolar epithelium permanently.[291]

32.114.8 Prevention and Control

The reader should also consult the OIE and USDA websites for current status of this disease. In endemic areas, vaccination and quarantine are the basis for prevention and control. In FMD-free areas (Great Britain, the United States, Canada, Japan, New Zealand, and Australia), the method of choice is rapid identification of an outbreak, quarantine, and slaughter of all affected and exposed herds.

Vaccines must be type specific. Most European and South American countries use trivalent inactivated vaccines against types A, O, and C from cell culture virus. Vaccine-induced and naturally occurring immunity is short-lived, and vaccination usually must be repeated two or three times a year.[287] Newer oil-adjuvanted vaccines can protect for up to 1 year. Because the protection is partial, infection usually results in subclinical or mild disease. Calves nursing immune dams are likewise partly protected by passive antibody for up to 5 months.[287] In an outbreak the most effective vaccine is autogenous.

32.115 RINDERPEST (CATTLE PLAGUE) AND PESTE DES PETITS RUMINANTS

Bradford P. Smith

32.115.1 Definition and Etiology

RP is an acute, highly contagious, and usually fatal disease of ruminants. Cattle and water buffaloes are most frequently affected, but the disease also occurs in yaks, gaur, sheep, goats, pigs, and other cloven-hoofed animals, in which it is usually less severe. It is rarer in camelids. Many wild animals in Africa are susceptible, including buffalo, lesser kudu, eland, giraffe, warthog, and wildebeest.[298] RP virus (RPV) is in the Paramyxoviridae family, genus Morbillivirus. There is only one known strain of RPV. It is closely related serologically to the virus that causes PPR. The virus can remain viable for at least 1 year in frozen tissue, but it is killed by direct sunlight in 2 hours. The disease is intermittently active in Africa, the Middle East, and Asia.[299] Other morbilliviruses pathogenic for animals include canine distemper and the 1995 Australian morbillivirus, which occurred in horses and humans.

RRP is a closely related highly fatal virus of goats and sheep. Cattle and pigs develop inapparent infections. Clinical signs of PPR in goats and sheep are similar to those of RP in cattle. Bronchopneumonia is also common. The reader is referred to the World Animal Health and OIE websites for current information.

32.115.2 Clinical Signs and Differential Diagnosis

The incubation period in cattle is 3 to 15 days, which is followed by sudden onset of fever, depression, and anorexia. The nose is dry, and mucous membranes are congested. Within days oral erosions appear where necrotic foci have sloughed. Purulent lacrimation occurs. Diarrhea is severe and may be bloody. Dehydration and emaciation often lead to death. The disease in sheep and goats usually is mild or subclinical,[300] but the PPR virus can cause outbreaks with high morbidity and mortality in small ruminants.

In endemic areas RP is suspected when the signs described earlier occur in groups of animals. In nonendemic areas diseases that appear similar clinically are BVD, MCF, arsenic poisoning, severe coccidiosis, and severe fulminating infectious bovine rhinotracheitis, as well as FMD and VS. Other causes of severe gastroenteritis and diarrhea (e.g., salmonellosis) must also be considered. Oral lesions of RP are similar to these seen with VS. In small ruminants, bluetongue, PPR, and Nairobi sheep disease must be ruled out.

32.115.3 Laboratory Diagnosis

Laboratory confirmation of RP can be accomplished by (1) virus isolation; (2) PCR; (3) detection of viral antigen by fluorescent antibody testing, virus neutralization, CF, or AGID; (4) detection of rising antibody titer by ELISA or virus neutralization; and (5) histopathologic evaluation including immunohistopathology.[301] Virus isolation is most successful in the first days of infection (often before the onset of diarrhea). Blood should be taken in heparin. The lymph nodes and spleen are reliable sources of virus, and in cattle, tears and ocular discharges are also reliable sources.[302] Lymph node biopsy after day 3 of infection is the most reliable means of diagnosis in a living goat.[300] Tissues should be shipped frozen on ice to the laboratory for virus isolation or detection of antigen. Detection of a rising antibody titer can help diagnose the disease retrospectively. Leukopenia may be noted in the acute early states of RP.

32.115.4 Pathophysiology

The virus usually enters through the respiratory mucosa. Lymphoid tissue is the primary target of the RPV. Lymphocytes are destroyed in the germinal centers of the lymph nodes, Peyer's patches, tonsils, splenic corpuscles, and cecal lymphoid tissue. Immunosuppression occurs as lymphoid tissue is destroyed.[303] The virus also attacks the alimentary tract mucosa; Peyer's patches are the most severely affected. As alimentary mucosa is lost, diarrhea and emaciation become severe.

32.115.5 Epidemiology

RP is highly contagious; it is spread mainly through airborne droplets, direct contact, feces, and contaminated fomites such as human beings. All secretions and feces of infected animals are contagious throughout the course of the disease. The virus is susceptible to most disinfectants. Wild ruminants frequently are a source of infection for livestock. The morbidity rate often approaches 100%, with a 25% to 90% mortality rate, making treatment unrewarding and the prognosis poor. Innate or specific resistance may protect individuals or herds from clinical signs after infection. Recovered animals do not appear to act as carriers. Valuable individuals may be helped by supportive therapy and hydration.

32.115.6 Necropsy Findings

Lesions are found mainly in the alimentary tract and lymphoid tissues. Subendocardial hemorrhages may also be seen in animals that die of acute illness. Oral erosions, edema, and congestion of the abomasum are typically seen, and ulcers and hemorrhagic to necrotic Peyer's patches occasionally are seen. The cecal and colonic mucosae are hemorrhagic, ulcerated, or necrotic. The lymph nodes are enlarged and have necrotic germinal centers.

32.115.7 Prevention and Control

Because there is only one known strain of RPV and protection after infection usually is lifelong, vaccination of cattle at 6 months of age and older in endemic areas with a live cell culture attenuated virus is an effective means of controlling RP.[304] Although there is some debate as to whether this vaccine causes immunosuppression,[305] it has been used safely and effectively in millions of cattle in Africa and Asia.[304] The vaccine does not produce adverse reactions, has a long shelf life, and produces solid immunity.[304] Its major disadvantages are that the lyophilized virus has to be kept cold, and once a vial has been reconstituted, it must be used quickly before the virus dies. A vaccinia-vectored gene vaccine currently under field testing is effective and has the advantages of long-term stability in harsh environments and ease of application (scratch on).[306] There is also a specific PPR vaccine available for goats and sheep.

Control of epidemics in areas where the disease is not endemic involves quarantine and slaughter of infected and contact animals, as well as other contact ruminants and swine. Disinfection of premises while under government quarantine is essential in controlling the disease. The virus is susceptible to most disinfectants and survives in the environment only for 2 to 3 days.

Global eradication of RP remains a viable goal.[298,306]

32.116 CHOKE AND ESOPHAGEAL DISORDERS

Charles L. Guard

32.116.1 Definition and Etiology

Choke is the term used for esophageal obstruction. In ruminants it is most common in cattle because of their eating habits. If the obstruction is complete, the condition is rapidly fatal (except in neonates) because of the inability to eliminate the gases of fermentation produced in the rumenoreticulum. Partial obstruction produces dysphagia or anorexia. Obstruction may be caused by the ingestion of foreign objects or large chunks of solid feedstuffs such as apples, potatoes, beet tops, or corn cobs. It also may be the result of space-occupying lesions in or near the esophagus. Choke must be differentiated from diseases that cause dysphagia by means of pharyngeal lesions and resultant neuromuscular dysfunction. Congenital or acquired lesions of the esophagus such as aortic arch anomalies and diverticula may cause signs similar to those of esophageal obstruction.

32.116.2 Clinical Signs and Differential Diagnosis

The earliest signs of complete esophageal obstruction from intraluminal objects are anxiety and ptyalorrhea (i.e., saliva dripping from the mouth because of an inability to swallow). The animal may violently swing the head from side to side and make repeated attempts to swallow. Staggering (which must be differentiated from ataxia caused by neurologic diseases) may be observed. In a 2-week-old calf with a cloth foreign body obstructing the distal esophagus at the cardia, regurgitation after drinking milk was observed.[307] Bloat develops soon after at a rate that depends on the nature of the ruminoreticular contents. Objects such as potatoes, apples, or mangels may be swallowed whole or in chunks too large to pass the entire esophagus, especially in cattle. Dry grain, particularly in pellet form, may be consumed so rapidly that sufficient saliva is not produced to lubricate the passage of the feed boluses. This is more common in sheep than in other ruminants; spontaneous resolution usually occurs within minutes to hours.

Obstruction from intraluminal objects commonly occurs in the cranial part of the cervical esophagus, at the thoracic inlet, or at the base of the heart. External palpation may localize the site of obstruction in the cervical esophagus. With more slowly developing and incomplete obstruction, anorexia and dysphagia may be observed. Bloat may occur repeatedly and resolve spontaneously or after passage of a stomach tube. The underlying cause may result in signs severe enough to mask the esophageal problem. Cellulitis along the cervical esophagus may result in a reluctance to lower the head or bend the neck laterally. Possible causes of cervical cellulitis include perivascular injection of irritating substances, abscesses, and reaction to *Hypoderma lineatum* larvae.

Esophageal stricture may follow a previous episode of esophageal obstruction or inflammation in adjacent tissues.[308] If no site of obstruction is externally evident, careful attempts to pass a stomach tube usually reveal the site of the problem. Radiography with barium contrast material may help identify the site of strictures, perforations, and diverticula.[309] Endoscopy of the esophagus may also aid in identifying the specific nature of functional or structural abnormalities. Megaesophagus has been observed after pharyngeal trauma,[310] as a congenital disorder,[311] and with hiatal hernia.[312] An animal with an esophageal stricture or a diverticulum may reflux boluses of feed mixed with saliva or regurgitate liquid ruminal contents. Failure to gain weight or progressive weight loss accompanies the failure to swallow feed successfully. Signs may be seen only when forage is consumed, whereas water and grain are swallowed normally.

Systemic diseases may lead to esophageal dysfunction. Rabies must always be considered when dysphagia is present, and appropriate precautions must be taken. Botulism also leads to esophageal transport failure, although dysphagia and a weak tongue are more prominent in the failure of affected animals to eat. Tetanus may be similar in appearance to esophageal obstruction because of the presence of bloat, dysphagia, and drooling. Several poisonous plants, including sneezeweed, larkspur, and milkweed, may cause excessive salivation, drooling, and bloat. Consumption of red clover infected with the fungus *Rhizoctonia leguminicola*, which produces the toxin slaframine, results in copious salivation. Pharyngeal trauma and subsequent cellulitis lead to dysphagia and drooling; severe bloat does not occur unless swelling is sufficient to occlude the esophagus. However, mild bloat frequently accompanies pharyngeal trauma caused by associated vagal nerve inflammation and dysfunction.[313]

32.116.3 Clinical Pathology

Common features of longstanding choke are dehydration and metabolic acidosis resulting from continued loss of sodium bicarbonate and sodium phosphate in saliva. As sodium depletion develops, the composition of saliva shifts to include more potassium under the influence of aldosterone. Inflammatory diseases lead to predictable changes in the hemogram.

32.116.4 Necropsy Findings

Animals that die of acute esophageal obstruction are bloated and may have saliva and feedstuffs in the upper airway. Postmortem examination of animals with protracted esophageal dysfunction may reveal focal dilations or stenoses of the esophagus. Esophageal perforation may have occurred because of pressure around an intraluminal foreign body or necrosis caused by extension of an adjacent septic process. 804 805

32.116.5 Treatment and Prognosis

In cases of complete esophageal obstruction, relieving bloat is the first concern. Passage of a stomach tube may be attempted if the animal is not in respiratory distress. Trocharization of the rumen or installation of a temporary fistula may be required. Until the esophagus has been cleared, it is important to keep the muzzle level or pointed down to reduce the risk of aspiration of saliva. Sedative drugs such as acepromazine or xylazine may be useful to calm the animal and permit careful examination. Suitable precautions should be taken if rabies is remotely possible. The history and an examination of the environment should enable the clinician to anticipate the nature of the obstructing object. Palpation of the neck along the left jugular furrow may reveal the site of obstruction in lean or thin-necked individuals. A manual oral examination should precede probing attempts with a stomach tube. Gentle pressure on the stomach tube as it passes down the esophagus should allow localization of the obstruction. A small hand can reach into the cranial part of the esophagus and may retrieve some solid objects. If the object is solid (e.g., a potato), it may be possible to massage it into the pharynx by pressing in the jugular furrow on both sides of the neck. Specialized equipment, such as a probang, is available with a corkscrew-like or pincer-like end that can be used to grasp or engage a foreign body and expedite its retrieval. If a mass of grain is obstructing the esophagus, external massage, probing with the stomach tube, or pumping fluid against the mass through the tube may break it up.

If the choke is intrathoracic and probing with a stomach tube does not relieve the problem, several courses of action are possible. A small ruminal fistula can be inserted to prevent bloat, and the animal can simply be placed in a pen without bedding, feed, or water. Many masses consisting of grain or hay spontaneously pass within 24

hours, whereas solid objects rarely pass spontaneously. If the obstruction does not resolve in 24 hours, the animal can be heavily sedated, a cuffed endotracheal tube can be passed to prevent aspiration, and vigorous lavage with water through a stomach tube can be attempted. The head should be held lower than the body to minimize the risk of aspiration. If the obstruction still cannot be relieved or it is believed that the obstruction is a solid object, a rumenotomy can be performed. Access to the esophagus through the cardia should allow snaring of the object with a loop of stiff wire or breakup of a mass of grain.

The long-term prognosis after choke is good unless esophageal mucosal damage has occurred. Stricture formation may follow cellulitis or pressure necrosis at the site of the obstruction. Aftercare for the choked animal consists of a soft diet and antiinflammatory drugs to minimize tissue swelling. Well-soaked alfalfa cubes made into a mush may pass partly obstructed areas. Hay and grain should be moistened before feeding, and grain should be offered only in small amounts at each feeding. Broad-spectrum antibiotics should be given if mucosal damage is suspected. Maintenance of an indwelling nasogastric tube for feeding for up to 10 days after severe esophageal trauma may be helpful in preventing strictures during healing.[309] Thick gruels made from soaked alfalfa cubes or pellets can be pumped into the rumen by a bilge pump designed for boats, or the animal can be fed and watered through a ruminal fistula. Surgical exploration may be required to determine the cause of esophageal obstruction from space-occupying lesions or strictures.[309] Abscesses may be drained, and granulomatous lesions resected. Esophageal diverticula, aortic arch anomalies, and intrathoracic surgical problems may not be easily treated.

32.117 ESOPHAGEAL DILATION (MEGAESOPHAGUS) AND HIATAL HERNIA

Bradford P. Smith

Megaesophagus rarely occurs in ruminants. It has been reported in association with pharyngeal trauma and resultant inflammatory involvement of the vagus[314] and with hiatal hernia (diaphragmatic hernia with herniation of the reticulum into the thorax) in which there was a large megaesophagus (10 cm in diameter by 20 cm in length).[315] Vagotomy and hiatal hernia are recognized as causes of diminished esophageal pressure.[316] A 4-month-old calf with megaesophagus lacked esophageal muscle cells and ganglion cells, and many fat cells were present.[317] The esophagus of a 12-month-old ram with megaesophagus was found to be heavily infected with *Sarcocystis arieticanis*, and eosinophilic inflammation and degeneration of muscle fibers were noted.[318] However, *Sarcocystis* species have been found in the esophagus of many sheep without megaesophagus,[319,320] making the diagnosis difficult. An 18-month-old heifer with megaesophagus also had eosinophilic submucosal infiltration, but no sarcocysts were seen.[321]

The principal clinical signs of megaesophagus are regurgitation or vomiting, usually shortly after eating. Mild, recurrent bloat and discomfort when a stomach tube is passed are also observed. In other cattle with a hiatal (diaphragmatic) hernia[322] or an esophageal diverticulum,[323] regurgitation or vomiting and bloat have also been reported. Contortion of the neck while eating, apparently caused by pain, was seen in one cow[315] and is reported in human beings with hiatal hernia.[324] In some cases of herniation of the reticulum into the thorax, bloat and regurgitation are not seen[325,326]; in others diaphragmatic hernia resulted in chronic bloat.[327] Diaphragmatic hernias may be either congenital or acquired. It appears that acquired diaphragmatic hernias are most common.

A stomach tube should be passed to the rumen to rule out choke or an intraluminal mass obstructing the esophagus as a cause. If a tube can be passed freely to the rumen, plain and contrast radiographs of the esophagus should be

taken. If this is not possible, surgical exploration of the abdomen for a diaphragmatic hernia and digital palpation of the cardia and terminal esophagus by means of rumenotomy should be considered.

Megaesophagus associated with pharyngeal trauma has a good prognosis,[314] whereas megaesophagus associated with hiatal hernia has a more guarded prognosis.[315,322] Supportive treatments and stomach tubing with fluids may be required for 1 to 2 weeks until the animal is able to drink unaided. Longer-term support can be given to a valuable animal by surgically creating a ruminal fistula fitted with a rubber cannula through which feed and water can be given until normal deglutition is resumed.

32.11 RUMINANT ABDOMINAL ULTRASONOGRAPHY

Betsy Vaughan

The key to diagnosing ruminant abdominal disorders is the thorough physical examination (see Chapter 1). A relatively new, noninvasive, and useful adjunct is the use of ultrasound.

Abdominal ultrasound provides a readily available, real time, noninvasive method of imaging the abdomen in ruminants suspected of abdominal disease. Radiographic examination of the adult bovine abdomen offers limited information because of the large size of the patient and the need for expensive equipment with high milliampere-seconds (mAs) and kilovolt peak (kVp). Although radiographic examination of the small ruminant abdomen offers clinically useful information, it should be used in conjunction with abdominal ultrasonography to evaluate the abdominal organs and to further characterize radiographic abnormalities. Exploratory laparotomy is still commonly performed in cattle with unexplained illness referable to the abdominal cavity. Ultrasonographic evaluation of the ruminant abdomen has become an important part of the diagnostic workup in ruminants suspected of abdominal disease in combination with CBC, serum chemistry, peritoneal fluid analysis, urinalysis, and ruminal fluid analysis and can often provide valuable information that may preclude the need for exploratory laparotomy.[328–331] Abdominal ultrasound is indicated in patients with signs of abdominal pain, stasis, decreased motility, increased motility, lethargy, anorexia, bloat, regurgitation, fever of unknown origin, and suspected renal or liver disease. Ultrasound is also useful for diagnosing thoracic disorders.

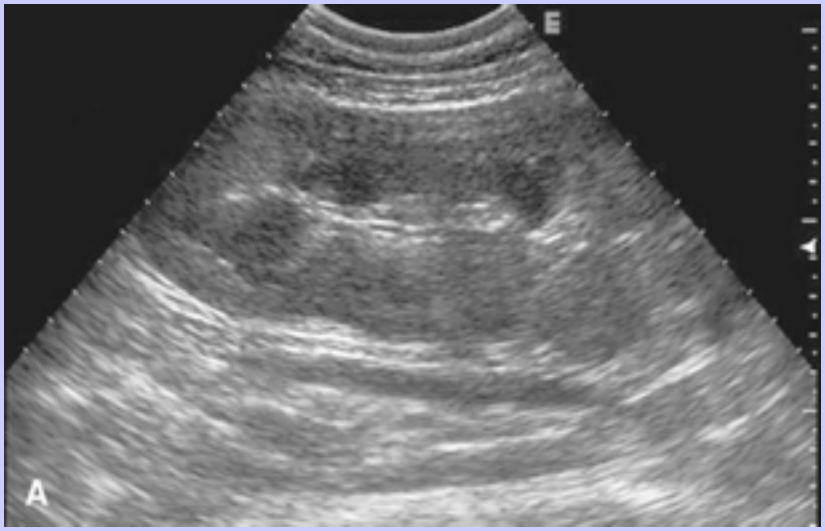
805

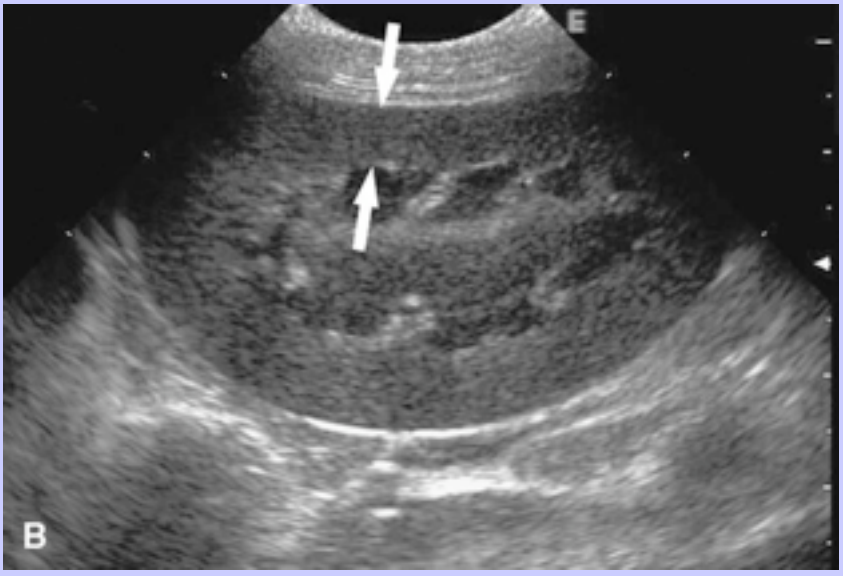
806

Bovine patients should be restrained in a head gate and standing stocks. Squeeze chutes are not ideal because access to the complete abdomen is seldom possible. Small ruminants can usually be restrained with halters or collars. Bovine and small ruminant patients seldom need sedation for restraint during the examination. Patients should be prepared for complete abdominal ultrasound examination by surgical clipping of the left and right sides of the abdomen ventral to a diagonal line extending from the transverse processes of the lumbar vertebrae to the level of the elbow joint approximately at the level of the ventral lung margin. The entire ventral abdomen should be clipped from the xyphoid to the inguinal region (Fig. 32-70). If only one organ is to be examined, then the specific anatomic region should be clipped with wide margins. The clipped area should be washed thoroughly with water, and ultrasound coupling gel should be applied to the region. If clipping is not possible, alcohol saturation of the skin and hair may be adequate in patients with a short hair coat. The examination is performed with a low-frequency, curvilinear transducer (2.5 to 5 MHz) in large patients such as adult cattle, which provides penetration to a depth of 24 to 30 cm. A medium frequency (4 to 8 MHz) “microconvex” curvilinear transducer is ideal for evaluating calves and small ruminants. In large patients, superficial structures near the skin surface should also be evaluated using the medium-frequency transducer when image quality permits. This transducer is also useful for performing transrectal ultrasonography of the left kidney, urinary bladder, ureters, and urethra in cattle.

Fig. 32-70 Patient preparation for abdominal ultrasound examination. The region to be clipped for complete abdominal evaluation is shown, including the paralumbar fossa region, the intercostal spaces from the ventral lung margin to the costochondral junctions and the entire ventrum from the xiphoid to the inguinal region.

Fig. 32-71 **A**, Sonogram of a normal right kidney viewed from the right paralumbar fossa region in a 5-year-old Holstein dairy cow. Note the lobulated shape and indistinct corticomedullary junction. This image was obtained with a 2.5-MHz curvilinear transducer at a depth of 20 cm. **B**, Sonogram of a normal right kidney viewed from the right paralumbar fossa region in a 4-year-old castrated male Nigerian Dwarf goat. Note the smooth renal capsule, ovoid shape, and distinct corticomedullary junction *(arrows)*. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 7 cm.





The examination should begin with detailed evaluation of the right paralumbar fossa region followed by evaluation of each intercostal space beginning at the ventral lung margin and scanning ventrally beyond the costochondral junctions. The ventral abdomen is then evaluated from xyphoid to inguinal region. The examination is repeated on the left side. The abdomen is evaluated for abnormalities of the kidneys, liver, gall bladder, pancreas, spleen, rumen, reticulum, omasum, abomasum, duodenum, small intestine, cecum, and colon and for the presence and character of peritoneal fluid.

32.118.1 Kidneys

32.118.1.1 NORMAL APPEARANCE (Fig. 32-71)

The right kidney is imaged from the right paralumbar fossa region and right eleventh to twelfth intercostal space at a scanning depth of 10 to 20 cm in cattle and 6 to 14 cm in small ruminants. The anatomic detail of the right kidney is greater than that of the left because of its more superficial location within the abdomen. In small ruminants the left kidney is routinely imaged in the right paralumbar fossa caudal to the right kidney at scanning depths of 8 to 14 cm. The left kidney in cattle can often be seen in this region as well. The left kidney cannot usually be visualized from the left side of the abdomen because it is obscured by the gas-filled rumen. Transrectal imaging of the left kidney should be performed in adult cattle suspected of having renal disease even when it is visualized transcutaneously, because it offers superior anatomic detail.

806

807

In cattle the normal right kidney has been reported to range from 8.1 to 11 cm in length and 4 to 7 cm in width.[332] Transrectally the left kidney has been reported to range in width from 4.5 to 7.5 cm in normal cattle. Transrectal length measurements of the left kidney were not reported, as it cannot be imaged in its entirety.[333] However, in the author's experience, normal bovine kidneys routinely measure up to 16 to 18 cm in length. Normal bovine kidneys demonstrate a lobulated appearance with an indistinct corticomedullary junction. Renal parenchyma should be less echogenic than hepatic parenchyma. The renal sinus demonstrates a hyperechoic appearance because of the presence of the renal calyces, adipose tissue, and connective tissue.[332,333]

In small ruminants, renal size can vary greatly depending on the size of the animal. In sheep the right kidney ranges from 7.1 to 8.9 cm in length and 3.4 to 5.5 cm in width, and the left kidney from 7.2 to 9.2 cm in length and 3.5 to 5.4 cm in width.[334,335] Small ruminants demonstrate smoothly marginated, oval kidneys. The renal capsule may be visible as a thin hyperechoic line. As in cattle, the renal parenchyma should be less echogenic than hepatic parenchyma. In contrast to cattle, the corticomedullary junction is clearly distinguishable. The renal pelvis demonstrates a hyperechoic appearance because of the presence of renal calyces, adipose tissue, and connective tissue.[334,335]

32.118.1.2 ABNORMAL FINDINGS

Changes in size, shape, architecture, and echogenicity are nonspecific ultrasonographic abnormalities that can be seen in ruminants with acute or chronic renal failure, amyloidosis, nephritis, and pyelonephritis. Abnormalities seen in patients with acute renal failure include renal enlargement, thickening of the renal cortex, and perirenal edema (Fig. 32-72). In cases of chronic renal failure, the kidneys are often smaller than normal and may be misshapen. Echogenic material can sometimes be seen within the ureters and renal calyces

of cows with pyelonephritis.[336] Ultrasound-guided percutaneous biopsy is commonly required to distinguish the specific cause of disease in patients with acute or chronic renal disease.

Fig. 32-72 Sonogram of the right kidney viewed from the right paralumbar fossa region in a 12-year-old pygmy goat buck with acute renal failure. Note the increased cortical echogenicity and thickness *(arrows)*. Perirenal edema *(arrowheads)* is seen surrounding the kidney. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 8 cm.

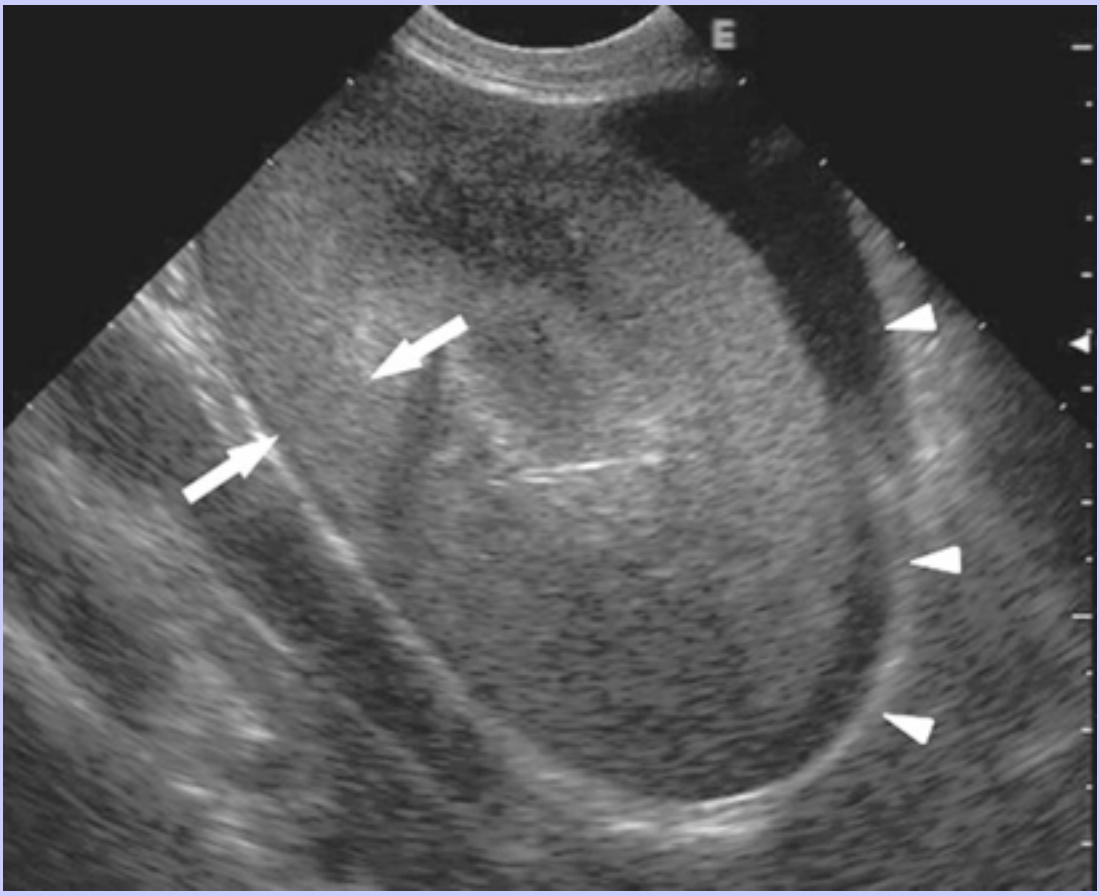


Fig. 32-73 Sonogram of a small right nephrolith *(arrows)* viewed from the right paralumbar fossa region in a 3-year-old Nigerian Dwarf doe presented because of abdominal pain. Note the strong shadow cast by the nephrolith. No dilation of the renal pelvis is seen. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 8 cm.

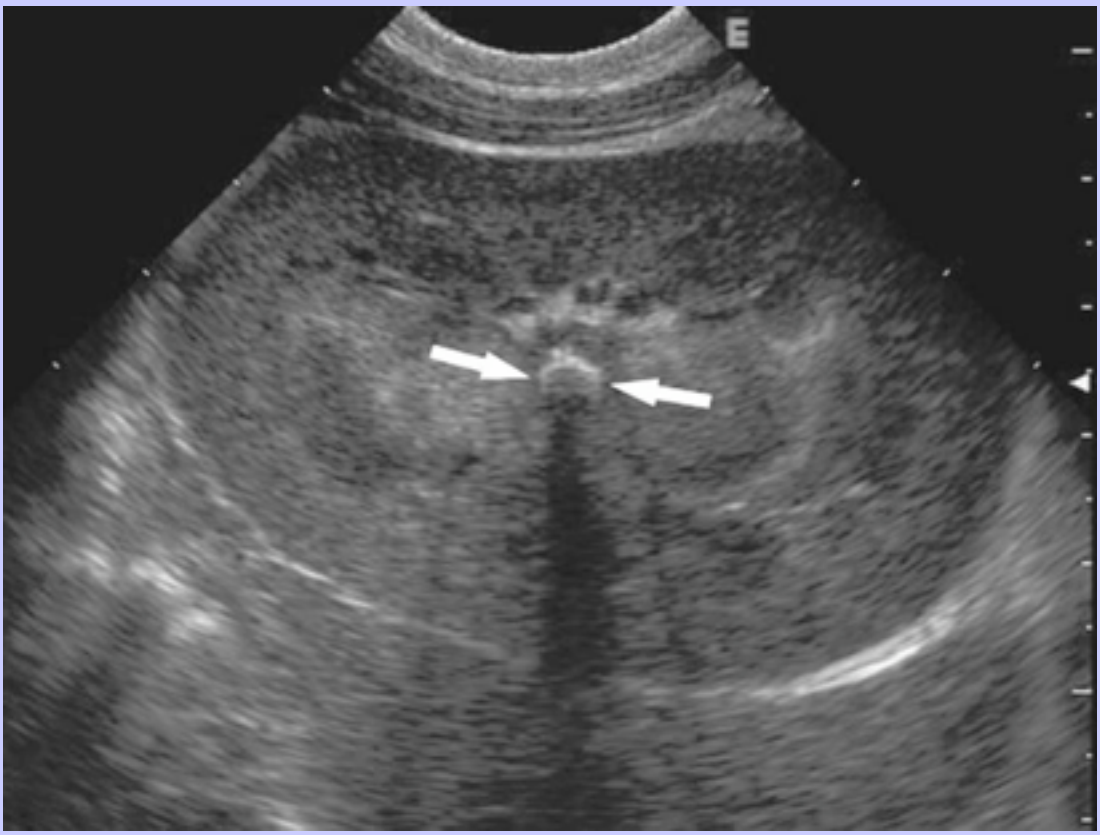
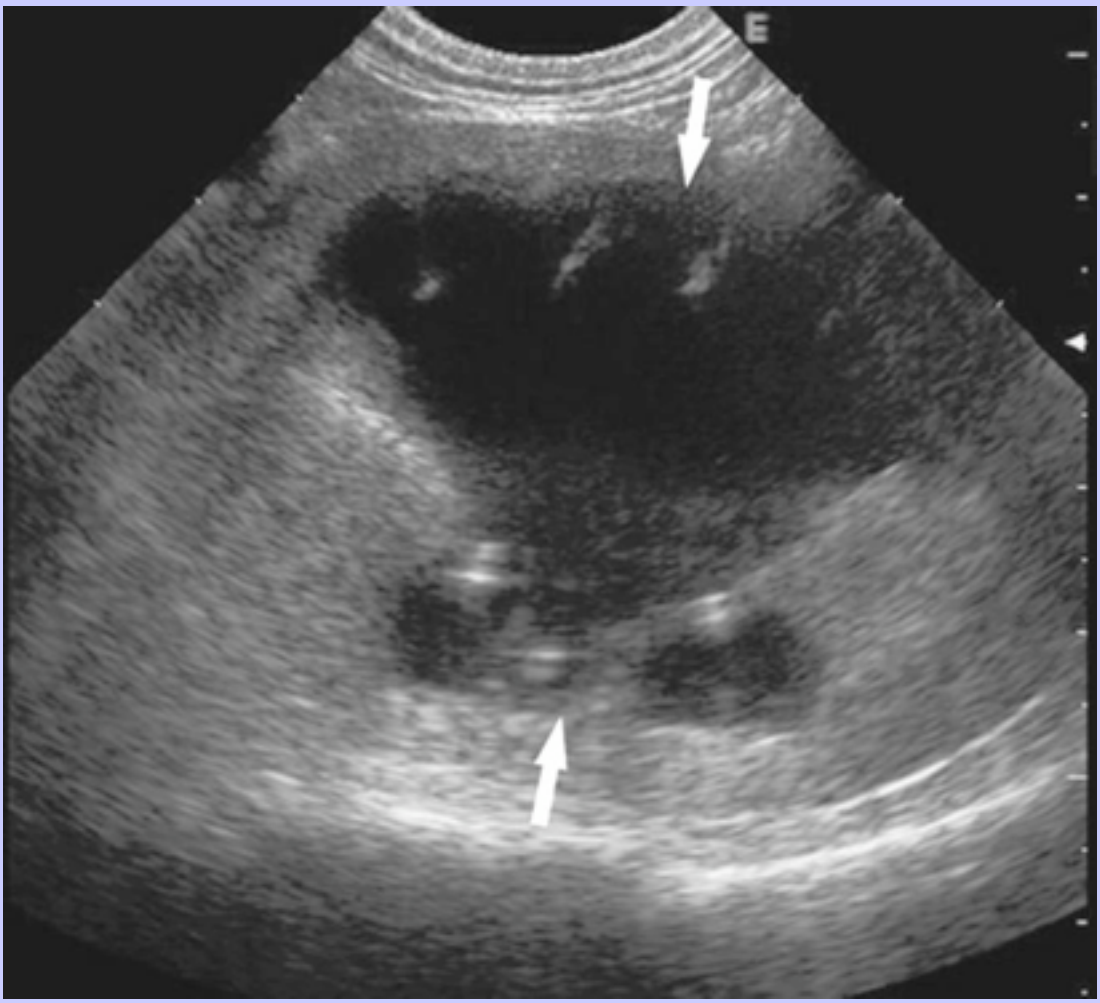


Specific renal abnormalities include nephrolithiasis, hydronephrosis, cortical cysts, renal neoplasia, and renal abscessation. Nephroliths are round or irregularly shaped, hyperechoic structures within the renal sinus that cast strong acoustic shadows (Fig. 32-73). Associated dilation of the renal sinus or calyces may be seen with obstructive nephrolithiasis. Hydronephrosis is characterized by dilation of renal calyces with anechoic urine and may be seen with a postrenal obstruction (Fig. 32-74). Hydronephrosis is commonly seen in small ruminants with obstructive urolithiasis. Transrectal evaluation of the ureters and urinary bladder is indicated in 807
bovine patients with hydronephrosis or obstructive nephrolithiasis to evaluate for the presence of ureteroliths 808
or uroliths within the bladder.

Fig. 32-74 Sonogram of severe hydronephrosis of the left kidney viewed from the right paralumbar fossa region in a 10-year-old pygmy doe. This doe had a uterine mass that was compressing the left ureter. Note the severe dilation of the renal pelvis *(arrows)*. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 7 cm.



The ultrasonographic appearance of cystic renal disease in ruminants has not been reported; however, congenital renal cysts are relatively common in cattle, sheep, and goats and should be readily recognizable via abdominal ultrasound.[337–339] Cortical cysts have been described in horses as thin-walled anechoic spheric structures seen within the renal cortex.[340] Single small cysts may be considered incidental findings.

Mass lesions within or obliterating the normal renal parenchyma can be seen with neoplasia or abscessation. Both renal abscessation and renal neoplasia are rare in ruminants.[337,338,341] Renal abscesses may be

distinguished from neoplasia based on their ultrasonographic appearance. Renal abscesses are usually encapsulated and contain anechoic to echogenic fluid. Ultrasound-guided percutaneous aspiration can be used to obtain a sample for cytology and culture and to facilitate drainage in affected animals. Ultrasound-guided biopsy is necessary to identify specific neoplastic processes.

32.118.2 Urinary Bladder and Ureters

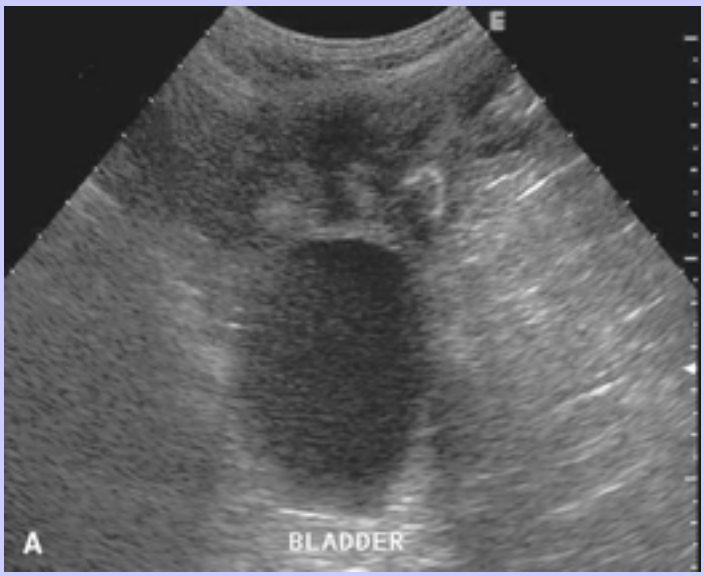
32.118.2.1 NORMAL APPEARANCE

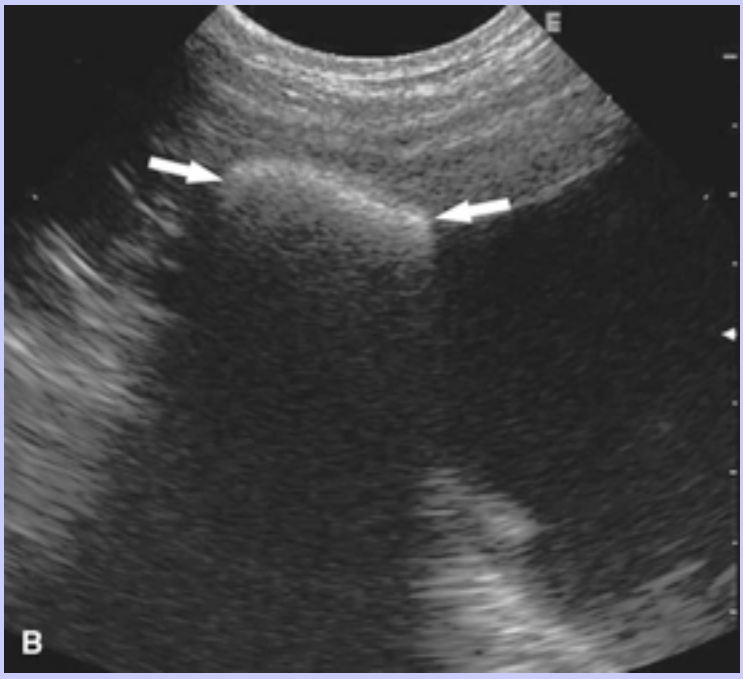
The urinary bladder is normally imaged from the right or left caudoventral abdomen in small ruminants at a scanning depth of 5 to 14 cm and appears as an oval or spheric structure with a thin wall containing anechoic urine (Fig. 32-75, *A*). The size and shape of the urinary bladder are dependent on its distention at the time of examination. The urinary bladder is often not visible transcutaneously in cows but can be evaluated transrectally along with the urethra and the distal portion of the right and left ureters.[333,342,343] The normal urethra is not visualized except at the onset of urination and appears as a thin anechoic line when distended with urine.[333] An attempt should be made to locate the ureters to the right and left of the urinary bladder at the trigone region. The ureters should then be followed cranially as far as they can be visualized.

32.118.2.2 ABNORMAL FINDINGS

Abnormalities of the urinary bladder include distention secondary to obstruction, thickening of the bladder (cystitis), cystic calculi, mass lesions, and rupture. Severe distention of the urinary bladder can be indicative of mechanical or functional obstruction. For this reason, transabdominal ultrasound examination is commonly used as a screening procedure for obstructive uropathy in small ruminants.[334,337,338] In affected animals the bladder will be markedly distended and may demonstrate multiple pinpoint echogenic or hyperechoic particles within the urine as well as cystic calculi.[334] Cystic calculi are seen within the bladder and can be hyperechoic or hypoechoic with a round or irregular shape. They may or may not cast strong shadows (Fig. 32-75, *B*). Mass lesions associated with the urinary bladder wall include neoplasia and hematoma that may be difficult to differentiate ultrasonographically.

Fig. 32-75 **A**, Sonogram of a normal urinary bladder viewed from the left inguinal region in a 2-year-old pygmy goat cross doe. This image was obtained with a 4-MHz curvilinear transducer at a depth of 15 cm. **B**, Cystic calculi *(arrows)* in an 11-year-old pygmy doe with urolithiasis. This image was obtained in the left inguinal region with a 7.5-MHz curvilinear transducer at a depth of 5 cm.





Urinary bladder rupture may occur secondary to obstructive urolithiasis or trauma. Ultrasound examination reveals an increased amount of free anechoic fluid within the abdomen. Definitive diagnosis can be made by comparing the concentration of creatinine in abdominal fluid to the serum concentration.

Ureteroliths may be seen on transrectal ultrasound examination in bovine patients and demonstrate the appearance of hyperechoic structures within the ureter that cast strong shadows. Marked ureteral dilation that appears as a tubular structure dilated with anechoic fluid is seen cranial to the ureterolith.[343] Thickening of the ureteral wall may occur secondary to inflammation. Ureteral rupture can occur secondary to obstruction and results in accumulation of anechoic fluid within the retroperitoneal space.[329]

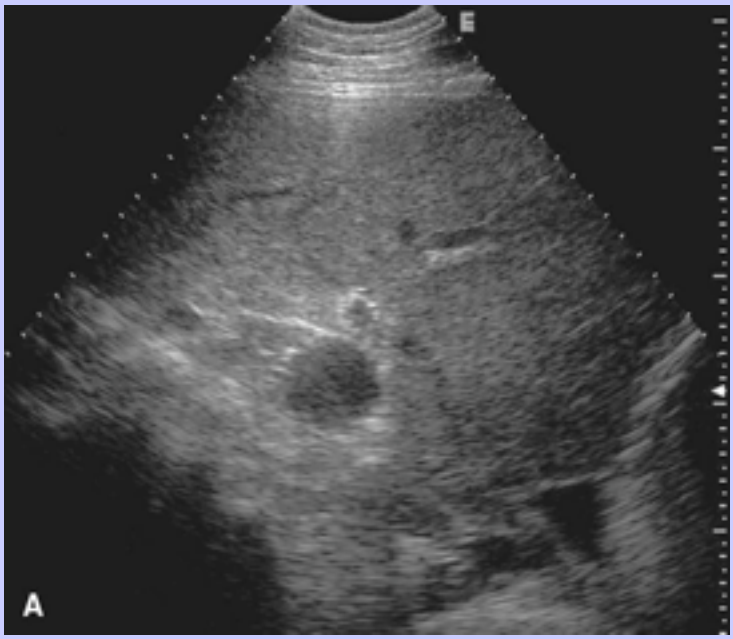
32.118.3 Liver

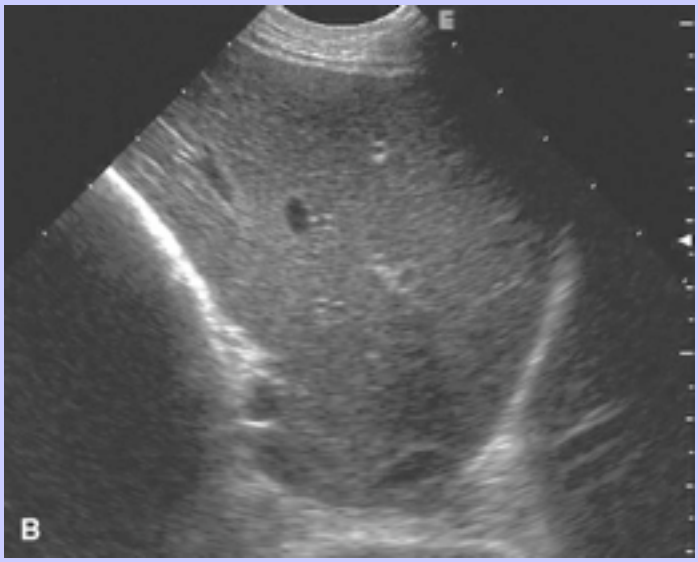
32.118.3.1 NORMAL APPEARANCE (Fig. 32-76)

The right liver lobe is imaged from the right sixth to twelfth intercostal spaces at a scanning depth of 6 to 14 cm in small ruminants and 20 to 30 cm in cattle and demonstrates a homogenous, echogenic appearance. The branching vasculature of the portal and hepatic veins can be seen in addition to fine vascular markings scattered throughout the hepatic parenchyma. The liver parenchyma is normally more echogenic than renal parenchyma and less echogenic than splenic parenchyma. In contrast to horses, an anatomic window for direct comparison of the liver and spleen does not exist in ruminants. Subjective comparison between the spleen on the left side and the liver on the right side should be undertaken with caution because changes in image quality and machine settings may lead to a false assessment of echogenicity. Bile ducts are not normally visible ultrasonographically. The ventral borders of the liver are usually sharp or mildly rounded and extend near or beyond the costochondral junctions. The most accurate method of assessing hepatic size in cattle is to measure the thickness of the liver overlying the portal vein (normally 5.1 to 14.1 cm) and the caudal vena cava (normally 8.2 to 15.4 cm).[344] Cows with high body condition scores and milk production will have larger livers than thin cows with decreased milk production.[334,345] The portal vein and caudal vena cava should also be assessed during the hepatic ultrasound examination. The portal vein is round and is commonly seen deep to the liver in the right eighth to twelfth intercostal spaces, ventral and lateral to the caudal vena cava. The caudal vena cava is usually seen only in the right eleventh and twelfth intercostal spaces, dorsal and deep to the portal vein.[345–348]

808
809

Fig. 32-76 **A**, Sonogram of normal liver viewed from the right tenth intercostal space in a 5-year-old Holstein dairy cow. This image was obtained with a 2.5-MHz curvilinear transducer at a depth of 27 cm. **B**, Sonogram of normal liver viewed from the right tenth intercostal space in a 12-year-old pygmy buck. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 10 cm. Dorsal is to the right and ventral is to the left.



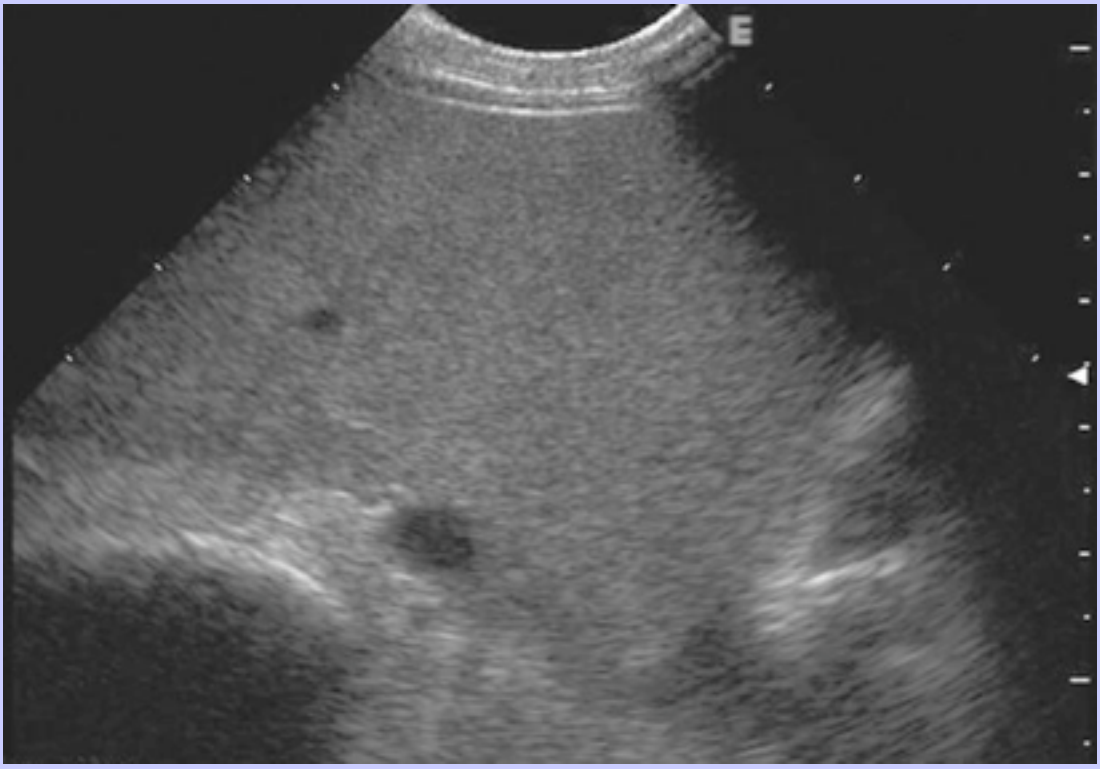


32.118.3.2 ABNORMAL FINDINGS

Nonspecific ultrasonographic abnormalities of the liver, including hepatomegaly, changes in echogenicity, and a decreased number of fine vascular markings, can be seen with hepatopathies from numerous causes including pyrrolizidine alkaloid toxicosis,[349] fatty liver disease, and diffuse infiltrative disease[350] (Fig. 32-77). Fatty liver disease, in particular, has been reported to result in an overall increase in hepatic echogenicity with decreased fine vascular markings.[350] Variable changes in echogenicity can also be seen during the parenchymal stage of fascioliasis.[351] Ultrasound-guided liver biopsies can be used to obtain a definitive diagnosis.

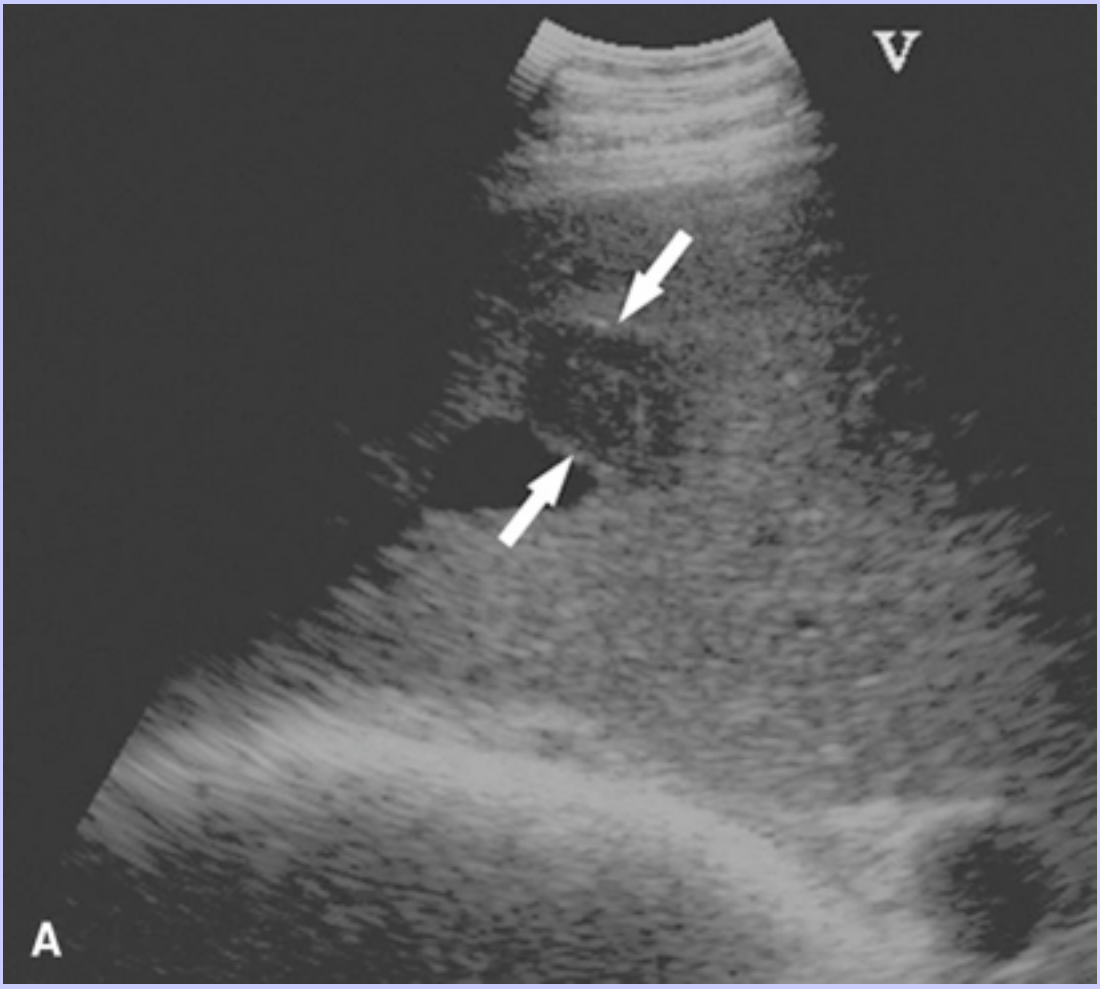
Hypoechoic or hyperechoic mass lesions within the hepatic parenchyma may represent abscessation or neoplasia. Hepatic abscessation is common in cattle and can occur with numerous disease processes, including cholangitis, traumatic reticuloperitonitis (TRP), or bacteremia secondary to rumenitis or omphalophlebitis. Hepatic abscesses demonstrate a variable appearance with a homogenous or mixed echogenicity, hyperechoic or hypoechoic contents, and a variable degree of encapsulation (Fig. 32-78).[345,352,353] The appearance of the abscess can change throughout the course of disease. Early abscesses may demonstrate a hypoechoic appearance without visible encapsulation. More chronic abscesses are usually well encapsulated with more echogenic contents. Gas echoes within the abscess are indicative of anaerobic infection. Ultrasound-guided percutaneous aspiration commonly yields fluid for culture and sensitivity.[345,352,353] Thrombosis of the caudal vena cava can occur secondary to hepatic abscessation. Affected cows show dilation of the caudal vena cava characterized by a change in shape from triangular to oval or round. Dilation of the hepatic veins may also be seen. Thrombi are typically not visualized ultrasonographically because of their location deep within the abdomen or in the thorax.[354]

Fig. 32-77 Sonogram of an abnormal liver demonstrating increased echogenicity and decreased fine vascular markings viewed from the right ninth intercostal space in a 4-year-old castrated male Nigerian Dwarf goat with hepatic lipidosis. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 8 cm. Dorsal is to the right and ventral is to the left.



Hepatic neoplasia is uncommonly reported in ruminants.[355] The ultrasonographic appearance of the liver is variable in these cases. The hepatic parenchyma may be diffusely affected, or discrete single or multiple masses may be seen. Metastatic lesions can be seen within the hepatic parenchyma or may distort the hepatic capsule along the serosal surface.[345,355] Ultrasound-guidance is recommended when obtaining percutaneous biopsies to avoid sampling unaffected parenchyma.

Fig. 32-78 **A**, Hepatic abscess measuring 3.6 cm × 2.2 cm *(arrows)* viewed from the right tenth intercostal space in a 4-year-old Holstein dairy cow with anorexia. This image was obtained with a 2.5-MHz curvilinear transducer at a depth of 20 cm. **B**, Small hepatic abscess *(arrows)* viewed from the right eleventh intercostal space in an 8-month-old Angora kid with disseminated *Rhodococcus equi* infection. This image was taken with a 13-MHz linear transducer at a depth of 3 cm. Dorsal is to the right and ventral is to the left.

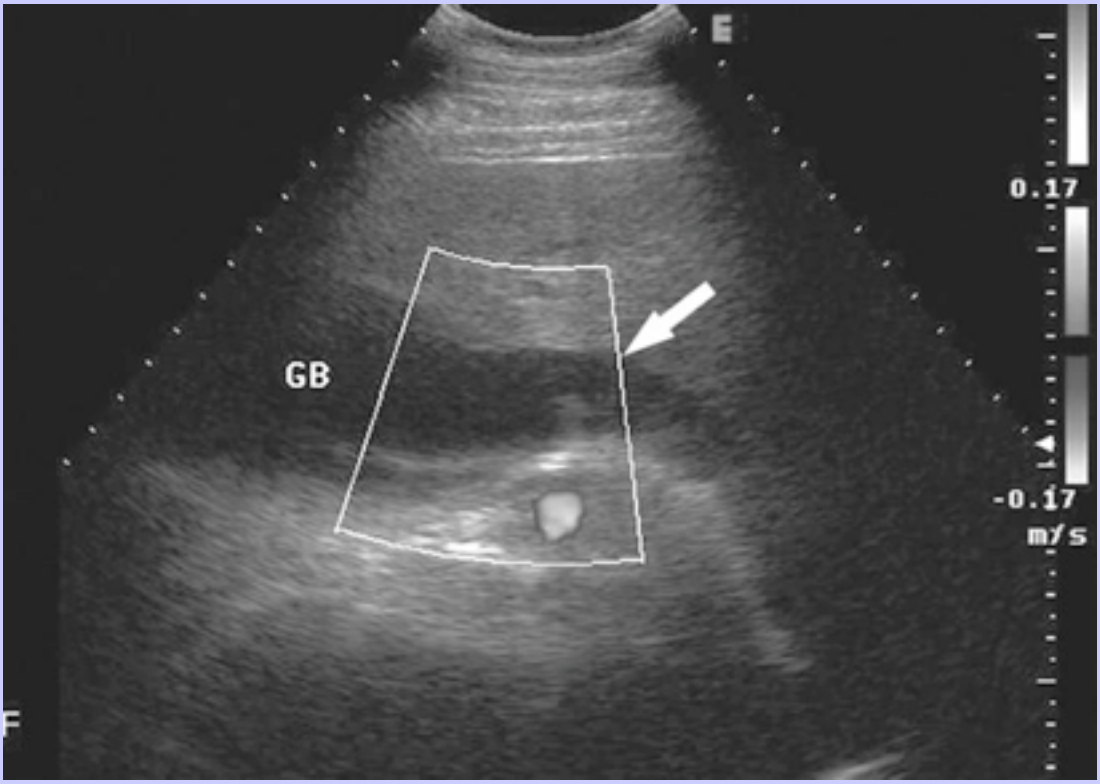


809

810

Ultrasound can be helpful to differentiate hepatocellular from obstructive cholestasis.[345,356,357] Ruminants with obstructive cholestasis will show changes consistent with extrahepatic or intrahepatic obstruction. Extrahepatic obstruction usually occurs at the level of the duodenal papilla. Ultrasonographic findings include dilation of the gall bladder with bile and echogenic sludge, dilation of the common bile duct, and dilation of the intrahepatic ducts (Fig. 32-79). Dilation of the intrahepatic ducts results in a “parallel channel sign” because intrahepatic ducts lie parallel to portal veins. The presence of gas echoes within the bile ducts is consistent with anaerobic suppurative cholangitis. The ductal phase of fascioliasis results in distention and tortuosity of the bile ducts.[351] Occasionally, moving echogenic forms can be seen within these bile ducts in infected sheep.[351] Mineralization of individual bile ducts can be seen in cases of chronic fascioliasis.[345,357] Ruminants with hepatocellular cholestasis may show ultrasonographic changes consistent with infiltrative disease or hepatic congestion or may have a normal hepatic ultrasound examination.

Fig. 32-79 Dilated cystic duct *(arrow)* viewed from the right ventral abdomen in a 3-year-old Holstein dairy cow with extrahepatic cholestasis. Color Doppler confirms the absence of blood flow in the cystic duct. This image was obtained from the right ventral abdomen using a 4-MHz curvilinear transducer at 21.5 cm. Dorsal is to the right and ventral is to the left.



32.118.4 Gall Bladder

32.118.4.1 NORMAL APPEARANCE (FIG. 32-80, *A*)

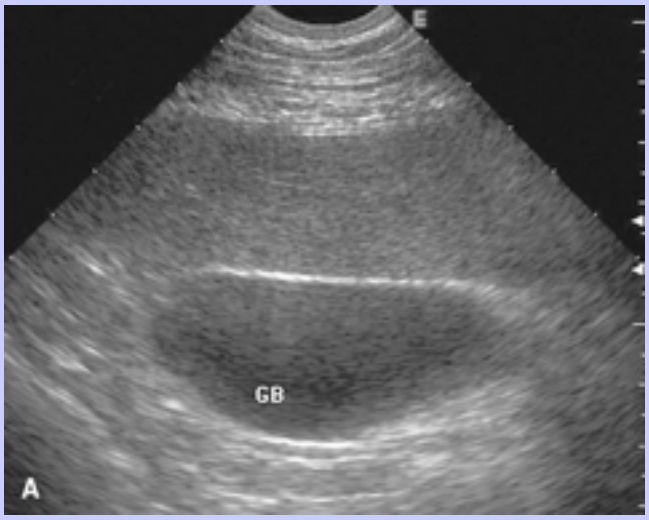
The gall bladder is visualized deep to the liver in the right ninth to eleventh intercostal spaces and is a thin-walled, round or oval structure filled with anechoic fluid that is usually visualized in only one or two intercostal spaces. However, ruminants with anorexia have no reflex stimulus for emptying the gall bladder. This creates a distended appearance without obstruction (Fig. 32-80, *B*).[347] The gall bladder is usually seen at a scanning depth of 6 to 10 cm in small ruminants and 12 to 18 cm in cattle.

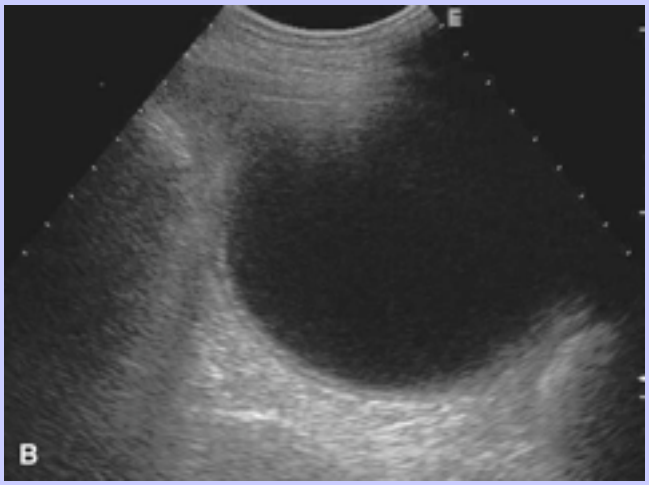
32.118.5

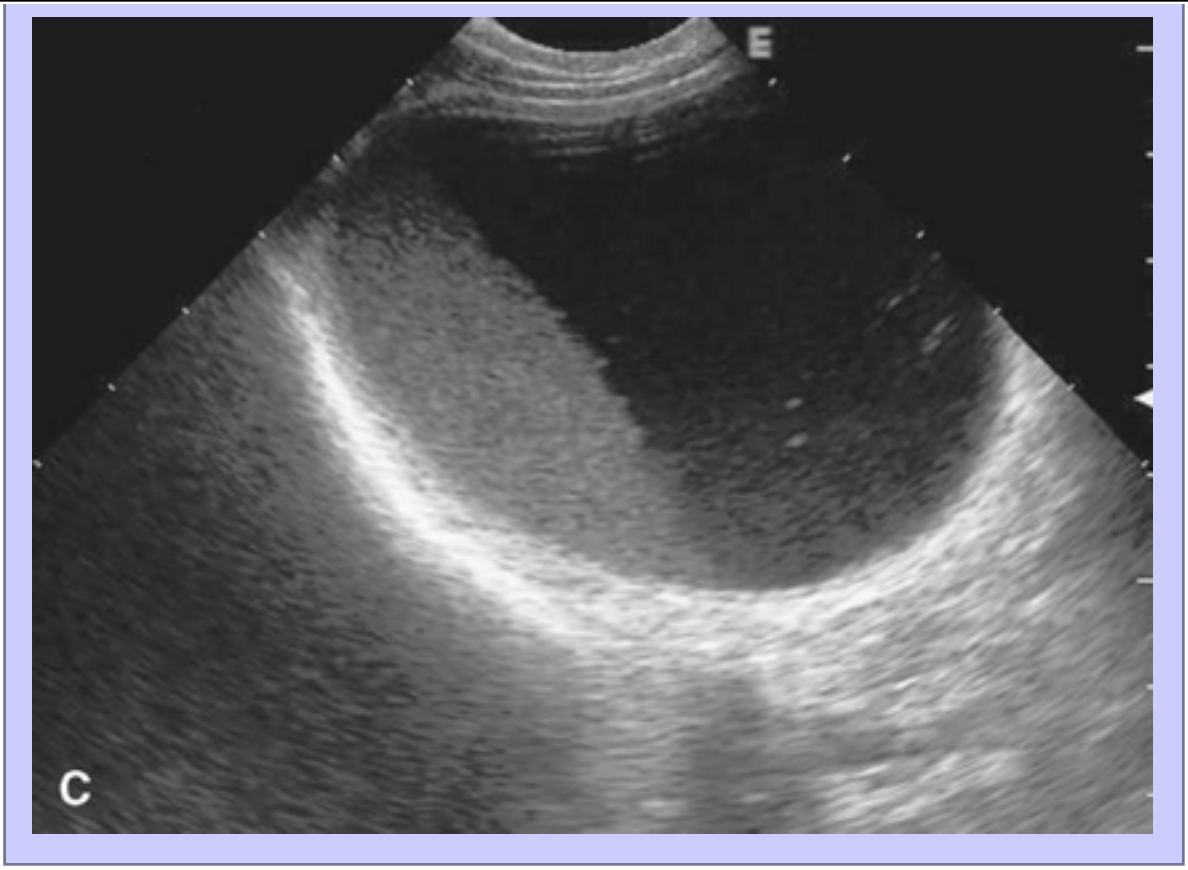
Abnormal Findings

Abnormalities of the gall bladder include, biliary distention, wall thickening, sediment accumulation, or cholelithiasis. As mentioned earlier, it is important to differentiate gall bladder distention secondary to anorexia or fasting from distention secondary to cholestasis. Cholestatic obstruction is a serious condition that can lead to rupture if the obstruction is not resolved.[358] Wall thickening may be secondary to edema or inflammation. Choleliths appear as discrete hyperechoic structures that cast strong shadows. Sediment, on the other hand, demonstrates an amorphous echogenic to hyperechoic appearance and will have a dependent location (ventral in standing animals) within the gall bladder (Fig. 32-80, *C*). Ultrasound-guided cholecystocentesis has been reported to be a valuable diagnostic technique in cases suspect for liver fluke infection *(Fasciola hepatica, Dicrocoelium dendriticum)*.[359] Transhepatic cholecystocentesis is considered safer than transcutaneous aspiration as it decreases the likelihood of peritonitis secondary to bile leakage into the abdomen.[360] Bile examination for detection of fluke eggs is superior to fecal examination because liver fluke eggs are stored in the gall bladder for weeks.[359]

Fig. 32-80 **A**, Sonogram of a normal gall bladder viewed from the right tenth intercostal space in a 2-year-old Hampshire ram. This image was obtained with a 5.5-MHz curvilinear transducer at a depth of 10 cm. **B**, Sonogram of a distended gall bladder viewed from the right tenth intercostal space in a 3-year-old Holstein dairy cow with anorexia. This image was obtained with a 3.5-MHz curvilinear transducer at a depth of 16 cm. **C**, Sonogram of gall bladder distention with bile sediment viewed from the right twelfth intercostal space in a 12-year-old Pygmy buck. This image was obtained with a 7.5-MHz transducer at a depth of 10 cm. Dorsal is to the right and ventral is to the left.







32.118.6 Pancreas

32.118.6.1 NORMAL APPEARANCE

Ultrasonographic imaging of the right lobe and body of the bovine pancreas has been reported in the literature.[361] The pancreas is visualized in the right paralumbar fossa region and the right eleventh and twelfth intercostal spaces ventral to the liver and right kidney. The left lobe cannot be visualized because of its deep location within the abdomen. The pancreas demonstrates a triangular shape and is isoechoic or slightly hyperechoic to the adjacent liver.[361]

32.118.6.2 ABNORMAL FINDINGS

Ultrasonographic abnormalities of the ruminant pancreas have not been described; however, changes in echogenicity secondary to pancreatitis and dilation of the accessory pancreatic duct secondary to masses or calculi have been reported in other species.[361]

32.118.7 Spleen

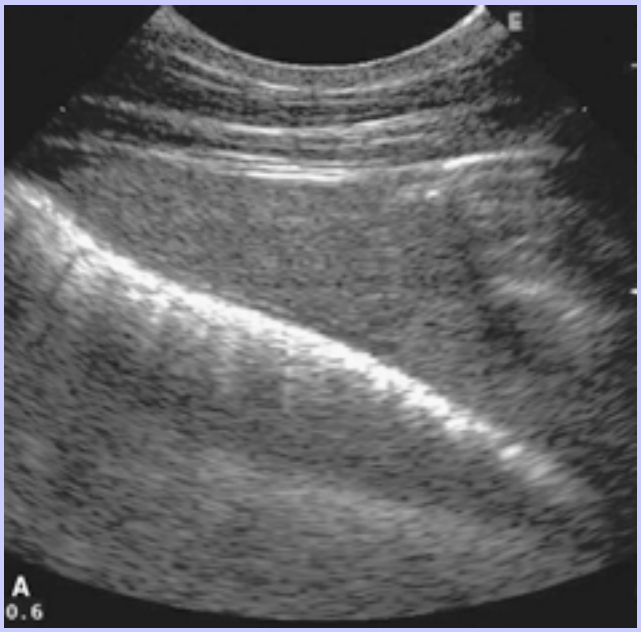
32.118.7.1 NORMAL APPEARANCE (Fig. 32-81)

The spleen is visualized in the left seventh to twelfth intercostal spaces between the rumen and body wall at the cranial extent of the rumen at a scanning depth of 6 to 14 cm in small ruminants and 16 to 28 cm in cattle. Splenic size is variable, and the spleen may extend to the ventral midline in normal cows.[362] The spleen demonstrates a homogenous appearance and appears more echogenic and less vascular than the liver. The splenic capsule appears as a thin hyperechoic line.[362]

32.118.7.2 ABNORMAL FINDINGS

Splenic abnormalities may include changes in echogenicity indicative of diffuse parynchemal disease or discrete masslike lesions consistent with neoplasia or abscessation. Suppurative splenitis or abscessation can occur secondary to septicemia or TRP (Fig. 32-82).[331] Splenic neoplasia has also been reported in ruminants.[362] Ultrasound-guided percutaneous aspiration or biopsy may provide definitive cytology, culture, or histopathologic diagnosis but should be undertaken with caution in compromised patients because of the risk of hemorrhage.

Fig. 32-81 **A**, Sonogram of normal spleen viewed from the left ninth intercostal space in a 12-year-old pygmy buck. Note that the spleen appears less vascular relative to normal liver. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 4 cm. **B**, Sonogram of normal spleen viewed from the left tenth intercostal space in a 4-year-old Holstein dairy cow. This image was obtained with a 2.5-MHz curvilinear transducer at a depth of 16 cm. Dorsal is to the *right* and ventral is to the *left*.



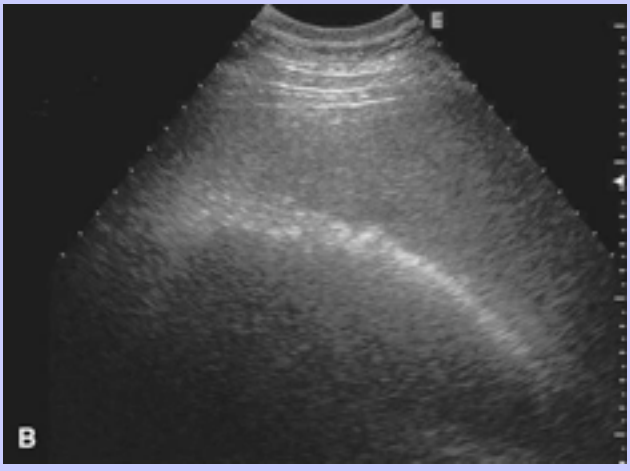


Fig. 32-82 Sonograms of severe diffuse splenitis viewed from the left twelfth

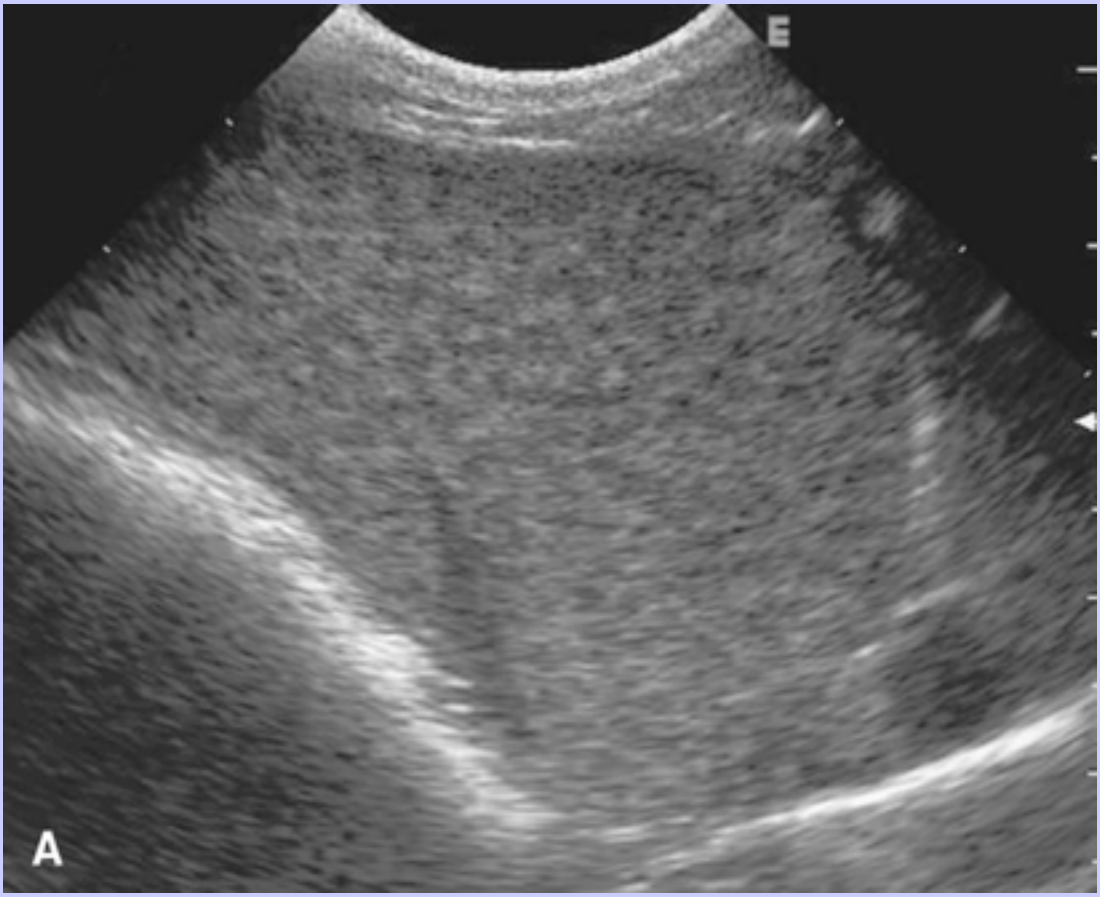
intercostal space in an 8-month-old Angora kid with disseminated *Rhodococcus equi* infection. **A**, Note the diffusely mottled appearance of the spleen. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 6 cm. **B**, This image illustrates the importance of evaluating superficial structures with the highest-frequency transducer available. Note the superior anatomic detail in this image obtained with a 13-MHz linear transducer at a depth of 4 cm. Dorsal is to the *right* and ventral is to the *left*.

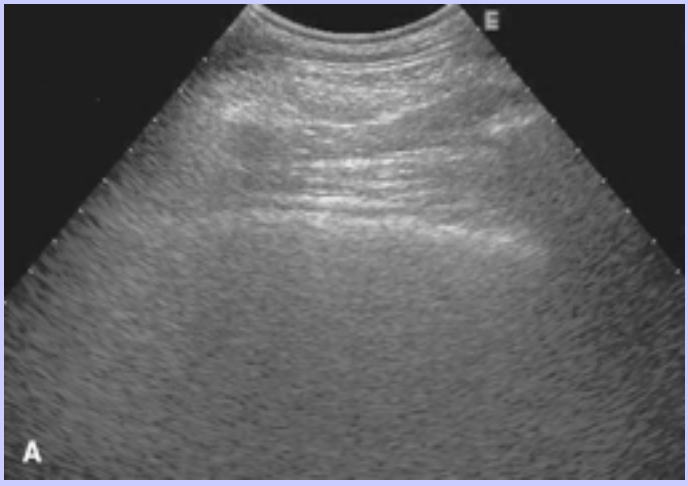


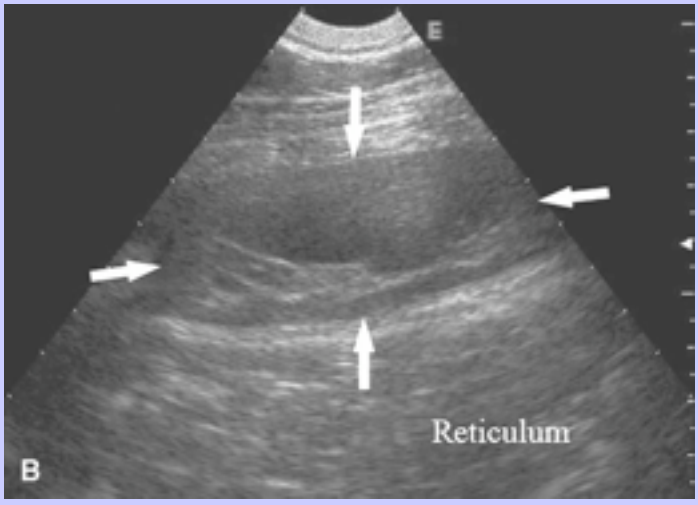
32.118.8 Reticulum

32.118.8.1 NORMAL APPEARANCE (Fig. 32-83, *A*)

The reticulum is seen in the cranioventral abdomen and both the left and right sixth and seventh intercostal spaces ventral to the spleen and cranial to the rumen at a scanning depth of 4 to 8 cm in small ruminants and 10 to 14 cm in cattle. The reticulum should be evaluated during the examination for normal biphasic contractions, which should occur approximately once per minute. The reticulum contracts approximately 5 to 10 cm away from the abdominal wall during the first phase of contraction and more than 17 cm away during the second phase of contraction.[363] When in a relaxed state the reticulum appears as a semicircular structure immediately adjacent to the ventral abdominal wall. Reticular contents cannot normally be visualized because of their gaseous composition. The honeycomb appearance of the reticular mucosa is not commonly distinguishable ultrasonographically.

Fig. 32-83 **A**, Sonogram of normal reticulum viewed from the left cranioventral abdomen in a 5-year-old Holstein dairy cow. This image was obtained with a 3.5-MHz curvilinear transducer at a depth of 14 cm. **B**, Sonogram of a small reticular abscess *(arrows)* viewed from the left seventh intercostal space in an 8-year-old Charolais beef cow suspected of having traumatic reticuloperitonitis. A small wire was seen within the reticulum on abdominal radiographs. This image was obtained with a 5.5-MHz curvilinear transducer at a depth of 12 cm. Dorsal is to the *right* and ventral is to the *left*.



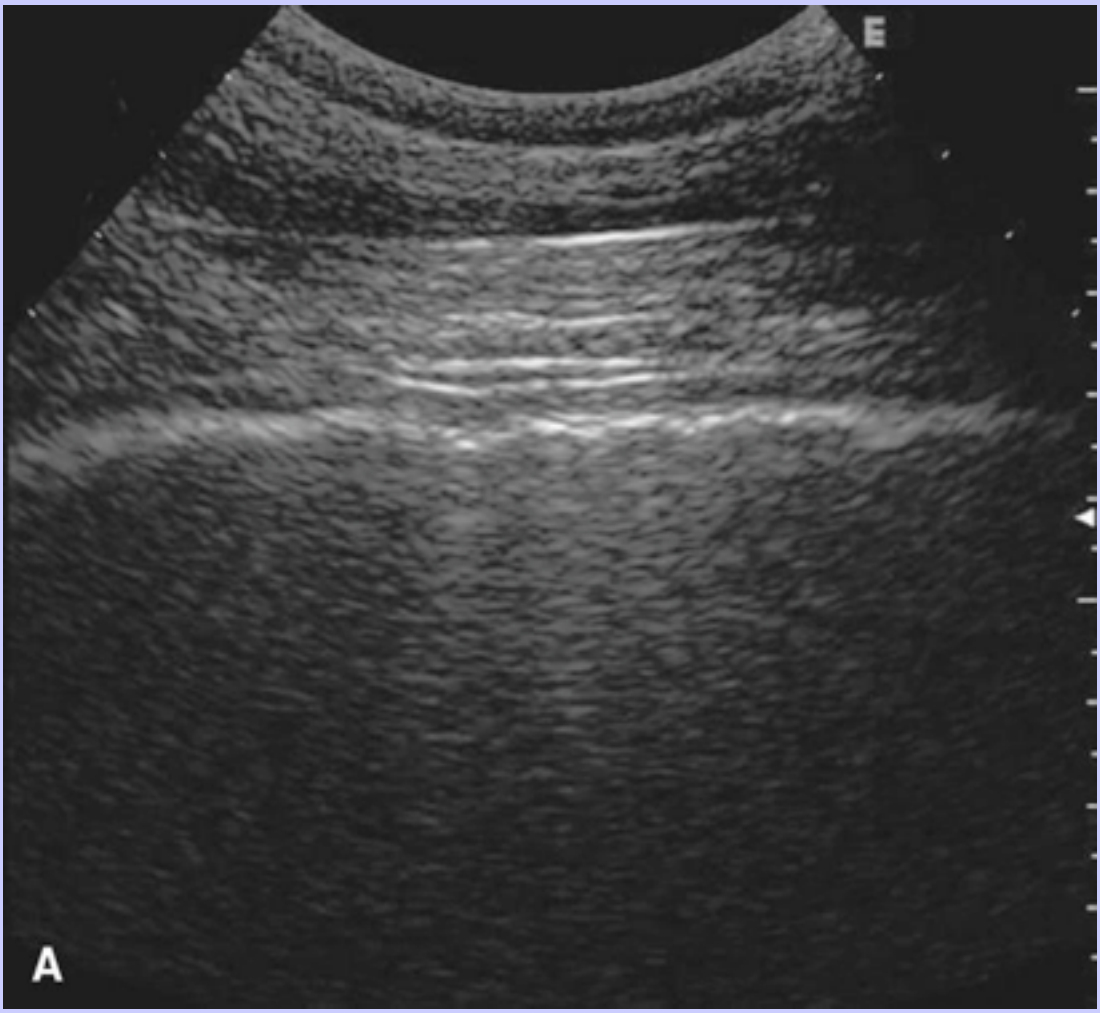


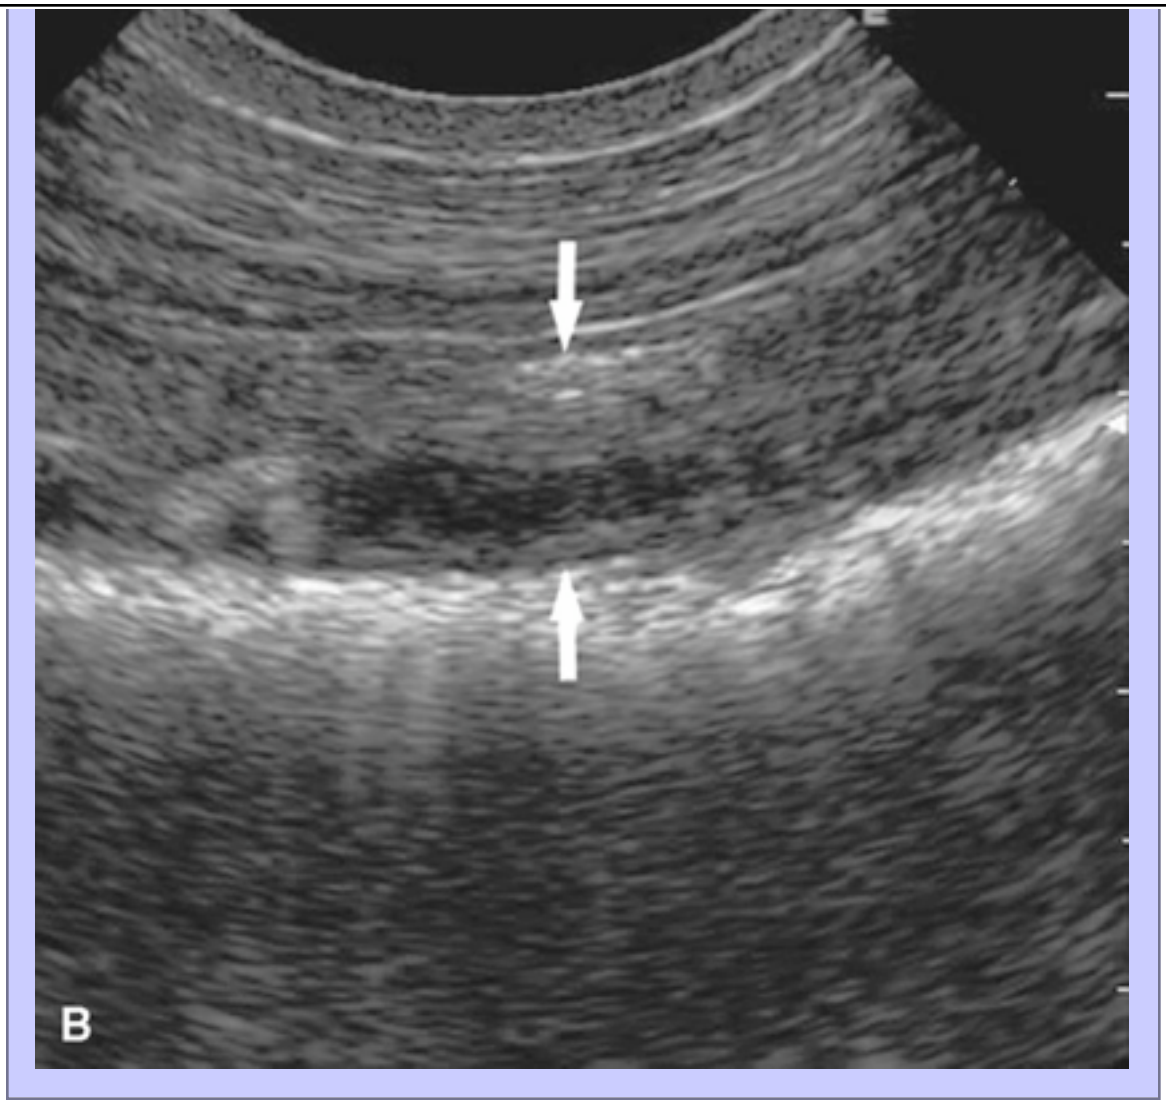
32.118.8.2 ABNORMAL FINDINGS

Reticular abnormalities are primarily associated with TRP. Reticular abscesses caused by TRP can be seen between the reticulum and body wall, spleen, diaphragm, or liver.[364] These abscesses are usually well encapsulated with an echogenic capsule and may contain anechoic to echogenic contents (Fig. 32-83, *B*). Abscesses adjacent to the body wall can be incised and drained transcutaneously with ultrasound guidance.[364] Other abnormalities associated with TRP include changes in the contour of the reticulum, echogenic fibrinous deposits on the reticular serosa, nonencapsulated fibrinous exudate between the reticulum and body wall, and adhesions between the reticulum and the peritoneum or adjacent organs.[331,364,365] Reticular contractions are often absent, reduced, or indistinct in affected animals and can be an indication of adhesions between the reticulum and body wall. The causative foreign bodies are rarely identified ultrasonographically because of the gaseous composition of reticular contents and are better assessed via radiography.[331,365] Reticular hypermotility has been described in cows with reticuloomasal obstruction.[366]

Fig. 32-84 **A**, Sonogram of normal rumen viewed from the left paralumbar

fossa region in a 5-year-old Holstein dairy cow. This image was obtained with a 2.5-MHz curvilinear transducer at a depth of 9 cm. **B**, Sonogram of severely thickened ruminal wall measuring 14.9 mm *(arrows)* viewed from the left paralumbar fossa region in a 12-year-old pygmy buck that recently underwent rumenotomy. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 4 cm. Dorsal is to the *right* and ventral is to the *left*.





32.118.9 Rumen

32.118.9.1 NORMAL APPEARANCE (Fig. 32-84, *A*)

The rumen normally occupies the entire left paralumbar fossa region, the left eighth to twelfth intercostal spaces, and the left caudoventral abdomen and is seen directly adjacent to the body wall. The ruminal wall is seen as a smooth, thin hypoechoic line. Hyperechoic gas within the rumen creates a hyperechoic line immediately adjacent to the wall. Ruminal contents are not commonly visualized because of their gaseous composition. The wall of the craniodorsal blind sac, the ventral sac of the rumen, and the ruminoreticular groove are seen immediately caudal to the reticulum in the cranioventral left intercostal spaces.[331] Contraction of the craniodorsal blind sac of the rumen is commonly seen after the second reticular contraction.[331]

813

814

32.118.9.2 ABNORMAL FINDINGS

Thickening of the ruminal wall may be seen in cases of ruminitis or secondary to ruminotomy or ruminal trocarization (Fig. 32-84, *B*). Abcesses between the rumen and the left body wall may also develop secondary to surgical procedures performed in the left flank region.[367] Such abscesses are usually well encapsulated and contain anechoic to echogenic contents. Echogenic strands of fibrin or fibrinous deposits may be found in association with the abscess. Localized or generalized peritonitis may also occur secondary to abscessation. Abscesses adjacent to the body wall can be aspirated via ultrasound guidance for cytology and culture.

32.118.10 Omasum

32.118.10.1 NORMAL APPEARANCE

The omasum is seen adjacent to the body wall in the right cranioventral intercostal spaces. Although fairly similar to the reticulum in appearance, the omasum can be differentiated by an increased wall thickness.[331] Omasal contents are seldom visualized because of their gaseous nature.

32.118.10.2 ABNORMAL FINDINGS

Ultrasonographic abnormalities of the omasum are uncommon and have not been reported in the literature.

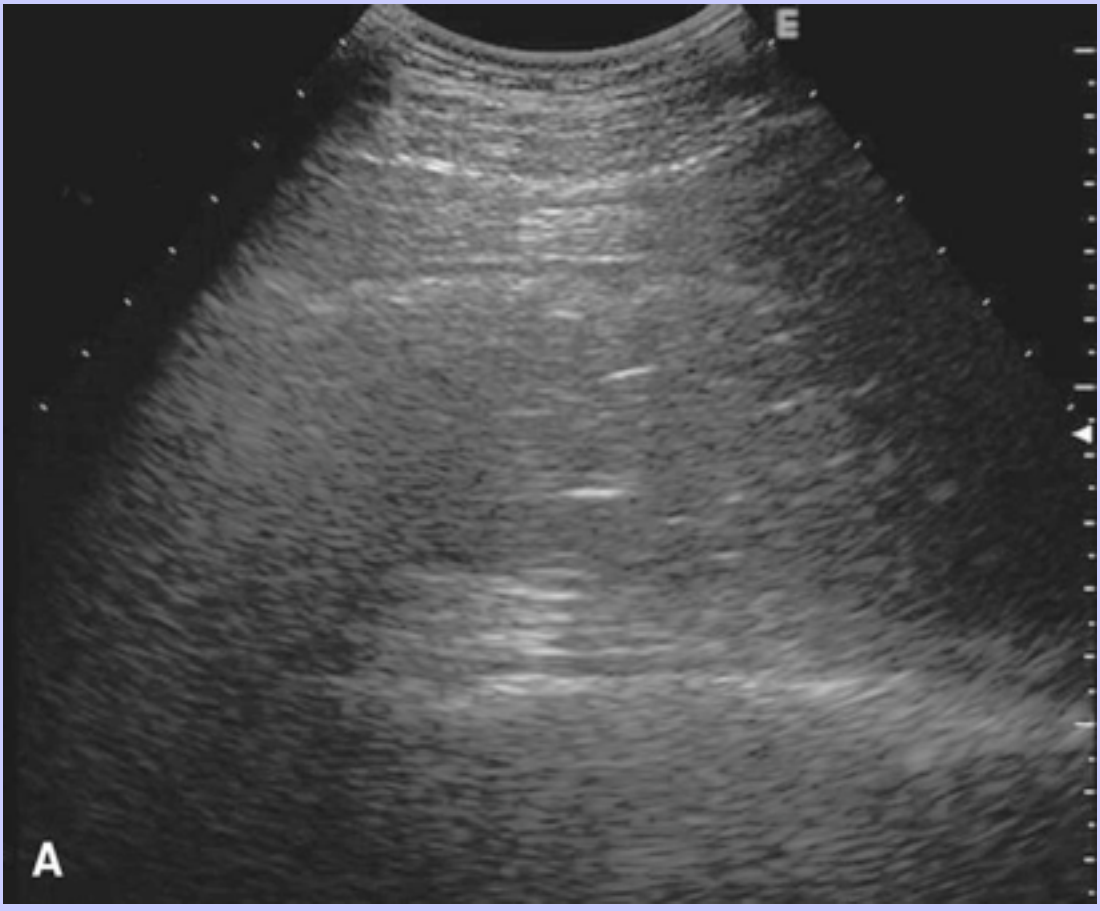
32.118.11 Abomasum

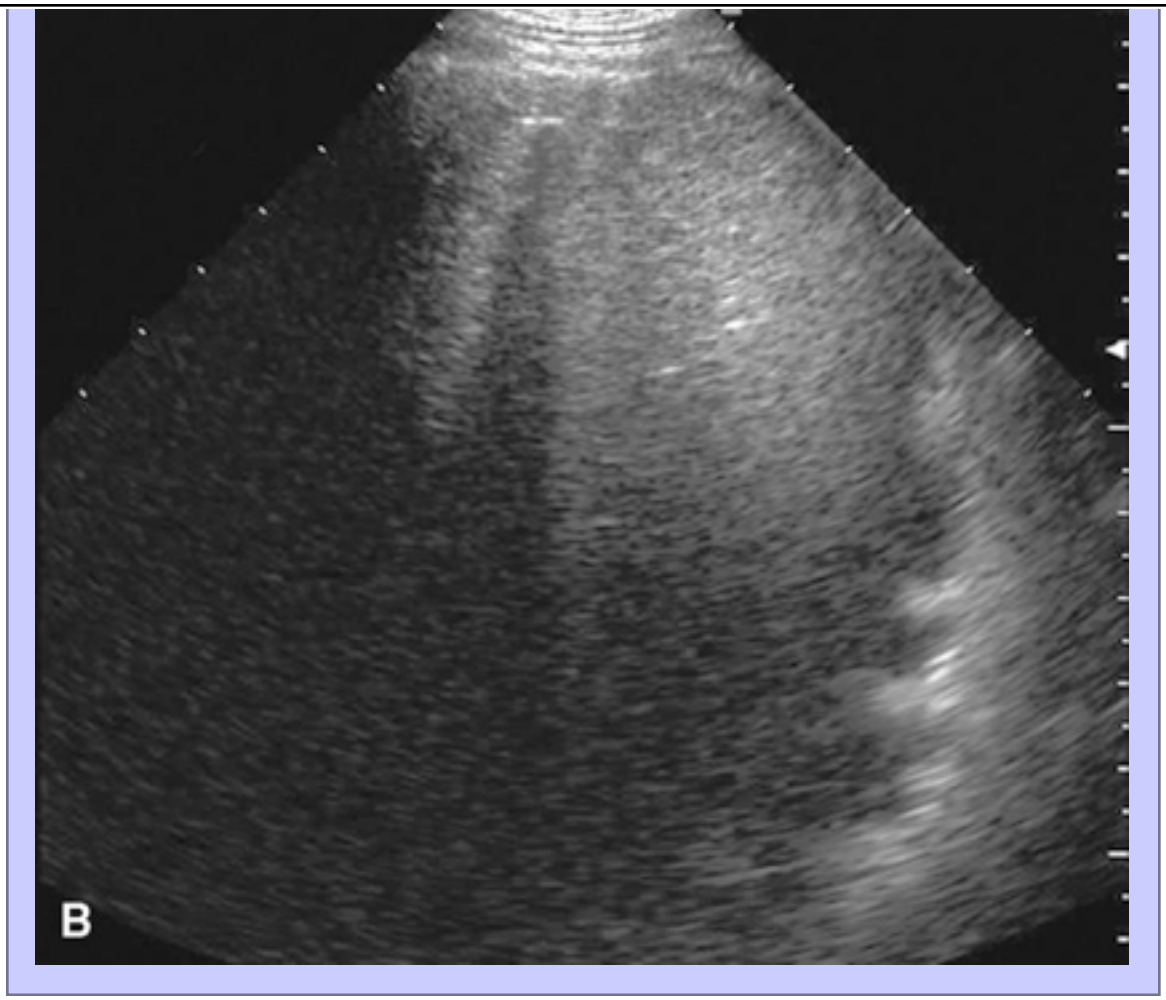
32.118.11.1 NORMAL APPEARANCE (Fig. 32-85, *A*)

The abomasum is normally visualized in the cranioventral abdomen along ventral midline and in both the right and left paramedian regions caudal to the xiphoid process. In general, the abomasum is situated more to the right of the ventral midline. The abomasum can be distinctly identified because of its visible fluid contents, which demonstrate a heterogeneous anechoic to echogenic appearance. The abomasal wall appears as a thin hyperechoic line. Abomasal folds are sometimes visible. Passive movement of the abomasum is seen during reticular contractions; however, abomasal contractions are usually not seen. The pylorus is rarely identified.[368]

Fig. 32-85 **A**, Sonogram of normal abomasum viewed from the right

cranioventral abdomen in a 5-year-old Holstein dairy cow. This image was obtained with a 2.5-MHz curvilinear transducer at a depth of 9 cm. Note that abomasal contents are visible. **B**, Sonogram of severe abomasal distention viewed from the right ventral paralumbar fossa region in an 8-year-old pygmy doe with severe bloat. Postmortem examination revealed marked pyloric stenosis. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 9 cm. Dorsal is to the *right* and ventral is to the *left*.





32.118.11.2 ABNORMAL FINDINGS

Reported ultrasonographic abnormalities of the abomasum in cattle include left and right abomasal displacement and functional or mechanical pyloric stenosis.[329,331] In cattle with left abomasal displacement, the rumen is seen adjacent to the body wall ventrally; however, the abomasum is imaged between the rumen and the left body wall dorsally. The rumen is displaced medially at this level, deep to the abomasum. Fluid and ingesta are visible ventrally within the abomasum, and a gas cap is visible dorsally.[369] With right abomasal displacement, the abomasum is imaged adjacent to the right body wall in the right intercostal spaces. In this case the liver is displaced medially, deep to the abomasum, and cannot be seen. Similar to left dorsal displacement, fluid and ingesta contents are visible in the ventral aspect of the abomasum, and a gas cap is visible dorsally.[329,331] In cases of pyloric stenosis, the abomasum is dilated but not displaced (Fig. 32-85, *B*).[331] No gas accumulation is seen, and the abomasal contents demonstrate an anechoic or hypoechoic, fluid appearance. If the abomasal distention is a result of delayed abomasal emptying secondary to ileus, distended, amotile loops of small intestine will be visible in the right ventral abdomen.[331]

32.118.12 Small Intestine

32.118.12.1

NORMAL APPEARANCE (Fig. 32-86, *A*)

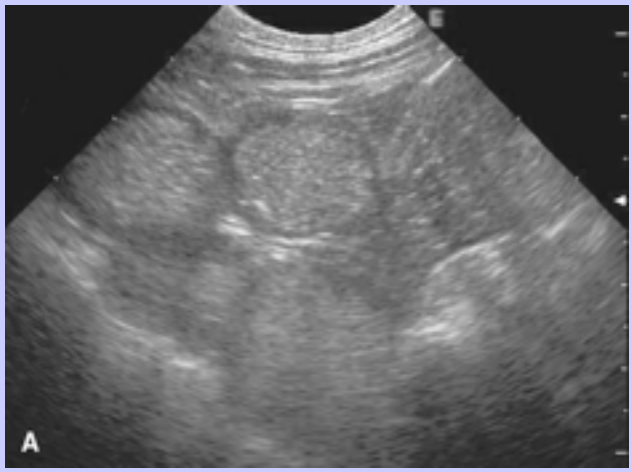
The descending duodenum is visualized from the right tenth intercostal space caudally to the right paralumbar fossa region. The ascending duodenum cannot be visualized because of its location deep within the abdomen. The cranial duodenum may be seen deep or ventral to the gall bladder in the right tenth or eleventh intercostal space. The descending duodenum is then visible deep to the liver in the right eleventh and twelfth intercostal spaces and becomes progressively superficial as it courses caudodorsally such that it is seen adjacent to the body wall in the right paralumbar fossa region. Duodenal contents are often visible and consist of a fluid, feed, and/or mucous mixture with mixed echogenicity. Occasionally, gaseous contents are seen within the duodenum. The descending duodenum can be differentiated from jejunum and ileum by its anatomic location within the abdomen.

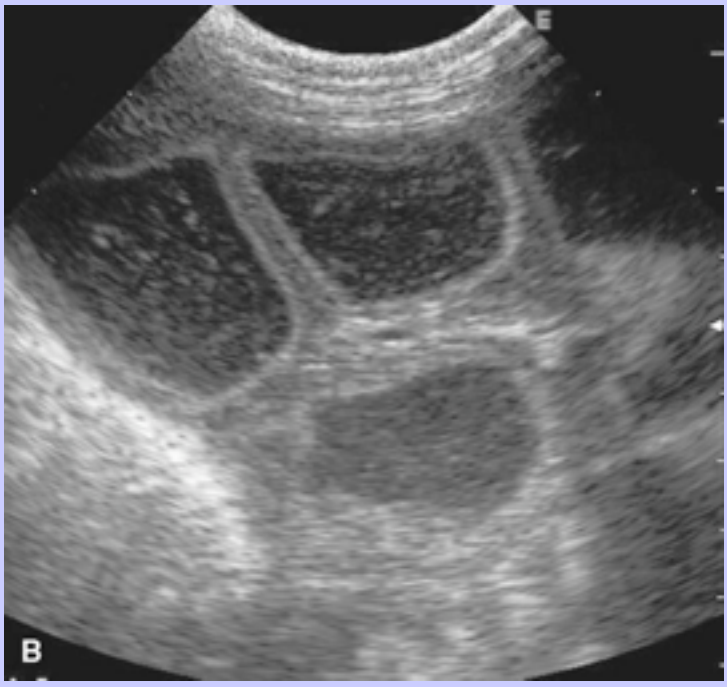
814

815

Fig. 32-86 **A**, Sonogram of normal small intestine viewed from the right

paralumbar fossa region in a 5-year-old Nubian buck. This small intestine demonstrated normal consistent motility. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 7 cm. **B**, Moderate small intestinal distention viewed from the right ventral abdomen in a 2-month-old Holstein heifer calf with clostridial enteritis. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 5 cm.





The jejunum and ileum cannot be differentiated from one another in adult cattle and are usually seen in the

right caudal intercostal spaces, right paralumbar fossa region, and right caudoventral abdomen. Loops of jejunum and ileum demonstrate a similar appearance to the duodenum, with anechoic to echogenic fluid and feed contents. Gaseous contents may also occasionally be seen in the jejunum and ileum. Loops may be seen both longitudinally and transversely and demonstrate consistent, active motility. The wall thickness of normal small intestine is 2 to 3 mm, and the normal diameter ranges from 2 to 4 cm in adult cattle.[370]

32.118.12.2 ABNORMAL FINDINGS

Motility, distention, and wall thickness are the most important variables for evaluating small intestinal abnormalities via ultrasound. Ultrasonographic evidence of ileus, characterized by distended, hypomotile to amotile loops of small intestine, can be seen in patients with functional ileus, obstruction, strangulation or incarceration, volvulus, intussusception, and impaction of the small intestine. Small intestinal obstruction may be intraluminal, caused by foreign body, bezoar, impaction, or intraluminal mass or clot formation (hemorrhagic bowel syndrome [HBS]).[329,331,370,371] The ventral abdomen should be carefully evaluated in patients suspected of having small intestinal obstruction because affected small intestine is heavier than normal and falls to the most dependent portion of the abdomen. Distended small intestine demonstrates the appearance of a static tubular structure filled with anechoic to echogenic fluid (Fig. 32-86, *B*). Small intestinal intussusceptions demonstrate a characteristic appearance often described as a “target sign” or “bull's eye” created by a loop of bowel imaged within a second loop.[371] Extraluminal causes of small intestinal obstruction include compression from adjacent structures such as intraabdominal abscesses or masses or entrapment, which can occur secondary to adhesion formation, rents in the mesentery, extramural masses, or malposition of other abdominal organs.[372] Regardless of cause, small intestinal distention will be seen oral to the obstruction. Small intestinal thickening may also be seen oral to the obstruction owing to secondary hypertrophy. Fluid and feed contents may be seen flowing back and forth with little to no progressive motility. This movement should not be confused with normal peristalsis. Small intestine aboral to the obstruction may appear collapsed and hypomotile. Despite thorough evaluation of the ventral abdomen, the specific cause of ileus may be obscured by the presence of gas-filled bowel or may be too deep within the abdomen to be imaged.[371]

32.118.13 Cecum and Colon

32.118.13.1 NORMAL APPEARANCE

The cecum is normally imaged in the mid to dorsal portion of the right paralumbar fossa region adjacent to the body wall and demonstrates a smooth, curved appearance. Estimates of the diameter of the cecum vary depending on the amount of gas distention present at the time of examination and have been reported to range from 5.2 to 18 cm in normal cattle.[373] The proximal loop of the colon and spiral colon can be visualized dorsal to the cecum in the right paralumbar fossa region and the right twelfth intercostal space. The spiral colon has been described as demonstrating a “garland” appearance with segmental arched lines adjacent to one another.[373] Estimation of the diameter of the proximal loop of the colon also varies dependent on gas distention and has been reported to range from 3.1 to 15 cm. The diameter of the spiral colon is smaller, ranging from 2 to 4 cm. The proximal loop of the colon and spiral colon may be difficult to distinguish from gas-filled small intestine; however, the proximal loop and spiral colon seldom demonstrate visible motility or contractions.[373]

32.118.13.2 ABNORMAL FINDINGS

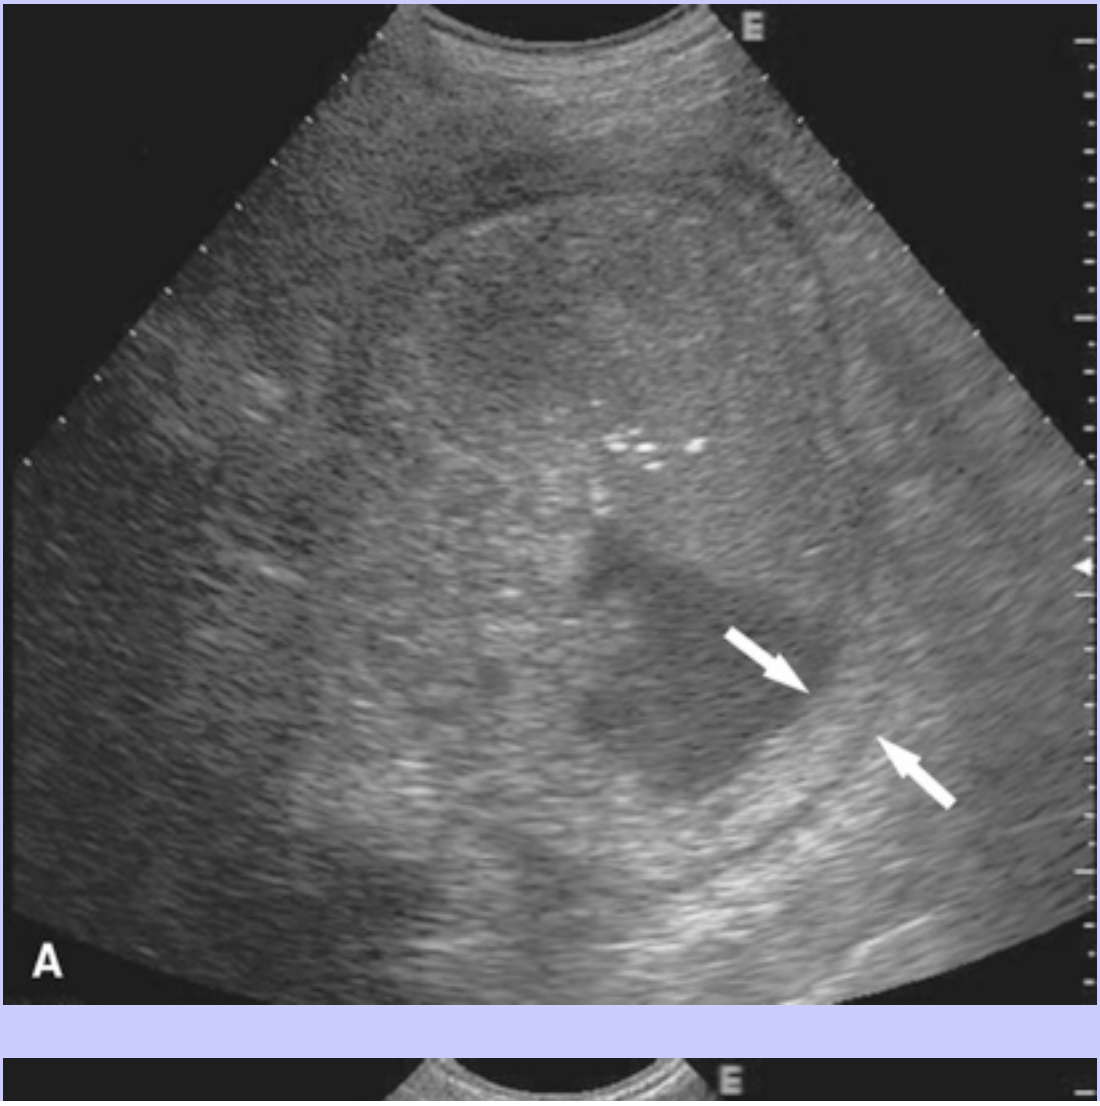
The diagnosis of cecal dilation is commonly made via rectal palpation but may be more challenging in cases in which dilation of the cecum is not palpable because of retroflexion.[374] In cows with cecal dilation, the cecum demonstrates a large radius of curvature and is seen to extend to the ventral portion of the right paralumbar fossa region and sometimes cranially into the right tenth to twelfth intercostal spaces. The proximal loop of the colon will also be dilated in and can be difficult to differentiate from the cecum. The liver may be displaced cranially in cows with severe cecal dilation. Torsion and retroflexion cannot be differentiated by ultrasonographic examination alone but may be diagnosed with a combination of rectal examination and ultrasonographic findings.[374]

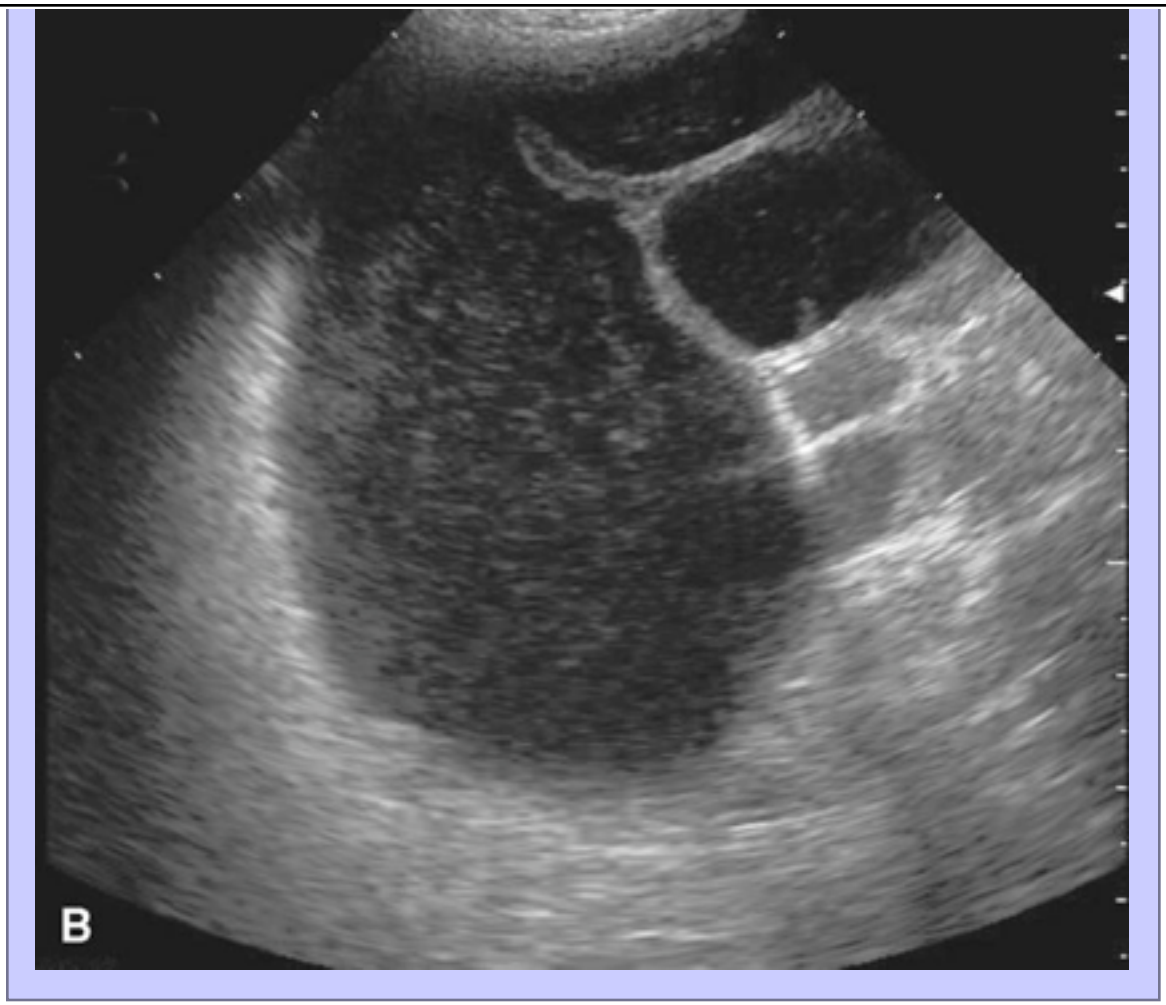
815

816

Fig. 32-87 **A**, Sonogram of an enlarged uterine horn distended with

echogenic fluid in a 5-year-old Holstein dairy cow with metritis. This cow had a history of aborting twins 4 days before presentation. Note the associated thickening of the uterine wall *(arrows)*. This image was obtained transabdominally in the right inguinal region with a 3.5-MHz curvilinear transducer at a depth of 18 cm. **B**, Sonogram of an enlarged uterine horn distended with relatively anechoic fluid in a 6-year-old Shetland ewe with hydrometra (pseudopregnancy). This ewe was reported to be 3 months pregnant. This image was obtained in the left flank region with a 7.5-MHz transducer at a depth of 9 cm.





32.118.14 Nongravid or Postpartum Uterus

Abnormalities of the uterus may be encountered during transabdominal ultrasound examination in ruminants and will be briefly addressed in the following sections. Evaluation of the gravid uterus and pregnancy diagnosis and monitoring are beyond the scope of this section.

32.118.14.1 NORMAL APPEARANCE

The normal nongravid uterus is seldom visualized during transabdominal ultrasound examination in ruminants. However, the involuting uterus may be encountered in females that have recently given birth.[375] Transrectal ultrasound is the method of choice to evaluate the bovine uterus.[376] However, abnormalities of the bovine and small ruminant uterus can be identified during transabdominal examination.

32.118.14.2 ABNORMAL FINDINGS

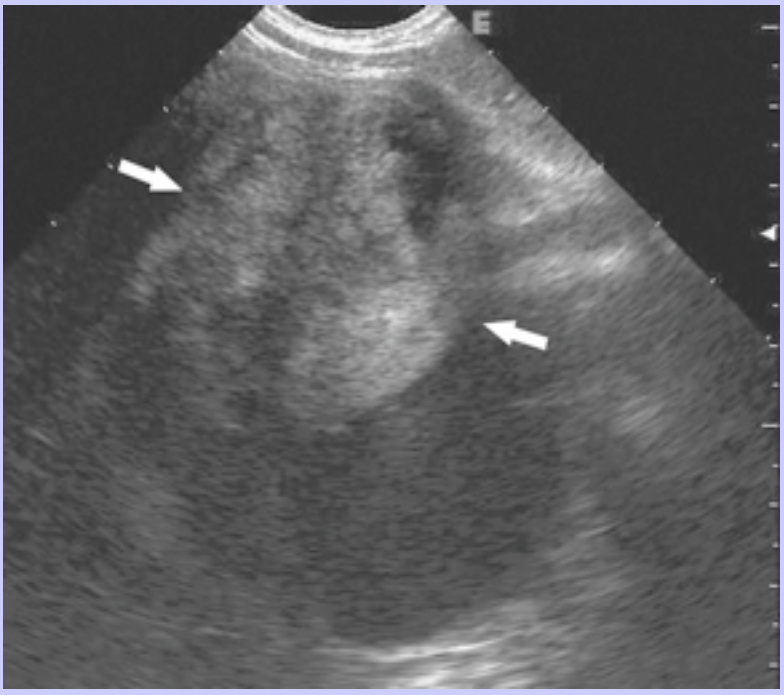
Abnormalities of the nongravid or postpartum uterus include metritis, pyometra, hydrometra, and uterine neoplasia. In ruminants with metritis or pyometra, the uterus is variably distended with fluid. This fluid may be relatively anechoic, echogenic, or hyperechoic depending on the nature of the debris and inflammatory material within the uterus[375–378] (Fig. 32-87, *A*). Hyperechoic gas echoes can be seen within the uterine fluid in cases of anaerobic or mixed infection. The uterine wall may also be thickened. Hydrometra, or pseudopregnancy, is most commonly reported in goats and is readily diagnosed via ultrasound.[375,379–380] The uterus appears distended with anechoic fluid in the absence of fetuses or placentomes. The dilated uterine horns may be curved or tortuous such that several cross-sections of the horn may be seen in any given scanning plane (Fig. 32-87, *B*).[375] It should be mentioned that small pockets of fluid may be seen in the normal involuting bovine uterus for up to 4 weeks postpartum.[376,381]

Uterine neoplasia is uncommonly reported in ruminants, but leiomyosarcomas, leiomyomas, carcinomas, chorionepitheliomas, fibrosarcomas, rhabdomyosarcomas, adenosarcomas, and multicentric lymphoma have been found.[382,383] Mass lesions visualized within the uterine wall or lumen are consistent with neoplasia. Masses may be single or multiple with variable echogenicity (Fig. 32-88). Diffuse infiltration of the uterine wall has been reported in cases of lymphoma.[382,383]

816

817

Fig. 32-88 Sonogram of a large uterine mass viewed from the right ventral abdomen in an 11-year-old pygmy doe diagnosed with uterine adenocarcinoma postmortem. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 10 cm.



32.118.15 Peritoneal Cavity

32.118.15.1

NORMAL APPEARANCE

The peritoneal lining can be seen as a very thin, smooth hyperechoic line adjacent to the body wall. Minimal free abdominal fluid is seen within the peritoneal cavity. Retroperitoneal adipose tissue appears as a hypoechoic layer of varying thickness between the body wall and abdominal viscera and should not be misinterpreted as cellular peritoneal effusion. Adipose tissue may also be seen within the omentum and mesentery, demonstrating a similar appearance between or among the gastrointestinal viscera. This omental and mesenteric adipose tissue can often demonstrate an organized appearance with visible fine vasculature that can be mistaken for liver, especially in small ruminants.

32.118.15.2

ABNORMAL FINDINGS

Peritoneal fluid is readily identified on ultrasound as anechoic to echogenic fluid between the body wall and abdominal organs (Fig. 32-89). In cases of severe effusion, the abdominal organs and viscera appear to float within the free fluid. Fibrin deposits are commonly seen in ruminants with inflammatory peritoneal effusion and appear as linear strands extending between organs or between peritoneal surfaces and serosal surfaces of abdominal organs (Fig. 32-90).[329,367] Fibrin can also demonstrate a “shag carpet” appearance along the peritoneal and/or serosal surface. Localized peritonitis may also be seen and has been reported in cows secondary to left flank laparotomy.[367] Hemoabdomen appears as hypoechoic cellular-appearing fluid that swirls with ballottement, peristalsis, or respiration. (Fig. 32-91)

Other abnormalities of the peritoneal cavity include mesenteric abscessation, mesenteric lymphadenopathy, and neoplasia. Intraabdominal abscessation may be identified within the mesentery or associated with abdominal incisions. Abscesses are generally well encapsulated with anechoic to echogenic contents. Enlarged mesenteric lymph nodes can be seen within the small intestinal mesentery and are a nonspecific finding that has been seen by the author in cases of abdominal disease from numerous causes (Fig. 32-92). Ruminants with neoplasia may demonstrate severe peritoneal effusion, most notably in cases of mesothelioma.[384,385] In cases of mesothelioma, multiple echogenic nodules are seen overlying the serosal surfaces of the peritoneum and abdominal organs (Fig. 32-93). Nodules can also be seen in the omentum.[384,385]

Fig. 32-89 Sonogram of mild peritoneal effusion *(arrows)* seen between

several loops of normal small intestine and the ventral body wall viewed from the right ventral abdomen in a 2-year-old Hampton cross ram. This image was obtained with an 8.5-MHz curvilinear transducer at a depth of 7 cm.

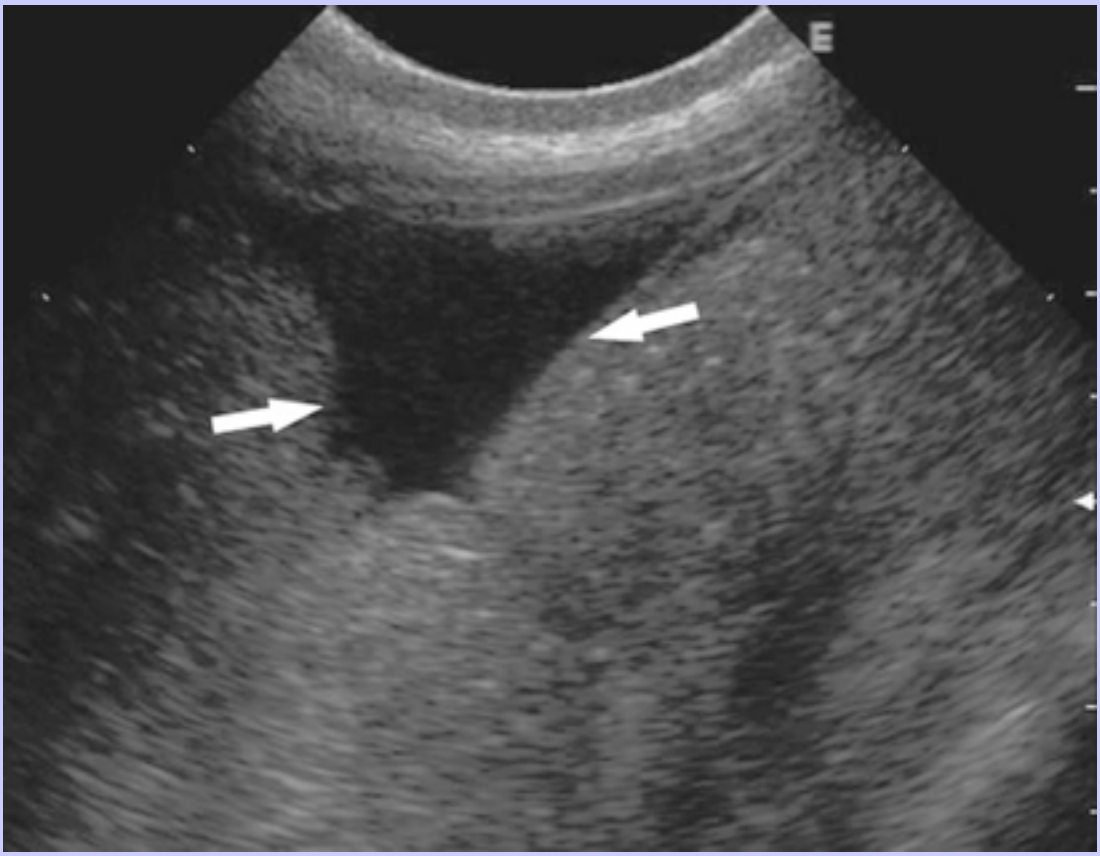


Fig. 32-90 Sonogram of severe fibrinous peritonitis thought to be secondary

to an intestinal rent viewed from the right paralumbar fossa region in a 3-year-old Holstein dairy cow. Note the hyperechoic fibrin strands creating a weblike appearance within the peritoneal cavity. This image was obtained with a 5-MHz curvilinear transducer at a depth of 27 cm.

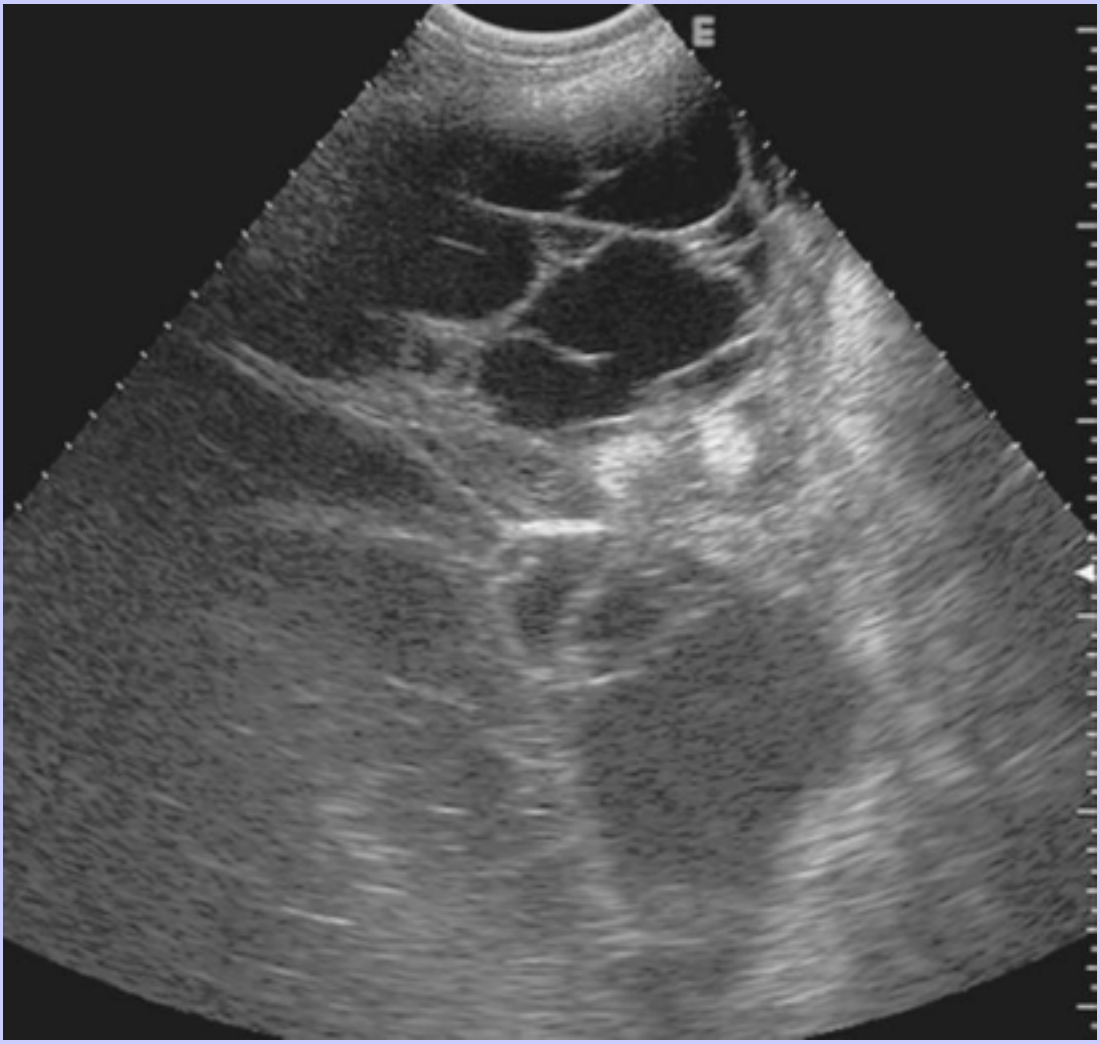

Fig. 32-91 Sonogram of severe hemoabdomen viewed from the right

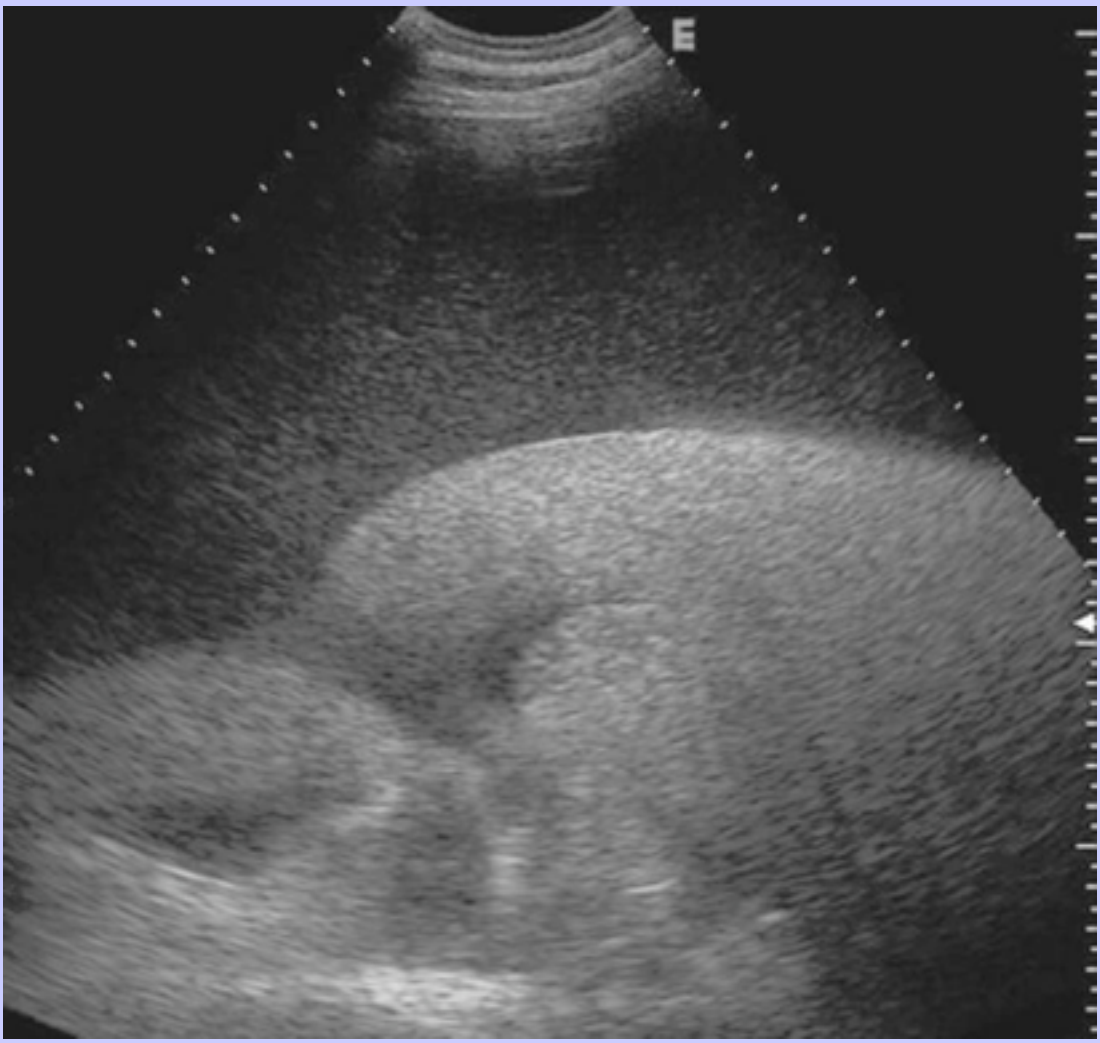
cranioventral abdomen in a 2-year-old Shorthorn heifer with metastatic granulosa cell tumor. Note the very cellular appearance to the fluid within the peritoneal cavity. The liver is displaced from the body wall and appears to float in the effusion. This image was obtained with a 2.5-MHz curvilinear transducer at a depth of 27 cm.



817

818

Fig. 32-92 Sonogram of an enlarged mesenteric lymph node viewed from

the left ventral abdomen in an 8-month-old Angora kid with disseminated *Rhodococcus equi* infection. This image was obtained with a 7.5-MHz curvilinear transducer at a depth of 5 cm.

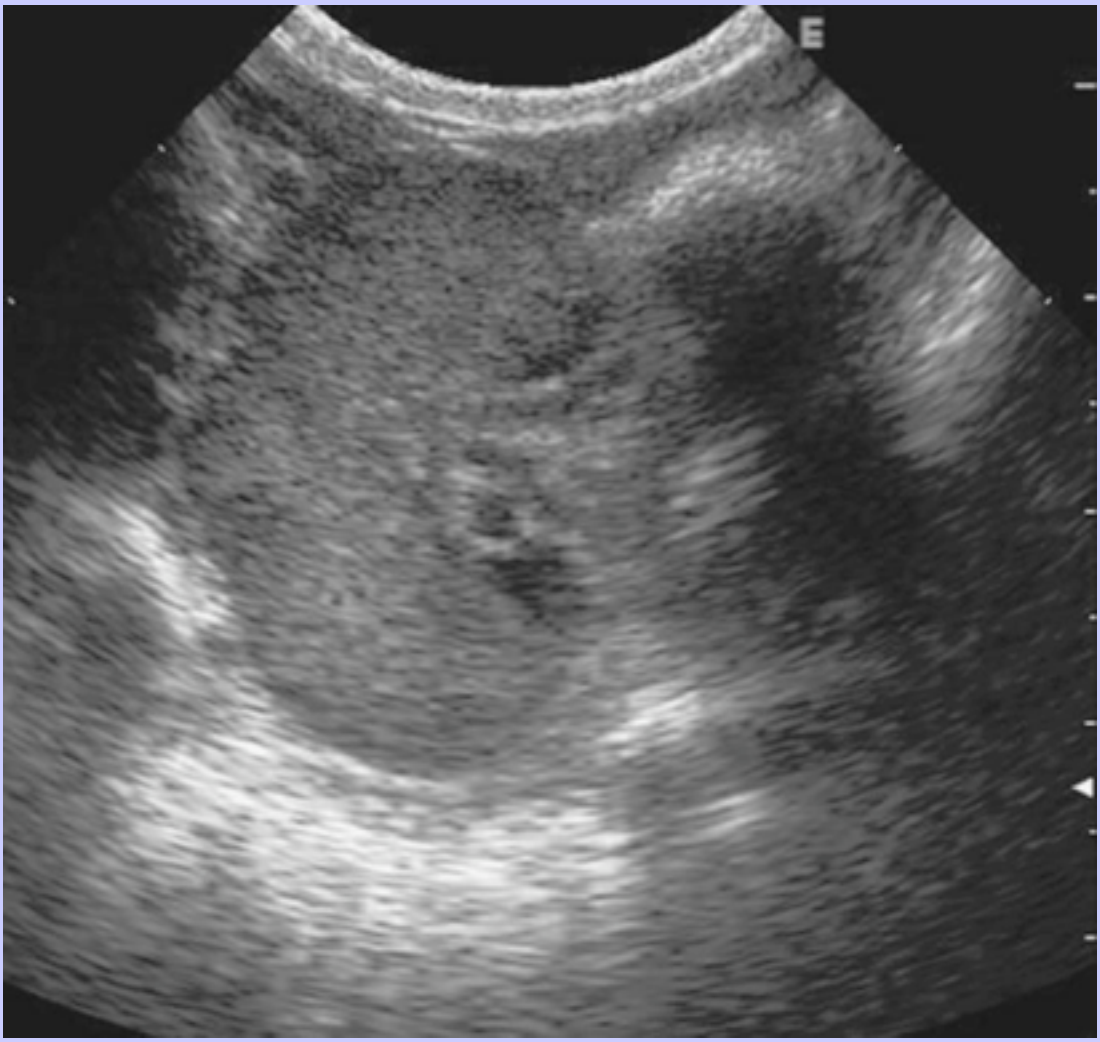


Fig. 32-93 Sonogram of multiple peritoneal masses *(arrows)* between the

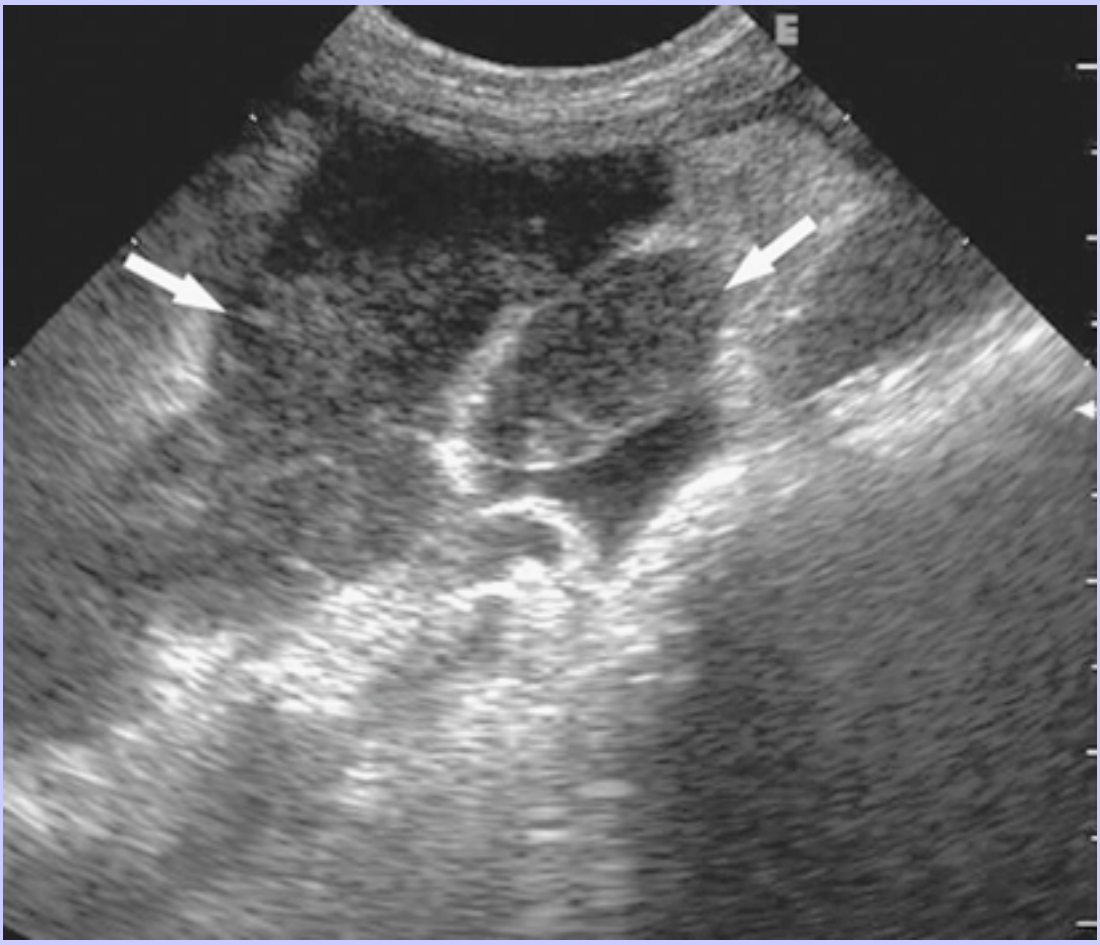
rumen and body wall viewed from the left paralumbar fossa region in a 10-year-old pygmy doe with mesothelioma. This image was obtained with an 8.5-MHz curvilinear transducer at a depth of 6 cm. Dorsal is to the right and ventral is to the left.



32.119 INDIGESTION IN RUMINANTS

FRANKLYN GARRY

CRAIG McCONNEL

32.119.1 Definition and Etiology

Indigestion is a general term for a group of diseases characterized by dysfunction of the reticulorumen. Some texts have limited the use of the term to a single, poorly defined entity that includes inappetence, decreased reticuloruminal motility, and abnormal feces, with a nonspecific cause that involves intake of abnormal feed.

The more generalized term applied here incorporates a pathophysiologic classification scheme of forestomach disturbances that has been devised by workers in Germany.[386] An absolute division of the pathologic processes is impossible because the various forestomach functions are interdependent; that is, abnormal motor function affects microbial fermentation by altered mixing or passage of ruminal fluid out of the forestomach chambers, whereas abnormal fermentation products secondarily alter motor function. Nevertheless, this classification provides a clinically useful diagnostic framework by emphasizing the underlying pathophysiologic mechanisms of different forestomach disturbances.

32.119.1.1 Box 32-5 Classification of Ruminant Indigestion

32.119.1.1.1 PRIMARY INDIGESTIONS

32.119.1.1.1.1 Reticuloruminal Motor Disorders or Diseases of the Ruminal Wall

Traumatic reticuloperitonitis (p. 849)

Frothy bloat (p. 855)

Free gas bloat (p. 821)

Reticulitis or rumenitis (p. 822)

Ruminal parakeratosis (p. 822)

Vagal indigestion (failure of omasal transport, failure of pyloric outflow, and free gas bloat) (p. 822)

Obstruction of the cardia (p. 825)

Obstruction of the reticuloomasal orifice (p. 825)

Diaphragmatic hernia (p. 825)

32.119.1.1.1.2 Reticuloruminal Fermentative (Microbial and Biochemical) Disorders

Inactivity of ruminal microbial flora (caused by poor quality roughage—ruminal impaction) (p. 827)

Simple indigestion (p. 827)

Acute ruminal lactic acidosis (p. 828)

Subacute ruminal acidosis (p. 829)

Ruminal alkalosis (p. 830)

Putrefaction of ruminal ingesta (p. 830)

32.119.1.1.2 SECONDARY INDIGESTIONS (SECONDARY TO SYSTEMIC ILLNESS)

Secondary reticuloruminal motor inactivity

Secondary reticuloruminal microflora inactivity

Abomasal reflux

The primary indigestions include those diseases in which the reticulorumen is directly affected and responsible for the major disease signs (Box 32-5). These problems can be divided into two categories:

1 Abnormal motor function of the reticulorumen, including disease of the reticuloruminal wall, its innervation, or impedance to the passage of ingesta

2 Abnormal contents of the reticulorumen, with dysfunction of microbial and biochemical fermentation

Secondary indigestions are the sequelae of systemic problems or disease in other organ systems. For example, problems such as endotoxemia, fever, or depression can produce anorexia, secondary ruminal hypomotility, and decreased microbial fermentative function. Primary abomasal disease can depress ruminal function, inhibit ruminal outflow, and reflux abomasal contents back into the rumen.

With the exception of penetrating foreign bodies and sporadic infections of the forestomach wall (e.g., actinomycosis, mucormycosis), indigestions are physiologic abnormalities. In the adult ruminant one or more of the homeostatic processes of the fermentative environment are disturbed (e.g., an excessive carbohydrate intake generates an excessive amount of acid product; abnormal neural regulation of the ruminal motility pattern disturbs the mixing or aboral passage of ingesta). In the young ruminant the forestomachs are actively developing, and indigestions can result from disturbances of the developmental mechanisms. The forestomach diseases of young ruminants generally have received little attention, but they can be recognized and appropriately treated within a classification scheme similar to that for adult ruminants.[387]

818

819

32.119.2 Pathophysiology

Digestion of feedstuffs in the reticulorumen is accomplished by microbial fermentation. The mucosal epithelium absorbs and exchanges products of fermentation but performs essentially no secretory function. Appropriate forestomach fermentation depends on the coordination of processes that provide a fairly constant reticuloruminal environment. The requirements include addition of appropriate amounts and types of feed substrate and water by ingestion; buffering of substances from the saliva to counteract the acid nature of fermentation products; eructation of the gaseous products of fermentation; coordination of reticuloruminal motility to provide mixing; rumination and remastication; aborad passage of ingesta; temperature maintenance; and exchanges of electrolytes and VFAs across the ruminal wall. Because these functions are intimately interrelated, abnormalities of any one of them can lead to digestive disturbances.

32.120 DISORDERS OF RETICULORUMINAL MOTOR FUNCTION

32.120.1 Normal Motor Activity

The two reticuloruminal contraction sequences function independently. The primary cycle of contraction occurs approximately once a minute but more often during feeding and rumination. It consists of a biphasic contraction of the reticulum followed by a contraction that runs caudally across first the dorsal and then the ventral ruminal sacs. At the height of the second reticular contraction the omasal orifice relaxes, and fluid, mostly composed of reticular ingesta, passes into the omasum. This reticuloruminal motility pattern directly influences ruminal fermentation by mechanically mixing the ingesta to provide contact with the microbes and to macerate the particulate matter. The mixing function prevents local accumulations of substrate or end products of fermentation, distributes the buffering saliva for neutralization of acids, and provides increased contact of the fluid with the ruminal wall to promote VFA absorption. The coordinated sequence of contraction of various parts of the ruminal wall maintains a stratification of fluid and particulate matter that selectively sorts the ingesta by particle size. The sorting function serves to retain large particles for further digestive breakdown while promoting passage of small particles (smaller than 6 mm) into the omasum and lower gastrointestinal tract.[388–391]

The secondary contraction cycle does not involve the reticulum. It begins in the caudal blind sacs, and a wave of contraction runs cranially across the dorsal rumen, pushing the gas cap into the cardia region. Eructation ensues, eliminating the gases generated by fermentation. Typically one secondary cycle contraction follows two primary cycles, so that three contractions occur every 2 minutes.[389–391] Two additional special contractions have been identified in sheep: primary-secondary contractions and prosecondary contractions.[392,393] These contractions appear when intraruminal pressure becomes elevated and function as secondary contractions by expelling ruminal gas. The primary-secondary and prosecondary contractions appear to help minimize free gas bloat when gas production is high.

Maintenance of the motility patterns requires well-coordinated neural control. The pathophysiologic mechanism of the first group of primary indigestions (i.e., diseases of the reticuloruminal motor function) involves disturbance of the mechanisms of normal ruminal motility, which secondarily affects ruminal fermentation.

The ruminal contraction sequences described rely almost completely on motor nerve activation arising from the

medulla oblongata, in contrast to the intrinsic segmental and peristaltic movements of the intestine. Gastric centers in the medulla integrate sensory input and generate motor impulses, both of which are carried in the vagus nerves. The gastric centers have neither spontaneous activity nor an inherent rhythm. Generation of motor impulses relies on a greater excitatory than inhibitory input from the sensory nerves to determine the rate, magnitude, and duration of primary cycle contractions. During the quiescent period between the primary contractions, while the medulla collects the sensory information, there are no tonic vagal motor impulses.[394–400]

The splanchnic nerves also affect reticuloruminal motility by direct innervation and by neurohumoral effects of adrenal secretion. These nerves are not required for generation of normal contractions. The effect of splanchnic stimulation is inhibition of reticuloruminal motility. Splanchnic sensory nerves innervate sensory receptors in other areas of the gastrointestinal system, and some abnormalities such as intestinal distention or surgical manipulation produce reticuloruminal inhibition by means of reflex from splanchnic afferent activity.[390,398,401]

32.120.2 Primary Cycle Activity

A decrease or absence of normal primary cycle activity (i.e., ruminal hypomotility or stasis) implies either a decrease of vagal motor discharges originating from the gastric centers or an ineffective motor response after motor impulse, as in cases of hypocalcemia. Causes of decreased motor discharges can include the following:

1 Decreased excitatory input to the gastric centers

2 Increased inhibitory input to the gastric centers

3 Depression of the gastric centers

4 Defective vagal transmission of motor impulses

5 Other factors

32.120.2.1 DECREASED EXCITATORY INPUT

The three most important excitatory inputs to the gastric centers are from (1) low-threshold tension receptors in the reticulum, (2) buccal receptors in the mouth, and (3) acid receptors in the abomasum (Table 32-11). The tension receptors are located in the musculature of the medial wall of the reticulum. They are stimulated by mild distention during the resting phase and thereby influence contraction frequency. They are further stimulated by the tension generated during contraction and thus increase amplitude and duration of the primary cycle contraction. This mechanism is probably responsible for the increased motility seen after feeding or during incipient bloat. Any cause of anorexia leading to decreased ruminal fill decreases this excitatory input, leading to ruminal hypomotility. Feeding mechanically stimulates buccal sensory receptors, providing a potent stimulus to both primary and secondary contraction cycles. This reflex can double the rate of primary contractions but is short-lived and declines as soon as chewing activity ceases. Therefore anorexia effectively eliminates this potent excitatory input. Abomasal acidity increases as the abomasum empties, and this, too, provides excitatory input to the gastric centers. The resultant increased reticuloruminal motility leads to increased flow of ingesta to the abomasum, diluting the abomasal acid and maintaining normal filling of the abomasum. Certain types of abomasal disease diminish this stimulus to forestomach motility.[396,398,402]

819

820

Table 32-11 Factors Influencing Vagal Motor Discharge from the Gastric

Centers of the Medulla*

Input	Location	Stimulus
EXCITATION OF THE GASTRIC CENTERS (CAUSES INCREASED RUMINAL MOTILITY)		
Low-threshold tension receptors	Reticulum, medial wall	Mild distention, and tension generated during contractions
Buccal receptors	Mouth	Feeding (only during chewing)
Acid receptors	Abomasum	Increased acidity as abomasum empties
Tension receptors†	Medial wall of cranial ruminal sac	Increased ruminal gas pressure
INHIBITION OF THE GASTRIC CENTERS (CAUSES DECREASED RUMINAL MOTILITY)		
High-threshold tension receptors	Reticulum and cranial ruminal sac	Bloat or other severe ruminal distention
Tension receptors	Abomasum	Abomasal distention
Chemical receptors	Reticulum, rumen	Increased concentration of undissociated volatile fatty acid with ruminal acidosis; also locally activated by some toxins
Pain receptors in body increase sympathetic tone and adrenal secretory activity	Anywhere in body; can act directly and through medullary gastric centers	Pain, especially abdominal
Gastric centers	Medulla	Anesthesia, depressant drugs, toxins, endotoxins, fever, acidosis
Hypocalcemia	Reticuloruminal smooth muscle	Hypocalcemia

* There is no inherent reticuloruminal motility such as that found in the intestines.

† Secondary cycle activity; independent of primary cycle activity.

Less well-defined stimuli of reticuloruminal motility include the physical and chemical characteristics of the ruminal ingesta. Fiber and water content, as well as the normal chemical products of fermentation, are important for normal ruminal contraction. The exact mechanisms by which these factors enhance ruminal motility have not yet been clearly defined, but low levels of any of these ingesta characteristics impair normal function, causing decreases of both rumination and primary cycle activity. That these excitatory stimuli are decreased or absent under some feeding regimens and with some of the diseases attributable to abnormal fermentation may account for the impression of hypomotility observed clinically.[396,403,404]

32.120.2.2

INCREASED INHIBITORY INPUT

Inhibitory inputs to the gastric center arise from (1) high-threshold tension receptors in the reticulum and cranial ruminal sac, (2) tension receptors in the abomasum, (3) epithelial receptors that detect high concentrations of nondissociated VFAs in the rumen, and (4) pain elicited at any site in the body (see Table 32-11). The high-threshold tension receptors are sensory nerve endings below the epithelial basement membrane of the reticulum and cranial ruminal sac. They respond to extreme distention of the wall and serve

to modify the end stage of reticuloruminal contraction. With severe bloat or gross ruminal distention from other causes, such as overfilling with indigestible fibrous roughage, they can be continuously activated, producing ruminal stasis. Abomasal distention can inhibit primary ruminal contraction cycles, presumably because of tension receptors in the abomasal wall. In normal circumstances this activity would serve to decrease the flow of ingesta to the abomasum when it is full. With abomasal displacement or impaction, this reflex may partly account for the observed ruminal hypomotility. Epithelial receptors in the reticulum and cranial ruminal sac are sensitive to increased concentrations of nondissociated VFAs. Inhibition of forestomach contractions occurs when conditions of excessive fermentation or acidosis increase the concentrations of these substances. Pain can reduce forestomach motility by increasing sympathetic nervous and adrenal secretory activity and by inhibiting the gastric centers. Although painful stimuli in the abdominal viscera are particularly potent, pain from anywhere in the body can inhibit or abolish reticuloruminal motility.[396,398,402]

32.120.2.3 DEPRESSION OF THE GASTRIC CENTERS

Depression of the gastric centers reduces vagal motor activation of forestomach motility and can be induced by CNS depressant drugs and anesthetics. Endotoxemia, fever, and possibly blood pH and electrolyte abnormalities can induce ruminal hypomotility or stasis through central effects on the gastric centers. These factors may also inhibit ruminal motility by increasing sympathetic nervous activity. In addition, some toxins or other abnormal fermentation products reduce ruminal motility. These substances may act locally at the ruminal epithelial receptors to generate inhibitory impulses, as do increased VFA concentrations, or they may act centrally after absorption into the blood. For the most part the nature of the substances capable of chemically suppressing ruminal function is unknown, but abnormal fermentation end products are the likely cause of ruminal stasis in indigestion associated with abnormal ruminal contents.[386,388,396,400,403–409]

32.120.2.4 DEFECTIVE VAGAL INNERVATION

Failure of vagal nerve transmission of motor impulses has been implicated as the cause of a reticuloruminal contraction abnormality that leads to failure of aborad flow of ingesta (hence the name *vagal indigestion*). The left and right vagi in the thorax divide into dorsal and ventral branches that unite to form dorsal and ventral vagi as the nerves enter the abdomen. The ventral vagus innervates the cranial and medial parts of the reticulum, the omasum, and the abomasum. The dorsal vagus innervates the rumen and parts of the other segments of the ruminant stomach. Sectioning of more than 50% of the vagal nerve trunks leads to impaired motility function, but most cases of vagal indigestion show much less nerve involvement. The importance of vagal nerve lesions in the pathogenesis of forestomach disease has been a subject of considerable debate and is discussed more fully later in this chapter.[396,397,401]

820

821

32.120.2.5 OTHER FACTORS THAT AFFECT THE PRIMARY CYCLES

Other influences on forestomach motility have been identified. Hypocalcemia inhibits motility by preventing contraction of the musculature after motor nerve discharge. This may explain the reduced ruminal motility seen in early cases of milk fever.[409–411] Low environmental temperatures[412,413] and milking[414] have been shown to increase ruminal motility mildly, whereas some drugs,[400,401,415–417] hyperglycemia,[418] and gastric hormones[400,419] are effective in decreasing reticuloruminal primary cycle contractions. These factors are not discussed further in this text.

32.120.3 Secondary Cycle Activity

The secondary cycle activity responsible for eructation is elicited independently of the primary cycles. An increase in ruminal gas pressure excites tension receptors in the medial wall of the cranial ruminal sac. This triggers relaxation of the cardia and eructation of the gas accumulated in the cardia region by the secondary contraction cycle. Receptors that apparently distinguish gas from fluid or solid matter inhibit opening of the cardia if it is covered by material other than gas.[420] This reflex inhibition of cardia opening is responsible for bloat in cases in which abnormal ingesta cover the area, such as in recumbent animals, in frothy bloat, and when abnormal motility or overfilling of the rumen precludes clearing of the cardia. Under such circumstances and when ruminal distention is not yet extreme, both primary and secondary cycle contractions may increase in frequency. In other forms of bloat, hypomotility is a prominent feature, and the gas accumulates as a result of the poor motility function.[391] This is the most probable cause of bloat in some of the disturbances of fermentative function.

Gross overdistention of the ruminal wall may inhibit motility by stretching the musculature beyond its ability to contract forcefully. If the process leading to the distention develops slowly, the high-tension receptor inhibition of motility appears to adapt, and complete inhibition of motor impulses does not seem to occur. Rather, in these cases motility is present but weak and relatively ineffective. This motility disturbance is likely when poorly digestible roughage accumulates in the forestomach. Patients with this condition often have mild to moderate chronic free gas bloat, which may result from poor ability of the weakened rumen to clear the cardia and dispel the gas.[386]

Table 32-12 Causes of Ruminal Tympany (Bloat)

Mechanism	Cause	Disease Examples
Obstruction of eructations	Esophageal obstruction	Choke, tetanus, thoracic inflammation or neoplasia with swollen mediastinal lymph nodes
	Cardia obstruction	Papilloma, fibroma, actinobacillosis
	Failure to clear cardia of fluid or ingesta	Lateral recumbency, reticulorumen overfilled with ingesta (as in vagal indigestion, ruminal microbial inactivity with poorly digestible roughage, obstruction of the reticuloomasal orifice)
	Gas trapped in stable foam	Frothy bloat
Ruminal motor dysfunction	Failure of smooth muscle contraction	Hypocalcemia
	Weakened muscle contraction	Chronic ruminal distention with indigestible roughage, outflow obstruction, or vagal indigestion, hypokalemia
	Abomasal distention	Displaced abomasum (especially in calves)
	Vagus nerve damage	Thoracic inflammation (especially in calves, neoplasia)
Chemical inhibition	Ruminal stasis	Ruminal acidosis, ruminal alkalosis, abnormal fermentation products with simple indigestion

32.120.4 Free Gas Bloat

Accumulation of free gas in the dorsal rumen should not be considered a primary disease entity but rather a sign of disease (Table 32-12). However, because free gas bloat often is the most prominent sign and because it accompanies several different forms of indigestion, its pathogenesis is reviewed briefly here.

Ruminal microbial fermentation and neutralization of salivary bicarbonate continually produce gas as an end product (primarily methane and carbon dioxide) in proportion to the rate of fermentation. Normally the ruminant can eructate volumes of gas that exceed the amount produced even at maximum rates of fermentation.[392,393] Therefore an excessive production of gas is not the cause of bloat. Bloat develops either because the evacuation of gas is hindered by a physical obstruction or because the mechanisms that expel the gas are inhibited.[421–424]

As in choke, physical obstruction of the esophagus by a foreign body can produce dramatic and peracute bloat. Other forms of esophageal occlusion (which may additionally involve inflammation of nerves or ruminal muscle malfunction) include muscular spasm (e.g., tetanus), swollen mediastinal lymph nodes (e.g., chronic pneumonia, thymic lymphosarcoma), and tumorous or inflammatory swellings of the cardia region (e.g., papilloma, actinomycosis). These problems tend to show bloat of a slowly progressive or chronic nature, although the degree of bloat may be marked.

Bloat is a common feature of indigestions caused by microbial fermentative disorders. When ruminal hypomotility occurs, the fermentative rate may decline, but weak ruminal contractions may be inadequate to move the gas layer and to clear the cardia preparatory to eructation. Thus dietary, microbial, or metabolic factors that affect the excitability of the gastric centers or the reticulorumen can result in bloat. Ruminal stasis can result in bloat because eructation occurs only with ruminal contraction. Bloat also accompanies indigestions that produce gross distention of the reticulorumen with fluid or solid ingesta (e.g., vagal indigestion, ruminal

acidosis, and microfloral inactivity caused by indigestible roughage). The cause of bloat in these cases may be a combination of ruminal stasis, weakening of the ruminal wall caused by the gross distention, and failure to clear the cardia.

Some authors have attributed chronic bloat in calves to a form of vagal nerve damage resulting from mediastinal inflammation.[425,426] However, it has not been demonstrated that vagal nerve involvement is the source of the failure to eructate in these cases. It appears that free gas bloat in calves has numerous causes, as is true in adult cattle, including fermentative indigestions, ruminal wall disturbances, and esophageal involvement in an intrathoracic inflammatory process.[427] Distinguishing between vagal nerve impairment and esophageal compression or inflammation as the cause of free gas bloat requires a thorough assessment of ruminal motor function, as described under the section on clinical signs (p. 832).

821 822

32.120.5 Reticulitis and Rumenitis

The most important inflammatory problem is reticuloperitonitis caused by sharp foreign body punctures (TRP, hardware disease). This disease is discussed elsewhere in the text (p. 848). The localized infection established by reticuloruminal perforation causes inflammation of the forestomach wall and adjacent peritoneal cavity and pain in the anterior abdomen, inhibiting forestomach motility, appetite, and aborad flow of ingesta. Other causes of ruminal wall inflammation can cause acute or chronic forestomach dysfunction.

Most infections of the ruminal wall follow primary mechanical or chemical damage to the mucosa. The secondary invaders colonize the damaged areas and may gain access to the circulation and invade other tissues as well. The ruminal wall may be the niche for some of these microorganisms, and isolates from the ruminal wall have been matched with those isolated from liver abscesses.[428] Probably the most common cause of the initial mucosal injury is acute ruminal acidosis produced by grain engorgement. Chemical damage resulting in ruminal ulcers also occurs in oak or acorn toxicosis and with ingestion of caustic chemicals. Common secondary ulcer invaders include *Arcanobacterium (Actinomyces) pyogenes, Fusobacterium necrophorum*, and several mycotic species.[428,429] Mycotic rumenitis can follow ruminal acidosis and septic diseases, especially after the use of oral antibiotics; it also can occur after feeding spoiled and moldy feeds and without apparent predisposing causes.[430–434] Diseases that cause anorexia plus abomasal reflux of gastric acids may predispose an animal to mycotic rumenitis and omasitis. Mycotic rumenitis can be severe, with vascular thrombosis and infarction and mural necrosis and gangrene sufficient to cause death. Less frequently occurring specific infections of the ruminal wall include actinobacillosis, actinomycosis, and tuberculosis. These infectious inflammatory diseases of the ruminal wall may be distributed widely throughout the forestomach, depending on the initial site of mucosal injury, but they tend to localize in the ventral regions of the reticulorumen. The granulomatous inflammatory lesions of actinobacillosis and actinomycosis are most commonly found in the cranial forestomach in the area of the esophageal groove.

Neoplastic growths in the rumen have also been identified. These uncommon lesions include papillomas, myxomas, fibromas, carcinomas, and lymphosarcoma.[386,435,436] These lesions are most commonly localized in the reticulum and cranial rumen near the cardia and esophageal groove.

The importance of these inflammatory reticuloruminal lesions depends on their extent and location. Acute and extensive lesions have been associated with signs similar to those of reticuloperitonitis caused by foreign body puncture, including pain, inappetence, impaired forestomach function, and in some cases death. The more chronic cases may cause forestomach motility disturbances and signs of vagal indigestion. Pedunculated masses especially, but not exclusively, may obstruct the cardia or reticuloomasal orifice, leading to bloat or

reticuloruminal outflow disturbance.

Reticuloruminal inflammation can also result from certain generalized infections. These include BVD, FMD, MCF, and RP. In these cases the forestomach problems are unlikely to be the most important clinical manifestation.

32.120.6 Ruminal Parakeratosis

In parakeratosis the papillae are darkly colored, enlarged, thickened, and clumped together. Histologic changes of the epithelial cells include a thickened, cornified layer with abnormal retention of nuclei in the cornified cells. These morphologic changes appear to represent a reaction to persistently high concentrations of VFAs. The changes occur predominantly in animals on pelleted or very finely ground rations, especially when the ration contains a high amount of energy. These rations tend to increase the proportions of propionate and butyrate, reduce the proportion of acetate generated by microbial fermentation, and produce a lowered ruminal fluid pH. The growth of the ruminal papillae is promoted by contact with the VFAs, especially butyrate, and secondarily propionate.[388,423] It appears that a disproportion of the concentrations of these VFAs may be the cause of an excessive change in the epithelium of the papillae.[437,438] Initial changes in the epithelium under these conditions appear to increase the absorption of the VFAs, but in severe cases the absorption decreases. This disease of the ruminal wall is not usually diagnosed as a primary problem. Although it may lead to impaired performance of the animal, the disease signs that lead to its discovery are usually those of chronic acidosis, a disease with which it often coexists. Parakeratosis can predispose to other injuries of the ruminal wall, however, because the abnormal papillae are more easily traumatized, leading to chronic inflammatory disease of the wall as discussed previously. In calves the problem is also associated with the development of hairballs (trichobezoars) because of the propensity of calves on the rations associated with parakeratosis to lick their hair coat.[386,422,439,440]

32.120.7 Vagal Indigestion

Vagal indigestion syndrome (vagus indigestion, Hoflund's syndrome) is composed of a group of motor disturbances that hinder passage of ingesta from the reticulorumen or abomasum or both. The pathogenesis of the disease has been debated for years and has yet to be completely clarified because many investigations have yielded conflicting information.[*]

The name *vagus indigestion* was introduced by Hoflund, who experimentally produced motor defects and disease signs similar to those seen in clinical cases by transecting various branches of the abdominal vagal nerve.[442] On the basis of his experimental results, he defined four types of functional disturbance, with obstruction of ingesta flow at two sites:

1 *Omasal transport failure* (anterior functional stenosis), which impairs flow of ingesta through the reticuloomasal orifice and occurs with

   a atony of the reticulorumen, often associated with chronic recurrent bloat, or

   b normal to increased ruminal motility

2 *Pyloric outflow failure* (posterior functional stenosis), which impairs flow through the pylorus and occurs

   a continuously or

b in an intermittent, recurrent pattern (incompletely)

Hoflund's description of the syndrome is convenient for explaining the observed functional defects, but its presumed pathogenesis is not supported by the findings of several later investigators.[400,441,444,449] The use of the term *stenosis* has also led to some confusion, although it was appropriate in its original context. *Functional stenosis* suggested that the defect was a functional one that mimicked a stenosis at the site of outflow. However, vagal denervation does not produce a true stenosis, but rather a paralysis and relaxation of either the reticuloomasal orifice or the pylorus. The paralysis can be appreciated in both experimental and clinical cases.

32.120.7.1

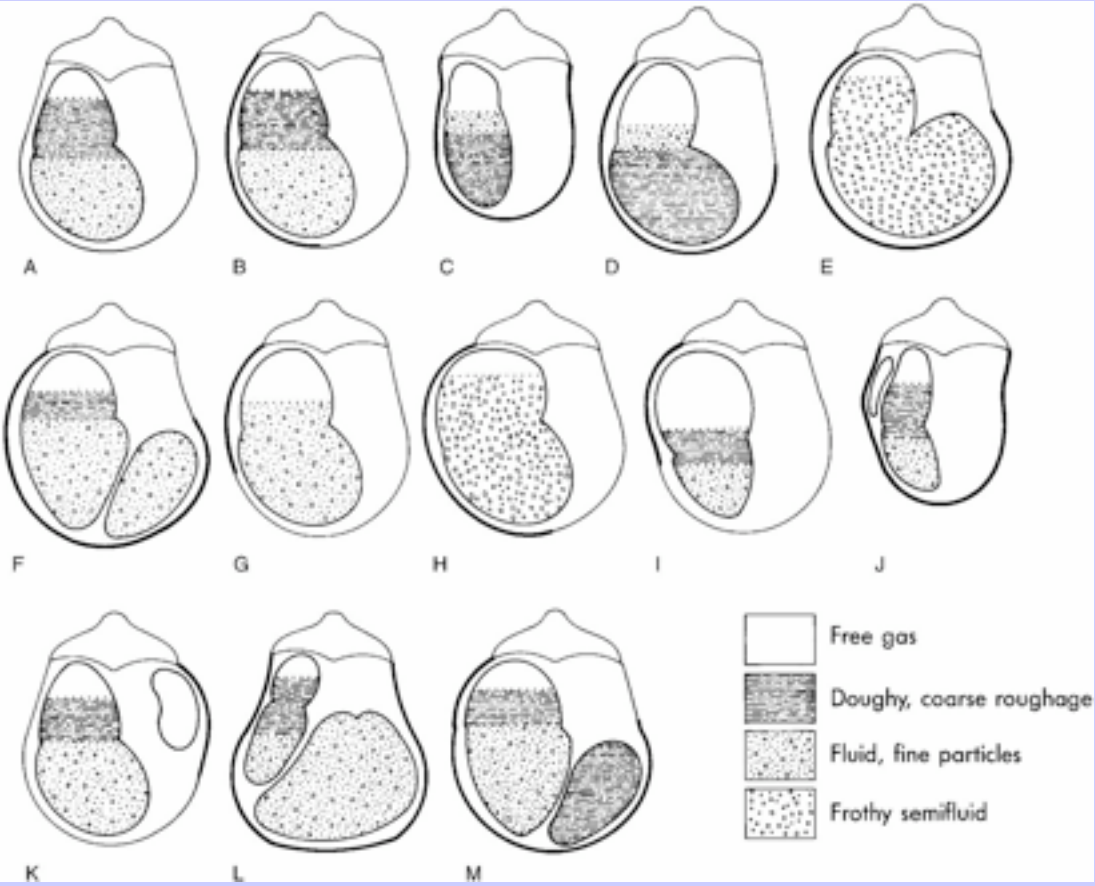
FAILURE OF OMASAL TRANSPORT

Failure of omasal transport with hypermotility of the rumen is the most common naturally occurring form of the disease. Accumulation of ingesta in the reticulorumen leads to gradually progressive distention of the forestomachs, whereas the omasum and abomasum remain relatively empty. The animal's appetite diminishes as the rumen becomes overfilled, producing one of the most characteristic signs of the disease: inappetence with gross distention of the rumen in the left flank. Continued dilation of the rumen eventually leads to a marked and almost pathognomonic overfilling of the ventral ruminal sac. The rumen assumes an L shape because the ventral sac occupies both the right and left ventral quadrants of the abdomen. The resultant characteristic abdominal contour often is called a “papple” shape (Fig. 32-94, *E*) because the left side of the abdomen is distended and assumes the appearance of an apple, whereas the right side assumes the contour of a pear. The diminished passage of ingesta results in reduced fecal volume. The normal ruminal process of selective retention of fibrous material is disturbed, leading to large particle passage and feces with increased fiber length and a greasy or pasty consistency. Some cases show firm feces with large particle size.[447,450] Affected animals often continue to drink water, but absorption from the rumen is poor, and the water accumulates in the forestomach while the animal becomes mildly dehydrated. Vigorous contractions of the rumen can be palpated in the left paralumbar fossa in most affected animals, although some display almost complete atony. The contraction pattern does not produce the typical stratification of material in the forestomach, but rather it churns the ruminal contents into a uniform frothy fluid.[450,453]

Fig. 32-94 Abdominal contours (viewed from the rear) and abdominal

palpation findings characteristic of cattle with various types of indigestion and other abdominal diseases. A thin line for the abdominal contour indicates the normal configuration. Bold lines indicate areas of the abdominal contour that typically deviate from normal in affected animals. **A**, Normal. **B**, Acute onset of ruminal stasis with simple indigestion, traumatic reticuloperitonitis (findings: mild ruminal distention with normal layering of ruminal content). **C**, Prolonged ruminal stasis, anorexia. The most common result of subacute or chronic disorders such as microbial or fermentative indigestions, traumatic reticuloperitonitis, and secondary indigestions (findings: reduced ruminal fill, "tucked-up abdomen," firm, doughy contents that gravitate ventrally). **D**, Ruminal inactivity with indigestible roughage (findings: rumen distended with firm, doughy contents that accumulate ventrally; recurrent free gas bloat often present). **E**, Omasal transport failure (findings: L-shaped rumen with gross accumulation of frothy ingesta; ruminal hypermotility often present; free gas accumulation varies). **F**, Pyloric outflow failure (findings: fluid accumulation in abomasum; abomasal reflux to rumen common; doughy ruminal content that usually accumulates dorsally until ruminal stasis or anorexia is prolonged; abdominal contour similar to that for omasal transport failure). **G**, Acute ruminal acidosis (findings: rumen distended with fluid; some free gas bloat common). **H**, Frothy bloat. **I**, Free gas bloat or chronic free gas bloat (findings: accumulation of gas in dorsal sac; layering or ruminal contents usually normal; with chronicity, ruminal fill often decreased; associated with some microbial or fermentative disorders and with esophageal and cardiac disorders). **J**, Left displaced abomasum (findings: gas-filled abomasum that often causes slight bulge of paralumbar fossa; ruminal fill usually reduced). **K**, Right displaced abomasum, abomasal volvulus, cecal torsion (findings: distention of right flank with gas-filled viscus; ruminal fill and consistency usually normal). **L**, Hydrops (findings: ventral abdomen distended with fluid-filled uterus; ruminal fill usually

abdomen distended with fluid-filled uterus. Ruminal fill usually decreased). **M**, Abomasal impaction (findings: abdominal contour similar to **E** and **F**; abomasum filled with firm ingesta).



The signs just described, with abnormal flow of ingesta and normal or increased forestomach contractions, can be experimentally reproduced by sectioning the ventral vagal trunk at the cardia and the dorsal trunk just distal to the branching of the ruminal nerves.[397,442] The forestomach distention, empty omasum and abomasum, and stasis of the forestomach with resultant free gas bloat can be reproduced by sectioning both abdominal vagal trunks along the esophagus. The paralysis produced by vagal denervation can explain the failure of ingesta flow into the omasum by two mechanisms. First, the lower end of the esophageal groove is formed by two muscular lips. These overlap in a manner that allows a passive valve effect that blocks flow into the omasum when they are relaxed or paralyzed. Second, it appears that the flow into the omasum is accomplished by an active pumping motion of the omasum that reduces pressure and draws fluid through the reticuloomasal orifice. Paralysis of the omasal musculature after denervation would eliminate this effect. Decreased reticular motility caused by adhesion or paralysis may contribute to the changes in ruminal content and the alteration in particle passage.[450,453]

The most common predisposing cause of naturally occurring omasal transport failure (anterior functional

stenosis) is TRP. Other causes of anterior functional stenosis include abscesses, adhesions, and peritonitis at the reticulum (especially the right side of the reticulum) or reticuloomasal area without identification of an offending foreign body; hepatic abscesses; diffuse peritonitis; neoplasia of the ruminoreticular fold and esophageal groove; inflammatory disease of the reticular and ruminal walls; papilloma or other mass at the reticuloomasal orifice; and herniation of the reticulum through a diaphragmatic defect. Foreign bodies that obstruct the reticuloomasal orifice cause a syndrome indistinguishable from vagal indigestion except by exploratory rumenotomy.[436] To reconcile the experimental findings with those from clinical cases, the development of omasal transport failure has been explained as involvement of the vagal trunks in the inflammatory process at the reticulum. Several findings make this an unlikely explanation in most clinical cases[396,397,443,449,451]:

1 Although sectioning the vagus nerves as described reproduces the syndrome, disturbing only one of the two trunks still allows normal cyclic contractions in most cases. For a clinical lesion to produce disease development, massive involvement of the vagal nerves would be required. By contrast, less than a third of examined cases reported show actual lesions in the nerve branches.

2 The ratio of sensory to motor nerve fibers in the abdominal vagi is approximately 9:1, suggesting the important sensory role of the nerve.

3 Inflammatory lesions of the reticuloruminal wall reported in cases of vagal indigestion are predominantly in the same areas as the important tension receptors that send afferent excitatory impulses to the gastric centers. Induration of the right (medial) wall of the reticulum and in the esophageal groove region may affect intramural nerves and ganglia and reduce the tension receptor activity and therefore the drive for primary cycle activity.

These considerations allow an explanation of some of the inconsistencies found in various cases. Anterior functional stenosis may occur with insufficient vagal sensory excitation, which in turn reduces excitatory input to the gastric centers, diminishes primary cycle motor drive, and results in paralysis of the omasum and reticuloomasal orifice. Alternatively, substantial reticular adhesions that develop after TRP could prevent normal delivery of small particle ingest, with fluid consistency, to the reticuloomasal orifice.[453] Because this reduces or abolishes flow into the omasum, both the omasum and abomasum would remain relatively empty, a common finding in these cases. The hypermotility observed in these cases may be the result of secondary rather than primary cycle contractions. Distention of the cranial ruminal sac would still be able to induce the secondary contractions if this region is not involved in the induration. Without normal primary cycle activity, the typical stratification of the ingesta would be disturbed, as is usually observed. The existence of hypermotile secondary contractions with absence or severe reduction of primary contractions can be detected clinically. Damage to the thoracic or abdominal vagi by inflammatory or neoplastic lesions may lead to the occasional cases that show both anterior functional stenosis and atony of the forestomachs, with resultant free gas bloat. This would be similar to the experimental sectioning of both vagal trunks.

32.120.7.1.1

Pyloric Outflow Failure

Failure of pyloric outflow (posterior functional stenosis) causes accumulation of ingesta in the abomasum and omasum. Advanced stages of this form of the syndrome also display gross distention of the reticulorumen. Generally the motility of the forestomach is not markedly affected in the early stages, and normal stratification of ingesta is maintained. Overfilling of the forestomach as a result of reflux of ingesta from the abomasum (internal vomiting) may occur, causing the chloride content of the ruminal fluid to increase (normal is less than 30 mEq/L). In contrast, the ruminal fluid of animals with anterior functional

stenosis has a normal chloride content.[444,446,447,453] With severe distention forestomach motility is reduced, and the ruminal contents become more fluid. Failure of ingesta to flow into the intestinal tract, combined with sequestration of chloride-rich fluid in the stomach chambers, can cause both marked dehydration and hypochloremic metabolic alkalosis. In cases with a gradual, prolonged development, however, as in anterior stenosis, any dehydration tends to be mild, and body fluid electrolyte concentrations do not show remarkable abnormalities. Fecal production in these cases tends to be even less than with the anterior stenosis form of the syndrome.[441,453]

Failure of pyloric outflow can be experimentally reproduced by sectioning the ventral vagus trunk at the cardia and the continuation of the dorsal trunk as it crosses the omasum.[397,442] This mimics the usual clinical form of the disease, which is characterized by complete inhibition of flow from the abomasum. Combinations of more distal resections of the nerves produce the syndrome of recurrent atony of the abomasum as it occurs in natural clinical cases. Again, the term *stenosis* is a misnomer, because a true stenosis or spasm of the pylorus is not identified. Rather, the experimental vagal nerve resection and the naturally occurring cases show a flaccid paralysis, and ingesta accumulate as a result of failure of propulsive activity. The dilation of the abomasum is in the fundus and body and not in the pyloric part.[399,441,442]

A common predisposing cause of pyloric outflow failure syndrome is volvulus of the abomasum. Other abomasal disturbances, including right and left displacements of the abomasum and abomasal ulceration, can cause the disease as well. After surgical correction of a volvulus, the abomasum remains atonic, and the disease may develop within several days. Clinical signs compatible with vagal indigestion may arise from gross distention and twisting of the abomasum and lesser omentum, resulting in potentially coexisting but distinct injury to the vagal nerves or structural damage to the gastric wall, with or without peritonitis. Although focally extensive vagal nerve lesions have been associated with concomitant vascular damage, indicating that even with nerve regeneration there may not be a return to normal function, the damage appears reparable in some cases, because a return to normal function has been observed.[452]

824
825

Inflammation and adhesions involving the abomasal fundus and reticulum have been associated with posterior functional stenosis in some studies.[441,453] Inflammation of the reticular wall may account for the reticular atony reported in some cases. This form of vagal indigestion may be more frequently associated with true vagal nerve impairment than appears to be the case in anterior functional stenosis. Alternatively, reticular adhesions may prevent normal motility, alter the flow of ingesta to the omasum and abomasum, and lead to abnormal filling of the abomasum because of decreased fluidity of abomasal contents.[453]

Another predisposing cause of pyloric outflow failure is advanced pregnancy with a large fetus. An exact pathogenesis has not been clearly defined. Presumably the large, gravid uterus distorts the positioning of the abomasum or physically compresses and obstructs the anterior small bowel, preventing outflow of ingesta from the abomasum. In these patients the gravid horn typically occupies most of the space in the omental sling. In support of these conclusions, the problem can be resolved by inducing delivery of the calf or performing a cesarean section. Supportive care may be required for severely affected cows, but the gastrointestinal system returns to normal function, suggesting that it was secondarily affected by the pregnancy. This problem is referred to as a form of vagal indigestion because it appears as a pyloric outflow failure. Some patients have such severe obstruction of ingesta passage that they may be diagnosed as having an anterior bowel obstruction. This disease has been called *indigestion of late pregnancy*.

Animals affected with any form of vagal indigestion for a prolonged time lose body condition because the

failure to pass ingesta into the intestinal tract produces a state of starvation. The weight loss may be overlooked because of the impression of full body size produced by the abdominal distention.

32.120.7.2 CHRONIC RECURRENT BLOAT

Chronic recurrent bloat is commonly identified with vagal indigestion in any of its forms. It is mild to moderate in severity, commonly waxes and wanes, and adds to the visual impression of gross abdominal distention. The pathogenesis of this ruminal tympany varies from case to case. Experimental resection of both abdominal vagal trunks stops eructation by causing complete forestomach stasis. In naturally occurring cases in which lesions of the vagal nerve truly inhibit motor impulse transmission, bloat may arise from this mechanism. When vagal nerve damage does not appear to be involved, other mechanisms may explain the bloat (see Table 32-12). Overfilling of the reticulorumen with frothy ingesta, a common finding, can inhibit the cardia dilation reflex that is a prerequisite of eructation. Gross distention of the forestomach can also weaken the contractile ability of the rumen, so that the contractions are not strong enough to clear the cardia before eructation.

Bradycardia is often identified in association with vagal indigestion but can also occur with other forestomach diseases. The finding that atropine administration can abolish the bradycardia of vagal indigestion suggests increased cardiac vagal tone as the direct cause.[425,454] However, the origin of the vagotonia is unclear. When vagal nerve lesions exist distal to the cardiac innervation, reflex excitatory discharges may effect bradycardia. Experimental resection of the vagal nerves causes bradycardia as a striking feature in most cases, although advanced cases show increased heart rates. By contrast, naturally occurring vagal indigestion shows bradycardia as a feature in only a third or fewer of the cases.[441,445,447] These variations may exist because the experimental and natural cases have different causes or because the disease varies in duration. Once the forestomach has become severely distended, the heart rate tends to be elevated, probably as a result of deterioration of hydration and cardiovascular parameters.

32.120.8 Obstruction of the Cardia or Reticuloomasal Orifice

True mechanical obstruction of the forestomach is an uncommon occurrence. The obstruction can be either full or partial and can occur at either the cardia or the reticuloomasal orifice. The inflammatory and neoplastic conditions described previously can appear to be obstructive disease when the tissues are sufficiently distorted and lesions involve one of these orifices. Papillomas are most prone to causing an obstruction when they become pedunculated. A variety of foreign bodies create obstruction. In calves, trichobezoars are most commonly the cause, occurring predominantly in animals on a low roughage diet that consequently lick their hair coats vigorously. In adult cows, ingestion of the placenta occasionally results in an obstruction. Curious ruminants, especially goats, sometimes consume plastic bags or discarded rectal palpation sleeves. These and other nondegradable materials can lead to obstruction even after considerable time has passed.

Cardia obstruction leads to the signs typical of esophageal obstruction, with free gas bloat as a prominent, perhaps life-threatening development. Obstruction of the reticuloomasal orifice produces the same consequences as some forms of vagal indigestion. Failure of ingesta flow beyond the rumen results in accumulation of fluid material in the forestomach and diminished or no passage of ingesta through the intestines. The degree and duration of obstruction determine the severity of associated problems such as dehydration, depression, elevated heart rate, forestomach stasis, colic, and muscular weakness. Only rumenotomy can effectively differentiate these obstructive diseases from other problems with similar signs.

32.120.9 Diaphragmatic Hernia

Defects in the diaphragms of cattle are uncommon. Most cases involve a tear through which the reticulum can herniate. Other abdominal organs may also be involved if the rent is large. The diaphragmatic defect may be congenital or an acquired lesion caused by a local inflammatory process (TRP), sudden external trauma (fighting, hanging up on a fence), or internal pressure (parturition, acute tympany). Entrapment of the reticulum may lead to acute changes in intrathoracic pressure and cause sudden dyspnea, tachycardia, and poor venous return to the heart. Generally, however, this reticular problem causes signs identical to those of vagal indigestion with anterior functional stenosis.[386,445] Failure of flow through the reticuloomasal orifice may result from vagal nerve damage, or the anatomic distortion alone may explain the motility defect. Entrapment of the reticulum hinders normal reticular movements and distorts the esophageal groove and reticuloomasal orifice. Reticular ingesta can be heard moving inside the thorax; therefore complete reticular paralysis is unlikely. Motility disturbance is reflected by hypermotility of the rumen, generation of frothy ingesta, persistent or recurrent moderate tympany, and overfilling of the rumen. Signs of pain may also be present, as in cases of TRP. Rumination usually is impaired, and large volumes of ingesta may be vomited, especially after eating.

826

32.121 DISORDERS OF RETICULORUMINAL FERMENTATIVE FUNCTION (SeeBox 32-5)

32.121.1 Forestomach Microbial Population

The continuous culture system of the rumen involves an ongoing selection of microorganisms best adapted to grow in a variety of ecologic niches that are in a dynamic state. Numerous control mechanisms govern the environment and the resultant microbial population. Some of these mechanisms are related to the animal itself, such as salivation, mixing and rumination, removal of substances by absorption or diffusion, outflow through the reticuloomasal orifice, and eructation. Others are related to the diet, including nutrient quality of the substrate (feed), balance of required elements, solubility, particle size, presence of inhibitory substances, nutrient quantity, and rate of delivery to the rumen. Control of fermentation also results from microbial interactions such as competition and symbiosis: cross-feeding between species, removal of inhibitory end products, and maintenance of the oxidation-reduction potential. The complexity of the system tends to promote an overall stability. Changes in the controlling factors create selective pressures that lead to population changes in the rumen.[424,455–456]

The ruminal bacteria are predominantly anaerobes, with some coexisting facultative anaerobes. Although the facultative organisms are not important in normal ruminal function, they may be in some forms of ruminal dysfunction. Some microbes ferment the primary nutrients in the feed such as cellulose, hemicellulose, pectin, starch, and simple sugars. Other species ferment the products of the primary group, such as pentoses, glucose, lactate, succinate, and formate. Many species are very specialized and have numerous growth requirements that may be supplied by the general fermentation. The last group is important for its role in removing end products and cycling essential factors back to the other organisms.[424,455–457]

Table 32-13 Effects of Feed Characteristics on Ruminal Digestion and Health

Feed	Ruminal Content	Effect on Health
Primary forage of high quality, long fiber length, crude fiber >18% of dry matter; with concentrate supplement at 20%–50% of total intake, moderate protein level	pH 5.5–7, VFA 60–120 mmol/L, acetic > propionic > butyric acid	Normal, healthy, productive
Excessive forage of low nutrient value (late cut) with little concentrate or protein supplementation	pH 6.5–7, VFA decreased, microbial activity decreased	Poor production or growth, microfloral inactivity and ruminal impaction, malnutrition caused by protein, energy, mineral, and vitamin deficiency
High level of concentrate feeding (>60%) with decreased forage and/or fiber length	pH 5–6.5, VFA increased, microbial activity increased	High production, rapid growth; possible chronic ruminal acidosis, milk fat depression, chronic laminitis, ketosis, ruminal parakeratosis, excessively fat condition
Extremely high level of concentrates (especially with sudden exposure to ration), low intake of forage	pH 4.5–5, VFA increased, lactic acid increased	Acute ruminal acidosis
Normal levels of forage intake, concentrate with very high protein or NPN supplementation	pH 6.5–7.5, VFA decreased, ammonia increased	Ruminal alkalosis, possible urea toxicity

NPN, Nonprotein nitrogen; *VFA*, volatile fatty acid.

32.121.2 Effects of Feed Characteristics

The concentrations and proportions of the microbial species vary with the composition of the diet (Table 32-13). An abundant supply of a certain substrate tends to favor a microbial population with a predilection or high capacity for using that material. The most important factors in the rate of digestion are the properties of the carbohydrates and protein in the feed. High-protein diets favor proteolytic organisms, whereas high-starch, low-fiber diets favor starch users. Cellulolytic bacteria are prominent in a high-fiber diet, but their numbers also depend on the fiber size, as this factor determines the rate of passage or retention in the forestomach; therefore cellulolytic species can be abundant with a high-concentrate diet if some long-stemmed roughage is included because the retention time of the fiber is prolonged. Diets with readily fermentable carbohydrates and low fiber favor species capable of rapid metabolism and tolerant of low pH. Acid production is rapid and high, and populations of microbes less tolerant of such changes decline.[455,457,458]

The microbial population is also influenced by the limits of supply of certain feed substrates.[455] High rates of fermentation and microbial growth on the abundant substrates depend on sufficient amounts of the more limited nutrients. Optimum carbohydrate use requires adequate sources of nitrogen, sulfur, and essential mineral nutrients.[459] When any essential nutrient is deficient, the rate of digestion and therefore the digestibility of the feedstuff decrease. Whether the affected animal shows signs of nutrient deficiency or forestomach dysfunction with microbial and forestomach inactivity depends on the limiting nutrient and relative requirement of the host and bacteria for the nutrient. Substances and conditions that inhibit fermentation further reduce digestibility.

The feed material also affects ruminal fermentation by influencing the rate of passage from the reticulorumen.

Fine grinding and pelleting of feed increase the rate of passage of the particulate matter from the rumen. Very finely ground rations also reduce the stratification of fibrous material in the rumen. This affects the ability to sort material in the rumen selectively by particle size and density, so that larger particles less thoroughly fermented pass more readily into the lower bowel. Microbes associated with the feed particles are passed out of the rumen with the feed. Thus a faster rate of passage influences the bacterial population because it competes with the generation time of the organisms. Populations of slower-growing microbes tend to be most influenced by changes in the retention or passage times. Slow-growing cellulolytic bacteria decline in numbers as the passage rate increases (transit time decreases). High passage rates usually produce faster digestion rates. Although these factors are primarily important to the feed efficiency of the animal, they also affect ruminal function and the adaptation of microbes to feeding changes.[388]

826

827

Adaptation of the microbial flora to dietary changes requires a week or longer. The abruptness of a dietary change determines the degree of alteration of the ruminal microbial population and fermentation pattern and the potential for digestive disturbances. With abrupt and dramatic shifts to higher-carbohydrate diets, the facultative species may overwhelm the more normal flora by producing excessive acid and lowering the pH. The importance of microbial adaptation to a particular diet is evidenced by the reduction in forestomach disturbances seen when the rumen is inoculated, before a feeding change, with fluid from animals already adapted to the new ration.[424,456]

The end products of microbial fermentation influence not only the microbial population but also ruminal function. High concentrations of nondissociated VFAs excite sensory epithelial receptors that reflexively inhibit ruminal motility.[424,460,461] If a sudden increase in concentrate feeding induces lactic acid fermentation, the ruminal pH suddenly declines and a greater proportion of the VFAs shift to the nondissociated state, inducing ruminal stasis. A consistently high level of concentrate feeding produces rapid fermentation, a high concentration of VFAs, and low pH, and the nondissociated VFA level may reach the threshold for stimulation of the inhibitory epithelial receptors. The ruminal stasis reduces the fermentation rate. Mild cases of ruminal acidosis may show spontaneous recovery of ruminal functions as the absorption of VFAs reduces the concentrations to a noninhibitory level. With more severe ruminal acidosis the generation of acid continues despite the ruminal stasis, giving rise to more severe complications of the disease.

In some instances the effects of ruminal microbial metabolism and microbial end products extend beyond impacts on nutritional status and digestive system function. Several ruminant diseases represent rumen-generated toxicities. These have extremely variable manifestations and include toxicoses from ammonia, nitrate and nitrite, 3-methylindole, dimethylsulfide (*Brassica* species, onion toxicity), and sulfur-associated polioencephalomalacia.[462–465]

In summary, excesses, deficiencies, or rapid changes of feed substrate can cause imbalance in the microbial population and the fluid milieu. The result can be bacterial overgrowth and overproduction of microbial end products or insufficient microbial growth and fermentation. The effects of these abnormalities on the animal range from ruminal motility dysfunction to poor growth and performance to outright toxicity and organic damage.

32.121.3 Inactivity of Ruminal Microbial Flora (Caused by Poor-Quality Roughage,

Haybelly, or Ruminal Impaction)

In ruminal microbial flora inactivity, the microbial populations and their metabolic and fermentative processes are diminished as a result of deficiencies of one or more nutrients. This occurs most commonly with poor-quality roughage deficient in protein and readily digestible carbohydrates (late-cut, highly lignified hay or straw). Microfloral inactivity can also occur when specific mineral nutrients are deficient, or it can be caused by inhibitory substances such as antibiotics or some plant products.[388,424,459] Microfloral inactivity also occurs with prolonged anorexia, which abolishes the intake of all nutrients and is the primary pathogenesis of many cases of secondary indigestion.

When microbial digestive processes decline, the breakdown of ingested feedstuffs is prolonged. Failure to reduce the particle size of the ingesta leads to a prolonged retention in the forestomach and gradual accumulation of the undigested feedstuff. Gradual distention of the reticulorumen is commonly observed (haybelly). In extreme cases this can mimic the signs of vagal indigestion. Forestomach distention can result in weak contractions and moderate recurrent tympany. Ruminal hypomotility alters the normal stratification of the ruminal contents, and the fibrous components are found mixed in the fluid or compacted ventrally on the ruminal floor. Abnormal passage of ingesta from the forestomach results in decreased fecal passage, and the feces usually are dried and contain undigested plant fibers. Other effects on the animal are those of generalized or specific nutrient deficiencies (e.g., decreased growth or production, ketosis, emaciation, and a poor hair coat). When anorexia is the cause of the microbial inactivity, the ruminal fill decreases and the lack of normal distention also induces ruminal stasis.[386,466]

32.121.4 Simple Indigestion

Simple indigestion is the most common sequela of an abrupt change in the ration. Such feed changes present the ruminal microflora with nutrient substrates (1) to which they are not metabolically adapted, (2) to which they are adapted but in lesser quantities, or (3) that contain inhibitory substances or produce inhibitory substances on fermentation. The result is an imbalance in the microflora and its fermentation products. The difference between this problem and some of the other fermentation disorders is mostly a matter of degree. Generally the disease is relatively mild and self-limiting. Most affected animals show anorexia for 1 to 2 days, break with diarrhea in about 24 hours, and return to feed without treatment when the ruminal fermentation has stabilized and inhibitory substances have been eliminated. Ruminal motility is reduced but usually not absent, the filling of the rumen is not remarkably altered, and if bloat occurs, it is mild. In some cases the ruminal fluid pH may change, but usually not dramatically. Mild acidosis or alkalosis of the ruminal fluid may develop, depending on the nature of the causative feedstuff and its resultant fermentative degradation. Signs of ruminal microfloral inactivity are common. Simple indigestion is an acute problem, in contrast to the microfloral inactivity discussed in the previous paragraphs, in which deficiencies produce microfloral inactivity over time.

Feeds commonly implicated as causes of simple indigestion include moldy or overheated feeds, frosted forages, and partly fermented, spoiled, or sour silages. This form of indigestion also occurs in animals fed high-quality feed, usually after an increase in the rate of feeding or after a change of one of the feed constituents. Thus these mild forms of indigestion can range from a mild acidosis to an excess of VFAs to the generation of some bacterial inhibitory products. Because the rumen and its fermentative bacteria are very adaptable, the ways, if any, in which animals given a certain feed experience the problem vary considerably. Often only one or a few animals from a group on the ration may have signs.

32.121.5 Acute Ruminal Lactic Acidosis (Grain Overload, Toxic Indigestion)

Acute ruminal acidosis is the most dramatic of the forms of ruminal microbial fermentative disorders and in some cases is lethal in less than 24 hours. It has also received the most research attention; therefore the events in its pathogenesis are more clearly defined than those of the other forestomach disorders. The condition has been named *lactic acidosis, acute ruminal impaction, ruminal overload, acid indigestion, toxic indigestion, grain engorgement, grain overload*, and *D–lactic acidosis*.

This problem is the result of excessive consumption of readily fermentable carbohydrates, which causes a rapid fermentation with production of lactic acid and a decrease in ruminal pH to physiologically inappropriate levels. This occurs when animals consume an excess of concentrate feeds (e.g., if animals are suddenly exposed to the feeds without prior adaptation; if animals already on such feeds suddenly consume an excessive quantity because of accidental access; or if animals that have been off feed return to feed and are offered unrestricted access to concentrates). The problem is more common when animals are grouped than when they are separate, probably because the psychology of competition induces them to overconsume. In general the feeds involved include the cereal grains commonly used in high-production rations and fruit and root crops (e.g., feed beets, sugar beets, potatoes) where they are available. Starch and soluble sugars promote an overgrowth of bacteria that produce glucose and organic acids. The acid end products increase ruminal acidity and osmolality, inhibit or destroy other ruminal microbes, and cause forestomach dysfunction and metabolic disturbances.[467–469]

Specific characteristics of the feedstuffs contribute to acidification of the ruminal fluid. Cereal grains inherently possess less buffering capacity than the fibrous forages. Low structured fiber content and decreased forage particle size induce less salivation at the time of ingestion and less rumination subsequently; therefore salivary buffering declines when concentrate feeds are consumed. Some silages contain both high carbohydrate and lactic acid and thus introduce more acid at both ingestion and fermentation.[437,468,470,471]

Feeding regimens that include significant fibrous roughage limit carbohydrate availability and rates of microbial fermentation and growth. Carbohydrate fermentation efficiency relative to the amount of ATP derived from each sugar provides competitive survival value. Slower-growing cellulolytic bacteria use substrate most efficiently. When starch or sugar is available in excess, the faster growing species such as *Streptococcus bovis* metabolize carbohydrate faster and produce more ATP per unit time, even though they are less efficient in ATP production per carbohydrate molecule. Under these conditions they can overgrow, producing lactic acid as their end product.[458,472]

The severity of ruminal acidosis and disease signs varies considerably, depending on the amount and type of carbohydrate-rich feed consumed and the degree of prior ruminal microbial adaptation to the carbohydrate substrate. The disease can range from a mild form of indigestion to an overwhelming toxemia that may be difficult to distinguish from other acute toxicities or various diseases with endotoxemia.

If consumption of fermentable carbohydrate is only mildly excessive, *S. bovis* proliferation decreases when the carbohydrate has been fermented, pH rises toward normal, and the efficient fermenters reestablish dominance. If the carbohydrate source is abundant and its supply is not exhausted, the acidosis becomes more severe. Continued production of lactate by *S. bovis* reduces the fluid pH to the range of 5 to 5.5, and the ruminal fluid osmolality rises concurrently. Both of these factors inhibit or kill the ruminal protozoa, which normally use starch and small sugars and help to limit increasing lactic acid levels. There are also numerous species of lactate-using bacteria, of which *Megasphaera elsdenii* and *Selenomonas ruminantium* are the primary examples. These bacteria, which increase in numbers when animals slowly adapt to a high-concentrate diet, are eliminated by abrupt changes and generation of excessive acid; therefore lactate use decreases when the acid is generated too quickly.[458]

The lactobacilli are the major group of lactic acid producers in the rumen. The increasing acidity of the fluid enhances the growth of these organisms. Because the lactate-using bacteria are killed off before the lactobacilli overgrow, their diverse end products are unavailable as substrate for other bacteria. The lactobacilli are left as the predominant organisms to use the available carbohydrates. Even the *S. bovis* organisms that began the lactic acid production are inhibited below pH 4.5, leaving the lactobacilli, the most acid-resistant species, to generate more lactic acid.[470]

The acidification of the fluid milieu enhances lactic acid production by altering microbial metabolism. The loss of the fluid bicarbonate buffer and the increase in available hydrogen ions block the conversion of lactate to propionate even before the lactate users die off. Also, when the pH is above 5, as pH declines, ruminal fluid amylase activity increases, liberating more free glucose from starch. However, glucose use is reduced, and ruminal glucose accumulates. Apparently the lactate-using bacteria such as *S. ruminantium* degrade less lactate to acetate in the presence of increased glucose concentrations. Therefore not only does the microbial population change, but the characteristics of the fluid accelerate the lactic acid production when the available carbohydrate is excessive.

The effects on the animal from the ruminal fluid changes are numerous and detrimental. In the early stages of the acidic fermentation, the VFAs are produced in abundance. Although VFA production decreases as the microbes are increasingly inhibited, VFA concentrations remain elevated in advanced acidosis. The VFAs are much weaker acids than lactic acid; thus, as pH drops they accept hydrogen from lactic acid and serve as buffers in the fluid, so that a greater proportion of the VFAs exist in the nondissociated state. This form is more readily absorbable than free ions through the ruminal wall. During absorption some VFAs undergo metabolism by the ruminal wall epithelium, resulting in the release of lactate and ketone bodies into the circulation. Excessive absorption of the VFAs leads to systemic acidosis, and circulating lactate and VFAs may also directly damage the liver.[473] In addition, the high concentration of nondissociated VFAs at the ruminal epithelium provides a strong inhibitory effect on reticuloruminal motility and leads to ruminal stasis. This effect tends to protect the animal because it reduces the absorption of detrimental fermentation products from the rumen.[460–466,468–470]

The osmotic pressure of the ruminal fluid increases as lactic acidosis develops.[437,468–470,474] In a normal animal, ruminal osmolality remains relatively constant at approximately 280 mOsm/L, but osmolality may double in some cases of acute acidosis. Lactic acid accounts for a major fraction of the increase, but some of the components of this change remain unidentified. The increased osmolality inhibits and kills some of the microflora and draws fluid into the rumen, mostly from the extracellular compartment. This accounts for the increased ruminal fluid volume, ruminal distention, and severe dehydration observed clinically. The loss of circulating fluid volume leads to circulatory impairment, decreased renal blood flow and glomerular filtration, and in some cases eventual anuria. Poor peripheral circulation results in hypoxic metabolism and contributes to systemic acidosis.

828

829

Although it has been assumed that the systemic acidosis that develops with this disease is attributable to ruminal lactic acid absorption, such absorption does not appear to occur readily.[470,475,476] Lactate is absorbed from the rumen at a much slower rate than are the VFAs because it is highly ionized at a pH near physiologic normal, which tends to inhibit absorption. At lower pH the rumen becomes static, thereby also inhibiting absorption. The hypertonicity of the ruminal fluid further limits absorption of lactate and other substances. It appears that the peak entry of lactate into the circulation occurs in the early phases of the disease. Some lactate may be absorbed from the intestinal tract from fluid passed before the onset of complete stasis. Many experimental trials do not show the development of severe systemic acidosis in the early phase of the disease. It may be that a large

component of the later severe systemic acidosis is attributable to circulatory insufficiency rather than to absorption of lactic acid.

Some absorption of the lactic acid does occur, however, as evidenced by the appearance of D–lactic acid in the circulation.[422,470,475] Microbes produce both the L and D forms of lactic acid, whereas animal tissues produce only L–lactic acid. The animals' pathways for metabolism of D–lactic acid are not as efficient as those for L–lactic acid; therefore absorption of both forms leads to an accumulation of predominantly D-lactate in the animal's system. The lactate is eliminated by oxidation, gluconeogenesis, and renal excretion. The animal's hydration status, liver and muscle metabolism, and renal function determine how readily it can eliminate excess lactate. Animals that survive ruminal acidosis often have metabolic alkalosis after the acidotic phase, as a result of lactate metabolism and production of bicarbonate.

Lactic acid is a strong corrosive agent that can destroy the ruminal epithelium, giving rise to the name *toxic rumenitis*. The increased ruminal fluid osmolality also damages the epithelium as extracellular water influx across the epithelium occurs in response to osmotic pressure imbalance and disturbed Na transport.[467] The effects of epithelial destruction can be far-reaching because the damage persists after resolution of the acute acidosis.[437,477] Some yeast and fungi that are resistant to the high acidity readily colonize the damaged sites, invade the vasculature, and cause thrombosis or spread to the liver and other organs.[430,431] Ruminal acidosis is considered one of the primary causes of mycotic rumenitis (discussed earlier under Reticulitis and Rumenitis) and mycotic omasitis, although other predisposing causes have been identified.[430–434] Bacterial rumenitis can also result from the chemical damage and may lead to abscess formation, diffuse cellulitis, or perforation and peritonitis. If the animal survives the acute acidosis, it may succumb to secondary ruminal damage.[431,433] Alternatively, the rumen may heal uneventfully, leaving scars in the ruminal wall, but access of bacteria to the circulation through these chemical lesions can result in hepatic abscessation, a common problem of animals fed high-concentrate rations.[429,478,479]

In addition to lactic acid, several toxic factors have been implicated in acute ruminal acidosis.[422,458,470] The altered metabolism of the ruminal microflora has been shown to generate increased quantities of histamine, ethanol, methanol, tyramine, and tryptamine. These may play a role in the pathogenesis of the disease, but conclusive evidence is lacking. Histamine has been implicated as an agent in the development of laminitis that sometimes accompanies ruminal acidosis. However, histamine is poorly absorbed from the rumen, especially at diminished pH levels. The destruction of ruminal gram-negative bacteria has been suggested to release large quantities of endotoxin for absorption through damaged mucosal surfaces. Endotoxin would contribute to most of the signs of the disease such as ruminal stasis, poor tissue perfusion with cardiovascular deterioration, weakness, and depression. Increased ruminal and blood concentrations of endotoxin and increased blood arachidonic acid metabolites have been found in cattle with experimentally induced ruminal acidosis, but their importance in naturally occurring disease is not clear.[480–483] With liver impairment or ruminal wall damage, toxin absorption and clearance are likely to be altered. Premature delivery and retained placenta may occur in pregnant animals after acute ruminal acidosis, possibly resulting from the effects of these circulatory toxins and metabolites.[484]

32.121.6 Subacute Ruminal Acidosis

Like acute ruminal acidosis, subacute ruminal acidosis (SARA) is caused by feeding of excessive quantities of concentrate with low levels of well-structured fibrous roughage; however, SARA results from continued ingestion of these feeds over a prolonged period rather than sudden exposure without adequate adaptation. Beef feedlot cattle may be chronically exposed to a ruminal pH of 5 to 5.5 from the start of the feeding period until slaughter. Dairy cattle are more likely limited to short periods of low ruminal pH typically between calving and approximately 5 months postpartum, with the risk for SARA very low outside these time periods.[485,486] The ruminal microbial population adapts to the high grain ration, and large numbers of lactate-using and lactate-producing organisms are found. The proportion of cellulolytic bacteria decreases, whereas the starch- and glucose-fermenting species proliferate. The overall effect of the adaptation is development of a microbial population that rapidly ferments the ingested feedstuffs. Lactic acid does not accumulate because it is further metabolized by the bacteria. The high rate of fermentation instead produces high concentrations of VFAs, resulting in moderately acidic ruminal fluid with pH values usually ranging from 5 to 5.5.[487] Ruminal buffering of the increased acid load is impaired because the fine particle size of the high-energy rations induces less chewing and less saliva production. As the name implies, the effects on the animal are chronic and insidious.

Along with the high concentration of VFAs and the low pH, a shift occurs in the proportions of the VFAs in the ruminal fluid. The proportions of butyric and propionic acids increase, and acetate decreases. Butyric and propionic acids stimulate proliferation of the ruminal papillae epithelium. When this process is exaggerated, it can progress to parakeratosis. The ruminal papillae develop an excessively keratinized epithelium and clump together. The parakeratotic changes are associated with decreased absorption of the VFAs and increased susceptibility to trauma and inflammation. Epithelial damage and the acidic nature of the ingesta appear to be responsible for inflammation of the deeper tissues of the ruminal wall in some cases. The ruminal wall lesions allow penetration by bacteria with dissemination to the liver. This commonly results in liver abscessation in a high proportion of affected animals. Liver abscesses usually have no pathognomonic signs. Affected animals tend to show reduced productivity and may have signs of a chronic inflammatory response.*

The diagnosis of SARA is made on a herd level rather than on an individual cow basis. Cattle afflicted with SARA may demonstrate numerous clinical signs including reduced appetite and ruminal hypomotility.[486] High ruminal VFA concentrations can inhibit ruminal motility by stimulating the inhibitory receptors in the epithelium. The finely ground ingesta also induce less active ruminal motility because it lacks the physical bulk of high-roughage diets that stimulate strong and sustained contractions. Although the bacterial population is metabolically very active, the number of species of bacteria is reduced. Likewise the protozoal population is inhibited when the pH remains in the lower end of this range. The microfloral environment is less stable when fewer species are present and is therefore more susceptible to sudden changes in the diet.

829
830

A continual high acid load may also reduce metabolic efficiency and overall animal performance. High-concentrate diets have been associated with poor use of dietary protein.[457,489] Other pathologic conditions have been attributed to SARA, including chronic laminitis[490] and cerebrocortical necrosis. These conditions may be induced by some of the toxic by-products of acidic ruminal fermentation, such as endotoxins and hydrogen sulfide.[464,465,470,480–483,488]

32.121.7 Ruminal Alkalosis

An alkaline ruminal fluid pH occurs most commonly when microbial fermentation is reduced while the animal continues to ingest saliva. A ruminal fluid pH between 7 and 7.5 is found with prolonged anorexia, microfloral inactivity caused by poorly digestible roughage, and some cases of simple indigestion. The low rate of fermentation does not generate enough acid to neutralize the alkaline pH of the saliva. In addition, the absorption of VFAs through the ruminal epithelium proceeds with the generation of bicarbonate in the ruminal fluid.[491] Acetate absorption is associated with greater generation of bicarbonate than is absorption of the other VFAs, and acetate is the predominant VFA produced during fermentation of roughage. Although the fermentation rate is low, the VFA absorption contributes to the ruminal alkalinity. Ruminal alkalosis occurring with these diseases is not the primary problem; therefore these entities are discussed separately.

Ruminal alkalosis can occur with the generation of excessive ammonia. Ammonia concentrations rise when high-protein diets are fermented. The pH usually does not increase above neutral because these diets also contain sufficient readily fermentable carbohydrate to maintain a slightly acidic pH.

More dramatic elevations in the ammonia concentration, with a ruminal fluid pH above 7.5, occur with overfeeding of nonprotein nitrogen sources such as urea, biuret, and ammonium phosphate (see Chapter 54). Accidental ingestion of some common fertilizers that contain ammonium salts can produce the same results. For the purpose of this discussion, it is important to realize that some of the signs of urea poisoning involve ruminal dysfunction. Severe cases of urea poisoning result in generalized signs such as muscle tremors, incoordination, weakness, tachypnea, and CNS excitation, and affected animals die quickly. Signs of forestomach dysfunction such as ruminal hypomotility, bloat, vomiting, and abdominal pain are also present. In milder cases, diminished appetite, ruminal hypomotility, recurrent tympany, and diarrhea may be the most prominent signs, along with muscular weakness and incoordination. Thus the disease may appear as a form of forestomach disease. The ruminal fluid shows an alkaline pH between 7.5 and 8.5 and has a strong odor of ammonia.[462,492,493]

32.121.8 Putrefaction of Ruminal Ingesta

Putrefaction of ruminal ingesta infrequently results from overgrowth of a microflora that decomposes feed material in a putrefactive manner. The existence of a high ruminal fluid pH, such as occurs with high-protein feeds, and repeated inoculation with abnormal bacteria allow the development of the putrefactive decomposition. Fermented feeds undergoing spoilage, feed and water contaminated with feces, and spoiling, contaminated concentrates supply the offending microflora, which includes the coliform group and *Proteus* species.[386] This type of abnormal decomposition is normally inhibited by the existence of an active physiologic microflora. Therefore most cattle are remarkably resistant to aberrant digestive patterns even when spoiled feeds are ingested. Cattle affected with this form of indigestion typically follow a chronic course of disease. Ruminal motility declines, appetite is poor, and recurrent tympany develops, sometimes with the generation of frothy ruminal contents. The ruminal fluid characteristically has a blackish-green color, a foul, putrefactive odor, poor protozoal and bacterial activity, and a pH in the neutral to alkaline range of 7 to 8.5. The cause of the forestomach hypomotility may be inhibitory products generated by the abnormal fermentation. In cases of prolonged duration, animals lose weight and display a poor hair coat, probably as a result of dietary deficiencies in the abnormal fermentation products.

32.122 FORESTOMACH DISEASES OF CALVES

Normal forestomach development and diseases of the forestomachs of calves have been reviewed.[387,388,494] The newborn ruminant has the same anatomic division of the stomach into four compartments as the adult ruminant. The abomasum is functional as a secretory digestive organ, like the stomach of monogastrics, and has a capacity approximately twice that of the other compartments. The remaining stomach compartments are small and do not perform digestive functions in the first days of neonatal life. The reticulorumen may not develop an adult-type function until 4 months of age or older and does not completely develop proportional dimensions similar to those of the adult until 9 to 12 months of age.[386–388,494–496]

The preruminant calf has been viewed as a functionally monogastric animal, and little importance has been assessed to diseases of the forestomachs. Under most management conditions, however, the forestomachs have begun to develop their digestive function within the first week or two after birth. During the development process the calf's forestomach is susceptible to problems different from those of the adult. After the rumen has developed a functional status similar to that of the adult, it is susceptible to the diseases discussed previously. Typically the feeding management of maturing young stock includes pasture or a mainly forage diet and does not predispose to digestive disturbance.

32.122.1 Esophageal (Reticular) Groove Function

Liquid feed bypasses the reticulorumen in the young ruminant, flowing directly into the abomasum through the esophageal groove. The groove consists of two lips that extend from the cardia to the reticuloomasal orifice. These lips close together, forming a tube to shunt liquid material to the abomasum when the soluble proteins and salts of milk stimulate a reflex through the glossopharyngeal nerve. Other salt solutions and even water can stimulate the reflex in very young animals, but the reflex weakens with age, especially after weaning. The response to stimuli varies among individuals, but generally milk produces the strongest response and plain water the weakest. Both nipple and bucket feeding stimulate closure in very young calves, but beyond 12 weeks of age closure is weak unless stimulated by nipple feeding. In older, weaned animals the reflex can be stimulated weakly for short durations by orally administered strong solutions such as copper sulfate or sodium salts. Intravenous vasopressin can induce more profound closure of the groove and has been advocated to aid ruminal bypass of orally administered treatment.[497,498]

830 831

Milk replacers that contain nonmilk protein appear to stimulate a weaker closure of the esophageal groove than do whole milk or milk replacers containing real milk protein. Likewise unpalatable fluids and spoiled milk do not seem to induce normal closure of the groove. Even in healthy calves that consume unspoiled whole milk, some overflow into the forestomach may occur.[499] Failure of esophageal groove closure allows these fluids to pass into the rumen rather than bypassing it. Milk or other fluid administered through a stomach tube or esophageal feeder does not contact the pharynx; therefore the reflex closure is not stimulated and the fluid deposits in the forestomachs. Under normal conditions fluid in the forestomach of neonatal calves less than 2 weeks old overflows into the abomasum when an amount more than 400 mL has accumulated.[500]

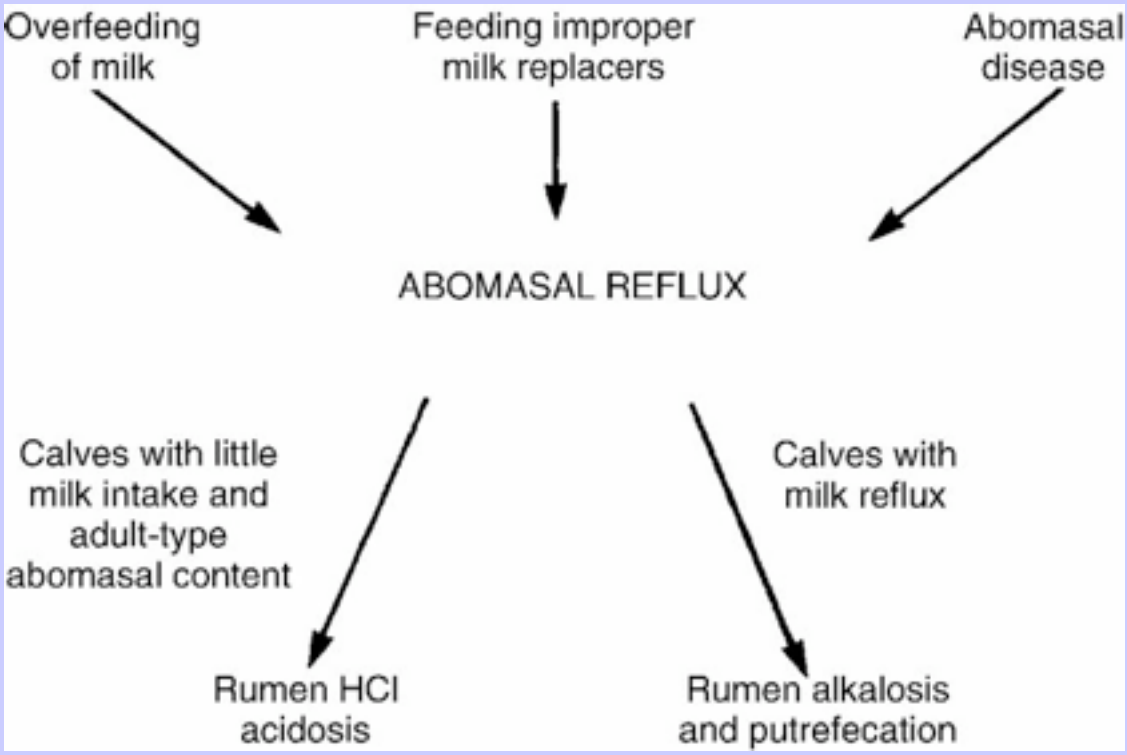
32.122.2 Reticuloruminal Milk Accumulation (Ruminal Drinking)

Milk can gain access to the reticulorumen by several means. Failure of esophageal groove closure, just discussed, is one possibility. In addition, if calves are maintained as preruminants for longer than 3 to 4 months, groove closure weakens and may allow greater escape of fluid to the reticulorumen. Fluid can also accumulate in the forestomach from abomasal reflux (Fig. 32-95). Overfeeding fluids beyond the capacity of the abomasum

(approximately 2 L in the newborn, 35-kg calf) promotes backflow into the reticulorumen. Certain fluids affect abomasal motility and emptying times, prolonging their retention in the organ. These include acidic and hypertonic fluids and severely heat-treated skim milk powder. Nonmilk protein does not curd in the abomasum, as does casein, when it contacts the abomasal enzyme renin. Prolonged fluid retention and failure of curd formation in the abomasum may promote backflow into the rumen, especially when more fluid feed is consumed. Abomasal inflammation or ulceration may also inhibit normal emptying and promote abomasal reflux.

Some amount of milk reflux from the abomasum appears to be a physiologically normal occurrence. In fact, this route supplies some of the inoculum for ruminal microfloral development and strongly influences the species distribution of the microbial population. But prolonged, repeated, or excessive retention of milk in the forestomach can lead to the development of abnormal fermentation patterns. Although amounts of fluid greater than 400 mL do not normally accumulate in the forestomach of the neonate, more fluid can accumulate when the abomasum is already filled and when ruminal size has increased during the development process. In some cases milk flow into the rumen accumulates significantly over prolonged periods.[499]

Fig. 32-95 Abomasal reflux in calves.



The predominant organisms comprising the forestomach microflora of the 1- to 4-week-old ruminant are the coliforms and lactobacilli. These lactose-fermenting, facultative anaerobes tend to maintain the ruminal pH in the acidic range before the adult-type, anaerobic, cellulolytic flora becomes established. The high fat and protein content of milk in the rumen can predispose to a flora that decomposes these constituents and produces spoiled and rancid ruminal ingesta. Problems associated with ruminal milk accumulation are compounded when the milk or other fluid ingested is already contaminated or spoiled. The abnormal microflora established under these

circumstances does not supply the young animal with the necessary digestive end products, and signs of dietary insufficiency develop. Affected animals fail to grow normally, show a poor hair coat potentially with widespread alopecia, and may have a depraved appetite. The stimuli for normal forestomach development are also deficient; affected animals have a potbellied appearance, and the rumen is distended with fluid and clots of milk. Ruminal motility is poor, and recurrent bloat is a common sequela. The ruminal fluid pH may be alkaline as a result of the proteolytic formation of ammonia, but in most cases the ruminal pH is acidic (below 6) because of an accumulation of VFAs and lactic acid from bacterial fermentation, and the fluid has a putrid, foul odor.[501] An enteric imbalance also seems to occur, and the feces are commonly pasty or fluid in consistency. Ruminal "drinking" appears to compound problems in calves with infectious enteritis and diarrhea, and affected calves frequently develop systemic acid-base and fluid balance disturbances.[502–504]

32.122.3 Problems in Ruminal Development

The age at which the calf has reticuloruminal digestion depends largely on its diet. A plentiful supply of milk delays the time until the calf consumes significant quantities of dry feed. Veal calves maintained without access to solid feed do not have forestomach development. The nervous reflexes that drive ruminal motility, eructation, and regurgitation are already functional before birth, awaiting only the drive of normal stimuli to begin operating. Dry feeds pass into the rumen, and bacterial inoculation from the environment or from abomasal reflux stimulates fermentation to begin. This process can be initiated as early as 1 week of age when calves are encouraged to consume dry feeds.[495,505]

The increase in the size of the forestomach results from the bulk effect of ingestion of bulky, fibrous feeds.[506] Mild distention stimulates ruminal motility and the development of the muscular wall. Mucosal development is stimulated by the presence of VFAs in the ruminal fluid, resulting from microbial fermentation. Butyrate and propionate are most effective in this regard, whereas acetate is less stimulatory. The thickness of the mucosa increases with proliferation of the ruminal epithelium and elongation of the papillae.[438] These changes serve to increase the ability of the mucosa to absorb the VFAs. Dietary excesses or deficiencies affect the developing rumen by altering the balance of these stimuli.

831

832

Calves fed concentrate diets to the exclusion of forages or mixed diets with the hay pelleted or finely ground may experience ruminal parakeratosis as a result of a lack of feed abrasion[507] and the excessive production of the stimulatory VFAs: butyrate and propionate.[438] These calves can have a form of chronic ruminal acidosis that results in a reduced growth rate and poor body condition. Ruminal contents are typically fluid with an acidic pH, ruminal hypomotility occurs, and recurrent free gas bloat is common. Affected calves often display a craving for fibrous materials. Hair coat licking is common in these individuals, and hairball formation in the reticulorumen is a common sequela. The hairballs may not be deleterious, but occasionally they cause obstructive disease or abrade the parakeratotic papillae or the abomasal mucosa, predisposing to ulcers and inflammatory lesions. Acute ruminal acidosis is not typically recognized in the young, developing ruminant, probably because feed consumption is limited and because the predisposing adult-type ruminal microflora has not yet developed.

An opposite extreme can occur when the young calf is fed dry forage to the exclusion of more readily digestible carbohydrates. Concentrates and grass contain soluble carbohydrates and are well digested by the developing ruminant. Hays contain much less soluble carbohydrate and an abundance of the structured, slowly digestible forms. These substances are not as well digested by calves because the appropriate cellulolytic microflora is not fully developed. With moderate hay intake and the supply of other sources of nutrition, problems are rarely encountered. When dry roughage is the only available feed, especially when the hay is of poor quality, adequate breakdown of the fiber is prolonged. The low availability of nutrient substrate that results from delayed digestion

of the structured carbohydrates decreases microbial proliferation and fermentation. Inadequate fermentation of the feedstuff deprives the animal of required nutrients as well and results in poor performance and growth. When the only available feed source is the hay ration, the calf continues to consume while the long undigested fiber accumulates in the rumen. The rumen continues to expand as a result of the increased filling, eventually becoming grossly distended. Recurrent bloat is common in these animals because of the overfilling and poor ruminal contractility. This phenomenon is a frequent occurrence under some management conditions and has commonly been called "haybelly." Affected animals display a typical abdominal contour, with gross distention of the abdominal wall that is more prominent on the left side. The ruminal contents are very firm, the fluid has a pH around neutral and shows little microbial activity or odor, ruminal motility is poor, and despite the full abdomen the animal is thin. This form of microfloral inactivity is more common in calves than in adults because the young ruminant is less able to ferment fibrous roughage.[386,387]

32.122.4

Recurrent Bloat (Ruminal Tympany)

Moderate gas distention of the rumen is a common sign of disease in calves, usually as a result of free gas accumulation, whereas frothy fermentation is very uncommon in the young ruminant. The pathogenesis of free gas bloat has been discussed, and the same principles hold for the young ruminant. The differences between free gas bloat in the adult and in the young calf are more a matter of chronicity and frequency of occurrence than cause. Digestive disturbances of the adult rumen tend to develop more rapidly and are more readily identified than those of the calf. Because of the involvement of ruminal developmental processes in the pathogenesis of calf indigestion, in young ruminants the diseases are more chronic than acute in nature. In most cases the calf continues to consume feed, and the abnormal ruminal function and development may be easily overlooked.

Ruminal tympany seems to accompany indigestion in calves more often than in adult cattle and also assumes a more prominent appearance in calves than adults. These factors may be reflections of the juvenile anatomy and the incomplete development of adult function. It is worth noting, for instance, that although left-sided abomasal displacement is an uncommon occurrence in young calves, it almost invariably is accompanied by marked ruminal tympany.[508] In contrast, the disease is common in adult cattle, but ruminal tympany is an infrequent sign of the disease.

Purulent lung infections appear to be a common cause of bloat in calves, probably as a result of intrathoracic compression or irritation of the esophagus or possibly the vagal nerves. However, other causes of bloat that are associated with abnormal ruminal function are also common in calves with indigestion. They include overdistention of the rumen, insufficient clearing of the cardia, and inhibition of motility by abnormal fermentation products. A thorough examination is required to determine the underlying cause of the individual case.

One presumed cause of bloat in calves that is not a cause of adult bloat is sudden filling of the abomasum by milk feeding during weaning. Calves not yet completely converted to a diet of solid feed still consume milk eagerly. In some cases acute free gas bloat occurs immediately after the milk feeding. Because the esophageal groove directs the milk into the abomasum but the abomasum is already partly filled by ingesta from the developing rumen, acute overdistention of the organ can occur and reflexively inhibit forestomach motility. Feeding smaller milk meals or discontinuing the milk feeding resolves the problem in these cases, lending support to the presumed cause.

32.122.5

Clinical Signs and Differential Diagnosis of Indigestion (Table 32-14)

32.122.5.1

GENERAL SIGNS

A general physical examination allows the practitioner to recognize signs of reticuloruminal problems and to assess whether a disease that could induce reticuloruminal dysfunction as a secondary phenomenon is present. General signs common to all forms of indigestion include a reduction or absence of appetite, dullness or depression, and decreased animal productivity. The most common signs of ruminal dysfunction are a decrease, absence, or abnormality of ruminal contraction sounds in the left paralumbar fossa or an abnormal left-sided abdominal contour. The left abdominal wall may show gauntness and decreased filling or may display gross distention. It is often the failure to detect signs of another primary disease as the cause of ruminal dysfunction that directs attention to the forestomach as the possible primary site of disease. Indigestion in calves effectively produces a state of malnutrition, and additional signs in these growing animals include poor growth rate and long, rough hair coat. The acuteness of onset and the severity of these signs depend on the inciting cause of the indigestion. Specific abnormalities in the ruminal motility pattern are discussed in more detail, but most indigestions are marked by decreased or absent ruminations (regurgitation and cud chewing) and depressed ruminal contractions. Only early cases of frothy bloat and some cases of vagal indigestion display increased ruminal motility.

Body temperature usually is within normal limits because the causes of indigestion are mainly physiologic abnormalities. Exceptions include TRP and occasional cases of rumenitis with significant inflammation. 832
Disturbances of heart rate, respiratory rate, and body fluid vary tremendously among different forms of 833
indigestion and different cases of any one form of indigestion. For example, an acute onset of severe ruminal bloat can produce severe embarrassment of the cardiovascular and respiratory systems, whereas mild or chronic bloat may produce no remarkable change in these systems. Rapid accumulation of fluid in the forestomach chamber in severe ruminal acidosis with grain overload can induce severe dehydration, systemic acidosis, and increased heart and respiratory rates, whereas slow fluid sequestration in some cases of vagal indigestion may not induce marked changes in these parameters.

Table 32-14 Clinical Signs Typically Associated with Primary Indigestions

Signs	Associated Problems
Fever	Traumatic reticuloperitonitis, reticuloruminitis
Decreased ruminal filling	Fermentative indigestions and secondary indigestions (especially with chronic anorexia) in which passage of material from the rumen is not impeded
Abdominal distention	See Fig. 32-94
Excessive fluid (or froth) in the rumen with loss of normal ingesta stratification	Acute ruminal acidosis, vagal indigestion, frothy bloat, anterior intestinal obstruction
Excessive firm, fibrous material in rumen	Ruminal inactivity caused by poor-quality roughage
Firm, doughy ingesta in ventral rumen with decreased ruminal filling	Prolonged ruminal stasis caused by chronic disease with anorexia
Ruminal hypermotility	Early cases of frothy bloat, some cases of vagal indigestion
Abdominal pain present or can be elicited	Traumatic reticuloperitonitis, abomasal ulceration, reticuloruminitis
Abnormal feces	
Decreased quantity, firm, dry, with increased fiber length	Traumatic reticuloperitonitis, omasal transport failure, ruminal inactivity with poor-quality roughage, also dental disease and some abomasal disease
Feces with abnormal amounts of whole cereal grains	Acute or chronic ruminal acidosis
Greasy consistency with very fine particle size	Pyloric outflow failure, abomasal displacement
Foamy, fluid, yellowish color, acidic odor	Acute ruminal acidosis
Pasty to fluid consistency with foul odor	Fermentative indigestions, enteritis
Decreased quantity, dry, otherwise unremarkable	Anorexia (various causes), acute indigestions before later developing abnormalities
Vomiting (rare)	Ruminal overdistention with vagal indigestion, inflammation of reticulorumen, reticuloomasal orifice obstruction, diaphragmatic hernia, some intoxications (differentiate from esophageal disease)

The anamnesis is important, especially with regard to the animal's feeding. Characteristics of the feed determine the type of fermentation pattern to be expected. Knowledge of the nutrient content thus allows an assessment of the biochemistry of microbial digestion. Consumption of a high-concentrate, low-fiber ration or legume pasture may lead to frothy bloat. A ration of poor-quality hay or straw may result in low microbial fermentative activity and accumulation of impacted indigestible roughage. Overeating of carbohydrates or sudden access to concentrate feeds without adequate adaptation time can induce chronic or acute ruminal acidosis. The feeding history should agree with the findings from inspection of the ruminal contents, or the history should be suspected to be inaccurate. The amount and consistency of the feces should also provide supportive evidence of the type and amount of feed intake.

32.122.5.2 ABDOMINAL CONTOURS AND ANIMAL STANCE (See Fig. 32-94)

Visual inspection of the abdominal contours allows assessment of the degree of abdomen filling. Indigestions can be characterized by decreased, normal, or excessive filling of the reticulorumen. Most primary and secondary indigestions are associated with ruminal hypomotility and anorexia. Therefore the rumen usually shows no obvious distention and may have less filling than normal, especially when the duration of the disease is prolonged. Forms of indigestion in which abnormal ingesta or abnormal ruminal motility prevents effective forward flow of ingesta (overfeeding of poor-quality roughage, vagal indigestion) or in which fluid is actively sequestered in the reticulorumen (acute ruminal acidosis) typically cause some degree of forestomach distention (see Fig. 32-94).

A left-sided or bilateral ventral abdominal wall distention indicates ventral ruminal dilation, although advanced pregnancy and hydrops conditions must be considered. Distention of the dorsal left flank results from ruminal tympany with or without distention of the ventral rumen. Abomasal displacement to the left can produce mild distention of the dorsal left flank under the caudal ribs and extending into the paralumbar fossa, but the abdomen usually is gaunt and empty when viewed from the side or the rear. Occasional cases of left-displaced abomasum appear to inhibit eructation and produce gross ruminal tympany as the primary sign. Release of free ruminal gas through a stomach tube and reexamination for abdominal pings reveals this cause of secondary ruminal dysfunction. Frothy bloat in ruminants is discussed further elsewhere in this text (see p. 855). Free gas accumulation often occurs secondary to the causes of ruminal motility inhibition and is important as a sign of indigestion (Table 32-15). Right-sided abdominal distention suggests the various conditions of dilation, displacement, and obstruction or ileus of the intestines and abomasum. The diseases that cause obstruction and reflux of abomasal ingesta into the rumen may result in reticuloruminal distention. Both prolonged cases of gastrointestinal obstruction at any site and generalized peritonitis can produce gross bilateral dorsal and ventral distention of the abdomen.

The animal should be studied for signs of pain. A pain-filled expression, a reluctance to move, an abnormal, stilted gait, an arched back with a tucked-up abdomen, and an extended neck are typical signs of anterior abdominal pain. These signs may indicate TRP, abomasal ulceration, or another source of pain. A similar stilted gait and reluctance to move are typical of laminitis, a common sequela of acute ruminal acidosis.

833

834

Table 32-15 Differentiation of Types of Bloat Through NasogastricIntubation

Results of Intubation	Probably Causes of Bloat
Tube does not pass	Esophageal obstruction
Tube passes with resistance and releases ruminal gas	Esophageal compression caused by thoracic inflammatory or neoplastic disease Distortion of the cardia caused by inflammation, neoplasia, or abnormal anatomy such as abomasal displacement
Tube passes easily and releases ruminal gas	Ruminal stasis caused by reticuloruminal fermentative disorder, hypocalcemia Obstruction of cardia with ingesta (overfilling of rumen) or pedunculated mass Rumenitis (reticulitis) Weakened ruminal contraction caused by chronic overdistention with ingesta (vagal indigestion, indigestion with poorly digestible forage)
Tube passes easily but does not release gas or releases small amount of foamy ingesta	Frothy bloat Frothy ruminal contents caused by abnormal motility in some forms of vagal indigestion

32.122.5.3 PALPABLE FINDINGS (SeeFig. 32-94)

Deep palpation of the left side of the abdomen is used to determine the consistency of the ruminal contents and thus the nature and volume of the ingesta. In normal animals the organized contraction sequence produces a layering effect.[388,454] Ventrally a fluid consistency can be palpated, whereas dorsally the consistency is firm and doughy. The doughy layer consists of the fibrous portion of the feed. Generally an animal fed a high-roughage diet has a more prominent layer of doughy ingesta. The ruminal contents of an animal fed concentrate feed are softer. In sheep and goats the normal dorsal rumen is softer than that of cattle no matter what the feed. In the normal condition a small layer of free gas is present in the most dorsal region. Distention with gas or foamy feed produces a taut, elastic tension. With free gas bloat the doughy layer can still be appreciated ventral to the gas accumulation, but in cases of frothy bloat the doughy layer is much less prominent. Most cases of vagal indigestion and some cases of high intestinal obstruction cause a grossly dilated rumen filled with fluid or foamy contents that may fluctuate on ballottement.

Overfeeding of indigestible poor hay or straw with resultant inactivity of ruminal microbial fermentation leads to accumulation of more fibrous material than normal that barely yields to deep palpation. With prolonged or severe ruminal stasis, as may occur in TRP, the lack of ruminal motility leads to failure to maintain the normal layering of the contents. In these instances the ventral portion of the forestomach is firmer than the area above. During severe ruminal acidosis, fluid accumulates in the forestomach. This can lead to some degree of abdominal distention, and on palpation the ruminal contents are fluid and may even splash with ballottement.

The rumen should also be palpated per rectum; a comparison of these findings with those obtained externally may be revealing. Moderate degrees of free gas accumulation are often more easily detectable per rectum. Palpation per rectum is also useful in distinguishing the presence of an L-shaped rumen, in which the ventral sac of the rumen is grossly distended in cases of vagal indigestion. It is important to differentiate an L-shaped rumen from either abomasal distention or impaction, which can display a similar external abdominal contour. It is also important to palpate for the size of the lymph nodes in the longitudinal groove of the rumen. These can enlarge to prominent size when rumenitis is present. The organs in the right half of the abdomen should be assessed as sources of abdominal problems.

Rectal examination is impossible in small ruminants and calves. External palpation using both hands can be valuable in these animals. In calves and goats it is the best method for detecting bezoars or clotted clumps of milk in the rumen and for palpating intussusception, umbilical abscesses, or grossly abnormal kidneys.

Palpation of the left paralumbar fossa reveals the presence of ruminal contractions. In a normal animal, three contractions should occur over a 2-minute period. One of these contractions should be associated with an eructation of gas, which can be appreciated both visually and audibly. The rate of eructation increases or decreases in proportion to the fermentative production of gas. Most indigestions produce decreased ruminal motility or ruminal stasis. Early cases of frothy bloat and some forms of vagal indigestion can result in prominent hypermotility. The motility pattern is characterized by changes in both frequency and strength, and weak contractions can also be detected by palpation. Some cases of secondary indigestion, in which the decreased ruminal function is a result of inappetence rather than an inhibition of ruminal motility, show a normal contraction frequency but decreased contraction strength. The duration and strength of ruminal contraction are primarily determined by the nature of the forestomach contents, whereas the frequency relies on medullary gastric center control. Decreased ruminal fill, decreased fiber content of the ingesta, or overdistention of the ruminal wall musculature results in reduced strength and duration of the contraction sequence. These distinctions can be important in determining the cause of decreased ruminal motility.

32.122.5.4 AUSCULTABLE FINDINGS

Auscultation of abdominal sounds is performed over several sites in the left flank and rib areas. Initial auscultation assesses the nature, frequency, and strength of ruminal sounds. This information can be compared with the assessment of ruminal motility gathered on palpation. The sounds represent the friction of fibrous ingesta rubbing against the ruminal wall as the ruminal sacs contract and mix their contents. In healthy cattle on a roughage diet, the normal rustling sound is prominent and prolonged with each contraction cycle. The ruminal contents of animals fed a high-concentrate diet produce less sound because very—low-fiber rations induce weaker contractions and because less fibrous material is in contact with the ruminal wall.

As with palpation, both the frequency and the nature of the sounds yield information about reticuloruminal motility. The ruminal motility pattern is disrupted in vagal indigestion. Although contractions are present and may be more frequent than normal, their lack of normal coordination can lead to a churning of the ingesta without the usual progression of transport. This disrupts the normal stratification of the contents and produces abnormal sounds that are heard as a rumbling, bubbling, or splashing. When stratification is disrupted because of a hypoactive rumen and more fluid is present in the dorsal area of the rumen, contractions produce splashing sounds. The accumulation of gas under these circumstances may produce ringing tones as the fluid moves, similar to the pings found with a displaced abomasum.

834

835

Some circumstances require a distinction between primary and secondary contraction cycles, and they can be differentiated by ausculting for reticular contractions. Holding the stethoscope at the seventh intercostal space at the level of the costochondral junction, the examiner can detect a tinkling fluid sound as the reticulum contracts. A hand held in the paralumbar fossa can detect the tensed bulging of the dorsal sac as it contracts, allowing the examiner to determine if the ruminal contraction is associated with a reticular contraction. Reticular contraction and motility can also be assessed by transabdominal ultrasound.[509] Hyperactivity of primary cycles associated with feeding or the immediate postprandial period is normal. Mechanical stimulation of buccal sensory receptors can lead to an approximate doubling of the primary cycle rate. Hypermotility that results from excessive secondary contractions, without the normal mixing and propulsion of primary contractions, is abnormal and represents ruminal dysfunction.

Combining the auscultation with percussion or ballottement allows assessment of gas or fluid accumulations. The sounds heard in the left flank should be compared with those in the left rib area and right side of the abdomen. High-pitched pings and fluid tinkling sounds suggest a viscus filled with gas and fluid. In the left flank this may represent a displaced abomasum, gas-forming abscess, pneumoperitoneum, or static rumen. Careful comparison of the sounds heard at different sites, combined with the results of rectal palpation, should allow localization of the source. Generally the rumen can be ruled out as the source of pings if palpation reveals normal doughy ruminal contents, no ruminal tympany is felt per rectum, and sounds of normal ruminal contractions are heard in the paralumbar fossa. Prolonged anorexia associated with infectious or inflammatory diseases such as pneumonia or mastitis can result in a static, underfilled rumen, and occasionally a prominent ping can be ausculted in the left flank, where a filled rumen normally would be found. This condition has been called “ruminal collapse,” and careful evaluation is required to distinguish it from left-displaced abomasum.[510] Ballottement of the rumen may reveal splashing fluid sounds without a high pitch in cases in which the rumen has accumulated significant fluid. This occurs frequently in cases of severe ruminal acidosis. It may also occur in cases of marked inactivity of the ruminal flora with loss of the normal stratification of ruminal contents.

32.122.5.5 PAIN ELICITATION

Tests of pain sensitivity in the anterior abdomen (percussion, deep palpation, withers pinch, xiphoid pressure) are performed to examine for localized peritonitis caused by TRP or abomasal ulceration. The same procedures, especially percussion or application of pressure to a localized area in the ventral abdomen, can be used to localize pain associated with rumenitis or ruminal abscessation or perforating abosomal ulceration.[511]

32.122.5.6 FECAL ABNORMALITIES

The rectal examination presents an opportunity to assess the volume and nature of the feces.[512] The feces are abnormal in most cases of forestomach dysfunction. In adult cattle, passage of ingesta through the digestive tract requires 1½ to 4 days. Changes in the feces caused by acute diseases therefore are often delayed by a day or longer beyond the first appearance of other clinical signs. Mature cattle typically pass a total of 30 to 50 kg of feces per day divided into 10 to 24 defecations. The color and consistency of feces are influenced by the feed and should be assessed in light of the feeding history.

Diseases that reduce the flow of ingesta from the rumen to the lower gastrointestinal tract typically result in feces of reduced volume that are firm and dry. These findings are also present with reduced feed or water intake. Assuming that normal intestinal function is present, a decreased flow of ingesta from the forestomach allows longer retention in the bowel with greater resorption of water. In severe instances the feces form into firm disks or balls with a dark, shiny mucous covering. These findings are typical of vagal indigestion and forestomach diseases that produce ruminal stasis without a grossly abnormal fermentative pattern. Indigestions with abnormal fermentation may produce decreased quantities of dry feces initially but usually result in other fecal abnormalities as the abnormal ingesta pass into the lower tract. Intestinal obstructions also decrease fecal passage to the point of absence, but usually the material passed also presents other gross abnormalities such as blood, melena, or discolored mucus.

The particle size of fecal material depends on the frequency and duration of rumination, the activity of the

ruminal flora, and the function of the rumen in appropriately sorting out material for passage through the reticuloomasal orifice. Abnormalities of these digestive functions lead to passage of ingesta of inappropriate particle size. Plant fibers in normal bovine feces measure up to 0.5 cm. Particles with inadequate breakdown may measure 1 to 2 cm or longer. This long particle size may be seen in the feces of cattle with TRP, some cases of vagal indigestion, and poor-quality roughage with insufficient microfloral activity.[447,450,512] Similar findings occur with tooth disease and some cases of abomasitis or cellulitis at the cardia or esophageal groove, in which rumination or activity of the reticuloomasal orifice is inhibited. Whole cereal grains (especially whole corn) may pass in the feces of normal cattle, but excessive amounts of grain should raise suspicion of excessive intake and acute ruminal acidosis. Feces with an abnormally fine particle size and greasy-pasty texture are associated with delayed passage from the forestomach. These are common findings in most cases of vagal indigestion and abomasal displacement.

The odor of bovine feces is relatively inoffensive in healthy individuals. Foul odors are the result of abnormal fermentation or decomposition. Thus abnormal odor typically occurs when the ruminal fermentation pattern is altered, as in simple indigestion caused by abnormal feed, ruminal acidosis, ruminal alkalosis, or ruminal content putrefaction. A repugnant odor is also typical of enteritis when blood products, inflammatory products, or tissues decompose in the intestinal tract (e.g., *Salmonella* enteritis). Foamy, fluid feces with a yellow-brown color and acidic smell are typical of ruminal lactic acidosis in adult cattle. Abnormal ruminal fermentation not only produces feces with abnormal odor but also typically leads to a pasty or fluid consistency as well. Exceptions occur in acute cases, when ruminal stasis or the delay in the passage of ingesta from the forestomach can result in normal or firm feces during initial stages of the disease.

32.122.5.7

ACUTENESS OF SIGNS

The various forms of indigestion may be manifested as acute, subacute, or chronic illness. In general they do not appear as critical emergencies with fulminating systemic signs and life-threatening conditions. The exceptions to this are frothy bloat (see p. 855) and acute ruminal lactic acidosis or grain engorgement.

Cattle examined a few hours after engorgement of grain may yet be alert but anorectic with a mildly distended rumen, weak ruminal contractions, and mild signs of colic. If the acidosis is mild, affected cattle show the signs of indigestion discussed in previous paragraphs and with or without treatment may show return of appetite within a few days. The severe form of indigestion leads to severe systemic involvement, with depression, severe dehydration, weakness, recumbency, profuse diarrhea, and eventually death. The temperature usually is normal to subnormal. The heart rate elevates with the progression of dehydration and systemic acidosis, with rates above 100 beats/min usually associated with a poor prognosis. Respiration generally is increased (60 to 90 breaths/min) and shallow. The rumen accumulates fluid. Animals capable of rising may show a staggering gait and appear blind. The pupillary light reflex may be slower than normal. Recumbent animals usually lie quietly and may be stuporous. As the cardiovascular system becomes more severely affected with increasing dehydration and acidosis, the extremities become cool, and mucous membranes dry. Anuria may follow poor renal perfusion. Rapid progression of signs leading to recumbency bespeaks a poor prognosis, and animals may die within 24 to 72 hours. Therefore if the progression of signs is rapid, emergency therapeutic measures are mandatory.

835

836

In cattle with intermediate degrees of ruminal acidosis, other signs may develop secondarily. Acute or chronic laminitis is a common complication. The damage to the ruminal mucosa can lead to mycotic rumenitis or ruminal wall abscessation or can disseminate infection through the bloodstream to other organs, most notably the liver, resulting in the formation of hepatic abscesses.[478]

32.122.5.8 HEART RATE

Bradycardia of 40 to 60 beats/min is frequently associated with certain types of indigestion. This sign suggests reflex vagotonia to the heart and has been considered indicative of vagal indigestion. The bradycardia can be alleviated by subcutaneous administration of 30 mg of atropine, differentiating increased vagal nerve tone from a primary cardiac conduction disturbance. The atropine test is not especially useful because only a minority of vagal indigestion cases show bradycardia.[444,445,447] Animals with advanced cases with severe abdominal distention or fluid imbalances (or both) frequently show elevated heart rates (over 80 beats/min). In most cases the other physical signs are more reliable for establishing the diagnosis. Furthermore, bradycardia may accompany other forms of indigestion when ruminal hypomotility is prominent and no significant abnormalities of fluid or electrolyte balance are present. Even in normal cattle, postfasting heart rates may drop below 50 beats/min.[513] Therefore recognition of bradycardia in association with other signs of ruminal dysfunction is probably most useful as evidence that stimuli for an increased heart rate, such as inflammatory, infectious, or fluid balance disturbances, are not prominent factors in individual disease occurrence.

32.122.5.9 VOMITING

Vomiting is uncommon in ruminants, but when it does occur, it generally reflects forestomach disease. Regurgitation from the abomasum frequently occurs with abomasal or intestinal disease. Abomasal reflux is not manifested externally and is discussed elsewhere (see pp. 837 and 838) because it relates to forestomach disease. Small volume regurgitation and remastication are routine and normal ruminant functions that do not result in expulsion of material from the mouth. Explosive vomiting of fluid ingesta in large quantity occurs when the reticulorumen is irritated and occasionally when it is overdistended. Vomiting may accompany diaphragmatic herniation of the reticulum, inflammation of the reticulorumen caused by actinobacillosis, vagal indigestion, or obstruction of the reticuloomasal orifice. Animals are more prone than normal to vomiting around an orally passed stomach tube when they have almost any indigestive disturbance. Vomiting also occurs with certain intoxications, most notably azalea, rhododendron, and sneezeweed toxicity and some organophosphate toxicities.

32.122.6 Clinical Pathology

32.122.6.1 RUMINAL FLUID ANALYSIS

Evaluation of ruminal fluid characteristics is an essential procedure in establishing the cause of the indigestions of abnormal fermentation.[454,468,514] Several important determinations can be made at cowside in an ambulatory practice. Acquiring an appropriate sample is simplified by using proper equipment. The advantages of various collection techniques and devices have been discussed.[515–518] Needle puncture of the ventral ruminal sac (rumenocentesis) may yield a satisfactory fluid sample, and studies demonstrate that rumenocentesis samples provide the most reliable evaluation of ruminal fluid pH for field evaluation of SARA.[517,518] Oral or nasal passage of a collection tube produces more fluid volume with no risk of peritoneal contamination but with an increased risk of saliva contamination. An adequate tube for aspiration of a ruminal fluid sample should be at least 2.3 m long to reach the ventral ruminal sac and should have an internal diameter of 1 cm or larger to reduce the incidence of plugging with ingesta. A plastic stomach tube passed orally or nasally can be adapted for use by cutting multiple holes into the ruminal end of the tube. A digital

examination glove can be placed over the end during passage to limit saliva contamination of the sample and then is forcefully blown off before sampling. The sample can then be withdrawn by a dose syringe. This technique is successful when ruminal fluid is accessible in the dorsal rumen, but the flexibility of the tube is disadvantageous when a prominent layer of fibrous feed is present. Several instruments with a flexible steel outer tube are commercially available and have the advantage of enough stiffness and weight to penetrate the overlying firm layer of ingesta.

Ruminal fluid samples collected in an expeditious manner yield the most useful results. When the animal strongly resists sampling and a prolonged time is required from introduction of the tube until the fluid is obtained, saliva contamination of the sample increases. This contamination alters the pH and consistency of the sample. The specially designed ruminal fluid collection tubes reduce this problem. If the sample must be collected with a standard nasogastric tube, passing the tube nasally avoids the presence of a device in the mouth. This reduces the amount of struggling (once the tube has passed the pharynx) and thus reduces excessive salivation.

The sample should be evaluated as soon as possible after collection to minimize the effects of cooling and air exposure on protozoal activity and pH. The more elaborate chemical tests such as chloride, acid, and ammonia concentrations can be delayed up to 9 hours for a room-temperature sample and up to 24 hours for a refrigerated sample and still yield reliable results.[519] Ruminal fluid collected for therapeutic transfaunation also retains its beneficial activity for a similar duration.[520] The ruminal fluid parameters important in a clinical examination are listed in Table 32-16.

32.122.6.1.1

Color, Consistency, and Odor

The color, consistency, and odor of aspirated fluid are assessed immediately after collection. Normal color varies depending on the nature of the feed. Animals fed a hay ration have olive to brownish-green ruminal fluid, those on grass show a deeper green color, and cattle fed grain or silage, a yellowish-brown color. Fluid from cattle with acidosis tends toward a milky gray. Ruminal fluid from animals with prolonged stasis or decomposition of the ruminal ingesta (or both) is a darker greenish-black, and fluid from calves with milk sequestered in the rumen as a result of abomasal reflux or esophageal groove failure is gray and may contain clots of milk.

Normal ruminal fluid has a slightly viscous consistency. The fluid becomes more watery when the microflora is inactive. Saliva contamination causes greater viscosity; therefore the results from a highly viscous sample should be evaluated with care, and it may be best to discard such samples. Ruminal fluid has a typical odor that has been called “aromatic.” The odor is less prominent when the microflora is inactive. Abnormal odors include the acidic smell of lactic acidosis, the putrid, foul odor of protein decomposition or spoiled milk with putrefaction of ruminal ingesta, or the ammonia smell of urea poisoning.

836
837

Table 32-16 Diagnostic Ruminal Fluid Analysis

Parameter	Normal
Color	Olive, brownish-green
Consistency	Slightly viscous
Odor	Aromatic, strong odor
pH	6–7 on roughage
	5.5–6.5 on grain diet
Sedimentation or flotation	4–8 min
Redox potential (methylene blue reduction time)	3–6 min
Protozoal activity	Multiple forms, active motion
Gram stain	Predominant gram-negative bacterial population
Chloride concentration	<30 mEq/L

32.122.6.1.2

Ruminal Fluid Ph

The pH of ruminal fluid fluctuates within a broad range of normal values, varying considerably during the course of a day with shifts of 0.5 to 1 pH unit common during a 24-hour period.[485,521] The pH measured in a given fluid sample depends on the type of feed and fermentation pattern and the interval since the last feeding. Physiologic ruminal fluid pH typically ranges between 6 and 7 in animals on a mostly forage diet but is lower, at 5.5 to 6.5, in animals fed mostly grain.[469,470,485,518,522] The lower pH develops with the faster rate of amylolytic versus cellulolytic fermentation. Immediately after feeding the pH tends toward the high end of normal with the addition of feedstuff and saliva, the production of which is determined by the duration spent eating, ruminating, and resting.[523] Over a 2- to 4-hour period the pH decreases to the lower range as the feed undergoes fermentation. With no further feed consumption, fermentation declines and the pH rises with salivary buffering and acid end-product absorption.[491] In animals held off feed the ruminal pH rises above 7 within 12 hours after a hay meal and within 24 hours after a high-grain meal. Therefore consideration of the most recent feed consumption is important to the interpretation of the ruminal fluid pH measurement.

Saliva contamination of the sample falsely elevates the measured pH value. Because it is impossible to exclude saliva completely from samples collected by tube, a minor false elevation of the pH likely occurs in all such examinations.[515,516,518] This can be minimized by expedient collection of a large fluid volume (more than 100 to 200 mL). If the collected volume is small and the sample viscosity is high, the pH measurement will be inaccurate. Modest contamination (5% to 10%) raises the measured pH by approximately 0.1 to 0.2 pH units, whereas excessive contamination with approximately 50% saliva may increase pH by 1 pH unit.[454,515] Ruminocentesis of the ventral ruminal sac below the left paralumbar fossa is preferred by some clinicians for preventing saliva contamination. This is particularly advantageous for samples collected to monitor ruminal pH for balancing rations and minimizing chronic ruminal acidosis. A sampling strategy that incorporates ruminocentesis and ruminal fluid pH measurement in groups of cows in a herd has been developed to optimally identify cow groups with feeding problems that lead to subacute ruminal acidosis.[517,518]

Ruminal pH values of 7 to 7.5 are common in animals with anorexia and in those that have ingested feed that is not suitable for fermentation (e.g., simple indigestion and inactivity of microflora caused by indigestible roughage). Even higher pH values may be measured with ruminal alkalosis caused by urea ingestion or putrefaction of ruminal ingesta. Low pH values result from engorgement with readily digestible carbohydrates and generation of ruminal lactic acidosis. In extreme cases values occasionally decline to 4 to 4.5. It is important to remember that prolonged anorexia and continued saliva ingestion result in rising pH values in these cases as well and that the ruminal pH of a cow with ruminal acidosis can be normal if a sufficient period of anorexia precedes the ruminal fluid analysis. Conversely, a ruminal pH of 5.5 to 6 is abnormal for a cow fed a roughage diet and may be indicative of unobserved access to grain and resultant lactic acidosis. Subacute or chronic ruminal acidosis usually is accompanied by a ruminal pH in the range of 5 to 5.5.[468,469,485,518] Abomasal reflux into the reticulorumen caused by abomasal disease, vagal indigestion, or intestinal obstruction can cause mild decreases in ruminal pH because of the acidic nature of abomasal contents. However, ruminal pH measurement is a poor means of detecting abomasal reflux because the pH will remain within the wide range of normal values. Abomasal reflux is better assessed by measurement of the ruminal chloride concentration.

32.122.6.1.3

Sedimentation

The sedimentation activity time, or sedimentation-flotation test, provides a quick evaluation of microfloral activity.[524] It must be conducted promptly after collection of the sample. The aspirated fluid is allowed to sit in a tube, and the time for completion of sedimentation and flotation of the solid particles is measured. Normally the finer particles settle to the bottom and the coarser particles float, buoyed by the gas bubbles of fermentation. Some of the finer particles sink and then rise again when the fermentation is very active. The normal time for completion of this activity is 4 to 8 minutes. Grossly inactive fluid shows very rapid sedimentation, and none of the material may float. This occurs with ruminal acidosis, prolonged anorexia, and inactive microflora caused by indigestible roughage. When the ingesta are particularly frothy, as in cases of frothy bloat or some cases of vagal indigestion, there may be no appreciable sedimentation or flotation. This test provides a crude evaluation of microfloral activity but does not differentiate well among the different forms of indigestion.

32.122.6.1.4

Redox Potential

The redox (reduction-oxidation) potential of ruminal fluid is a biochemical characteristic that reflects the anaerobic fermentative metabolism of the bacterial population.[455] An indirect determination of the redox potential can be achieved by measuring the time required by ruminal fluid to decolorize methylene blue dye.[525] A mixture of 1 mL of 0.03% methylene blue with 20 mL of ruminal fluid at normal body temperature is observed in a tube and compared for color with another unaltered tube of the fluid. With a highly active microflora from an animal fed a hay and grain diet, the initial dark blue color of the mixture decolorizes within 3 minutes, leaving a narrow ring of blue color at the top of the decolorized sample. Fluid from a diet of hay alone requires 3 to 6 minutes and from a mostly grain ration requires as little as 1 minute for methylene blue reduction. Reduction times up to 15 minutes and longer occur with diets of indigestible roughage, in anorexia of several days' duration, and after ruminal acidosis.[466,514] Thus the methylene blue reduction time provides an assessment of the degree of bacterial fermentative activity.

32.122.6.1.5

Microscopic Examination

Evaluation of the number and activity of protozoa in the ruminal fluid provides a sensitive indicator of the normalcy of the sample.[454,455] This is easily accomplished by examining a drop of fresh, warm fluid under a microscope. The examination requires only low magnification (×40 to ×100) and no special stains. In very active fluid samples the largest protozoa can be seen with the naked eye. They are detectable in a tube as small gray specks of material in active motion in the fluid, and they tend to localize above the sedimented particulate matter. Microscopically both ciliate and flagellate forms of varying sizes and shapes can be observed, with ciliates usually outnumbering the flagellates. The protozoa are normal inhabitants of a healthy ruminant's ruminal fluid, although their specific function is not completely clear and their presence does not appear to be a prerequisite of normal digestive activity. The importance of the protozoa from a clinical viewpoint is their sensitivity to abnormalities in the fluid milieu. The normal animal should show a wide variety of sizes of protozoa, in large numbers that are easy to see, and with active motility. Reduced numbers occur in inactive fluid samples. The larger species are more susceptible to abnormalities; therefore a predominance of only small protozoa would suggest a mild indigestive disturbance. All protozoa are killed off when the ruminal pH drops below 5. A recent bout of acidosis would result in lack of protozoal activity, even if the pH has subsequently risen back into the normal range. Fluid from such an animal should also show other abnormalities of color and consistency. Very recent disturbances of the fluid may result in the observation of a large number of dead protozoa.

Although elaborate isolation methods for evaluating ruminal bacterial growth are not clinically applicable, examination of an air-dried, Gram-stained smear of ruminal fluid can be useful in diagnosing ruminal acidosis. Normal ruminal fluid should contain a variety of morphologically distinguishable bacterial forms, with a predominance of gram-negative organisms. After the overconsumption of readily digestible carbohydrate (grain engorgement), a population of streptococci and lactobacilli proliferates as ruminal lactic acidosis develops. This shift in the bacterial population can be distinguished microscopically, and a predominance of gram-positive cocci and rods is seen. The findings are best confirmed by comparing a smear from a herdmate.

32.122.6.1.6

Ruminal Fluid Chloride

The chloride concentration in ruminal fluid can be determined from the supernate from a centrifuged sample using standard chloride titration devices. A delay in measurement does not appreciably affect the value. Saliva contains concentrations of chloride similar to those of normal ruminal fluid, so that saliva contamination has minimal effect on the results. The normal ruminal fluid chloride concentration is less than 30 mEq/L, with elevated values demonstrating reflux of abomasal ingesta into the rumen or administration of chloride in the feed or as therapy. Accurate assessment of measured values requires information about possible previous administration of electrolytes via the rumen. In the clinical evaluation of forestomach dysfunction, elevated ruminal chloride suggests secondary indigestion caused by abomasal disease or obstruction of intestinal flow. This test can be very helpful in differentiating abomasal reflux from ruminal lactic acidosis as the cause of low ruminal pH and abnormal fluid accumulation in the reticulorumen. With vagal indigestion a high ruminal chloride level suggests that the failure of aborad flow is posterior at the pylorus rather than anterior at the reticuloomasal orifice.[446,453,454] Generally cattle with elevated ruminal chloride also have hypochloremia and metabolic alkalosis as a result of the chloride sequestration in the forestomach, although very slow development of the sequestration may allow the animal to maintain normal plasma levels by altering other excretion rates.

Numerous other tests of the ruminal fluid have been described for the evaluation of digestive activity of the

ruminal microflora. These include cellulose digestion, glucose fermentation, nitrite reduction, and measurements of titratable acidity, VFAs, lactic acid, and ammonia concentration. These procedures can more clearly define the nature of the ruminal fluid but are not generally used in a clinical setting.

32.122.6.2 HEMATOLOGY

Hematologic abnormalities are not generally a significant feature of the indigestive disorders. The primary exceptions are TRP or rumenitis, in which neutrophilia and hyperfibrinogenemia are routine findings. This feature of the disease can aid in its differentiation from other forestomach diseases. An inflammatory leukogram can also be observed in some cases of vagal indigestion when inflammatory disease is responsible for dysfunction of vagal innervation and forestomach motility. Chronic bronchopneumonia in calves and TRP in adult cattle are commonly implicated as causes of vagal dysfunction. A hematologic reflection of an inflammatory response may also be seen after ruminal acidosis if the ruminal wall and other organs suffer secondary pathogen invasion, and likewise in the occasional cases of primary rumenitis or reticulitis.

The more common hematologic abnormalities associated with indigestion are reflections of fluid disturbance or stress response. Hemoconcentration is routine and may be severe in ruminal acidosis. Mild dehydration may also accompany the other forms of indigestion, especially when the disease shows a protracted course. A stress leukogram would be anticipated in cases of indigestion that are acute or distressing, such as acute bloat. The hematologic response in secondary indigestions depends on the primary disease.

When indigestion is chronic, especially in calves, in which the indigestive disturbance may go unrecognized or undiagnosed for a long time, a state of malnutrition may develop. In these instances a mild to moderate anemia may develop that may be attributable to micronutrient or macronutrient deficiencies.

32.122.6.3 BIOCHEMICAL ABNORMALITIES

Most of the primary forestomach diseases do not induce remarkable changes in the biochemical profile. In lactating or heavily pregnant animals, anorexia may induce a secondary form of acetonemia, which is detected by the presence of urine ketones. The animal must be carefully examined to differentiate ketosis with secondary anorexia and decreased ruminal activity from primary indigestion with secondary ketosis. Mild to moderate hypocalcemia and hypokalemia are commonly identified abnormalities in many cases of indigestion, especially when anorexia has been prolonged.

Dramatic alterations of the blood biochemical characteristics may accompany severe ruminal acidosis. Usually the laboratory findings correlate with the degree of severity assessed on physical examination. Affected animals have metabolic acidosis with decreased blood pH and plasma bicarbonate. Blood lactate levels rise with the acidosis. The urine pH falls into the acidic range as the kidneys excrete some of the excess acid, but eventually severe dehydration results in renal failure and anuria, eliminating this route of acid excretion. Decreased renal function is reflected by elevated serum creatinine and urea nitrogen concentrations. Other findings commonly include increased serum phosphate concentration, possibly caused by massive cellular destruction, and mildly decreased serum calcium concentration, presumably the result of decreased gut absorption. Other serum electrolyte abnormalities, such as changes in the sodium and chloride concentrations, may reflect fluid balance changes in response to ruminal fluid hyperosmolality.[467] Concentrations of serum enzymes of muscle and liver origin rise when acidosis and dehydration produce cardiovascular impairment with poor tissue perfusion, increased recumbency, and cellular destruction. Portal bacteria and toxins from the damaged ruminal mucosa contribute significantly to the increased serum liver enzymes: AST, sorbitol dehydrogenase, and ornithine carbomyltransferase.

Vagal indigestion may cause no significant blood biochemical abnormalities or can result in severe disturbances of fluid and electrolyte homeostasis.[446] Measurement of the serum electrolyte concentrations provides important clues about the site of obstruction of ingesta flow and is useful in adjusting fluid therapy. When the primary problem is failure of flow through the reticuloomasal orifice, the rumen fills and grossly distends with fluid, but significant abomasal reflux does not occur. Affected patients generally show mild or no serum electrolyte abnormalities. When ingesta fail to pass from the abomasum, reflux of the high-chloride abomasal contents into the rumen results in elevated ruminal chloride concentrations and associated hypochloremic, hypokalemic metabolic alkalosis. In some instances these abnormalities can be dramatic. Prolonged or severe hypochloremia and hypokalemia may also result in the paradoxic aciduria associated with avid renal sodium resorption in the face of low concentrations of chloride and potassium. Some slowly developing cases may accumulate significant fluid in the reticulorumen but have minimal blood electrolyte changes.

32.122.7 Treatment and Prognosis

32.122.7.1 Ruminal Wall and Motor Function Disorders

Signs such as ruminal tympany, ruminal hypomotility or stasis, and forestomach distention can all result from a number of causes. Eliminating the underlying causative problem more effectively resolves the disease than does treatment directed at the disease signs. Ruminal hypomotility, for example, is commonly a physiologic response to problems such as abnormal ruminal contents, a ruminal wall lesion, pain, or overdistention. In many cases the ruminal motility disturbance serves as a protective role for the animal. Former treatments that were directed at stimulating ruminal motility without addressing the causative disturbance included rumenatorics (e.g., nux vomica, ginger, tartar emetic) or parasympathomimetics (e.g., neostigmine, carbamylcholine). Such agents are not indicated under these circumstances.[400] Likewise the treatment of indigestions with alkalinizing agents such as magnesium hydroxide is indicated only when the pH of ruminal contents is low.[526]

32.122.7.2 FREE GAS BLOAT

When ruminal tympany is a prominent sign, it requires very critical assessment. Frothy bloat and free gas bloat can be differentiated by a thorough physical examination and knowledge of the feeding history. Passage of a stomach tube to help in this differentiation is very important and may alleviate the acute problem if free gas is present (see Table 32-15). Evidence of respiratory or cardiovascular distress indicates that the bloat is an acute, life-threatening problem that requires emergency treatment. With the exception of cardia or esophageal obstruction, the free gas bloat associated with indigestive disturbances is mild to moderate in severity and chronic or recurrent in nature. It does not represent a major threat to the animal and can be handled by treating the primary forestomach disturbance. Chronic free gas bloat does not respond to the antifermentatives or surfactants commonly used for frothy bloat. Only the restoration of physiologically normal reticuloruminal function corrects this type of bloat. Inhibition of eructation caused by lesions of the cardia region can usually be confirmed only by exploratory rumenotomy. This approach also determines whether the lesion is surgically correctable. Inflammatory lesions may respond to long-term administration of broad-spectrum antibiotics. This is also the treatment of choice when purulent lung infections appear to be the cause of the bloat. Failure to respond within about 3 weeks suggests that the treatment is not effective, and slaughter should be recommended after an appropriate withdrawal time. Detection of abnormal forestomach ingesta should direct

treatment to the primary fermentative or feeding disorder.

The various causes of chronic or recurrent bloat usually require chronic treatment for correction. It follows that the bloat will also not completely resolve until the underlying disturbance is corrected. Repeated relief of the bloat may be accomplished by passage of a stomach tube during the treatment regimen. In many cases this proves too tedious or too traumatic for the animal, and the most viable alternative often is the establishment of a temporary ruminal fistula. Several devices are manufactured for this purpose, or the fistula can be created by suturing the rumen to the skin. Release of the fermentative gas in this manner is important for the reestablishment of normal forestomach motility, which is inhibited if distention is extreme. When free gas bloat is the result of an obstruction of eructation or another gastrointestinal tract disease such as abomasal displacement, surgical treatment of the primary problem may be necessary. The tympany responds rapidly in these cases, and ruminal fistulation is not required.

32.122.7.3

LESIONS OF THE RUMINAL WALL

Diseases of the ruminal wall may be suspected on the basis of the physical examination findings and results of a CBC, abdominocentesis, and ruminal fluid analysis. In most cases exploratory laparotomy is required to confirm the diagnosis. Rumenitis or reticulitis may respond to antibiotic therapy, but the prognosis in these cases is guarded. Not only is the forestomach inflammation difficult to resolve, but the hematogenous spread of infection to other organs often causes intractable multiple organ system disease. Parakeratosis is best treated by correcting the causal feeding error (reducing the amount of concentrate and increasing the feeding of long-stemmed forage). The ruminal papillae can grow or regress in a period as short as 3 weeks when the feed is changed from low- to high-concentrate content or vice versa. Exactly how long it takes for parakeratotic papillae to return to normal is not certain, but it probably depends on the degree of change of the diet. The prognosis associated with this problem is good if inflammation of the ruminal wall is not also involved.

32.122.7.4

RUMINAL DISTENTION

Vagal indigestion is a chronic and insidious problem that generally warrants a guarded to poor prognosis. The syndrome of abdominal distention with an L-shaped rumen and possibly ruminal tympany has several different causes. Exploratory laparotomy and rumenotomy are essential for establishing an accurate assessment (see Fig. 32-94). Diaphragmatic herniation and masses that obstruct the reticuloomasal orifice cause signs indistinguishable from those of vagal indigestion that results from inflammatory lesions of the reticulum. Surgical correction of a diaphragmatic hernia involving the reticulum can be attempted but has usually proved unrewarding, especially if the lesion is chronic, involves a large defect, or is accompanied by inflammatory reaction. Removal of pedunculated masses or foreign bodies at the reticuloomasal orifice can promptly correct such problems.

The two most common causes of vagal indigestion syndrome are inflammatory lesions of the reticuloomasal region and abomasal diseases that involve gross distention, twisting, or vascular impairment of the organ. Vagal indigestion caused by abomasal disease carries a poor prognosis, whereas the prognosis for animals with reticular involvement is more variable. Animals in either category may respond favorably with appropriate therapy[448,451,527] (Box 32-6). Surgical exploration not only allows an assessment of the cause of the problem but may also allow repair. When abscesses are identified at the reticulum or liver, surgical drainage may help resolve the forestomach motor disturbance.[448,453] Identification of adhesions and active inflammation indicates that broad-spectrum antibiotic therapy may be beneficial; it is essential that aggressive antimicrobial therapy be administered before and after the surgical correction of a right-sided abomasal

839

840

displacement or volvulus.[452] Gross abomasal distention, indicating pyloric outflow failure, usually warrants a poorer prognosis, as does the presence of granulomatous or neoplastic processes or generalized peritonitis and adhesion formation.[453] When the presence of a large gravid uterus appears to be the inciting cause of outflow failure, induction of parturition or cesarean section usually resolves the problem completely.

32.122.7.4.1

Box 32-6 Principles of Treatment of Vagal Indigestion

1 Determine likely cause, often by means of exploratory laparotomy

2 Administer specific therapy (e.g., antibiotics, antiinflammatory agents, removal of foreign body or relief of obstruction, drainage of abscesses) for causative lesion

3 Relieve forestomach distention; often must be repetitively performed

4 Limit feed and water intake; feed palatable, high-fiber ration

5 Transfaunate

6 Fistulate rumen if chronic bloat is a problem

The evaluation of animals with vagal indigestion with a large fluid-filled rumen should include assessment of the fluid and electrolyte status. Abnormalities such as dehydration, hypocalcemia, hypochloremia, and hypokalemia should be addressed with supportive fluid therapy. Treatment should be administered parenterally, because oral treatments are ineffective or deleterious. The forestomach should be emptied of the excessive ingesta accumulation either at surgery or with a large-bore stomach tube. This procedure may have to be repeated if the recovery period is prolonged. Relief of persistent forestomach distention is *critical* to the reestablishment of normal motility. Limited feed and water should be offered to prevent repeated accumulations in the reticulorumen, and intravenous fluid therapy should be continued until reticuloruminal motility is reestablished and oral fluid intake can be allowed at normal levels. Once the ruminal distention has been alleviated, several liters of ruminal fluid transfaunate from a healthy donor should be administered.[528] The limited diet must be palatable and should consist primarily of long-stemmed hay or green feed for maximum stimulation of the normal forestomach motility pattern. A temporary ruminal fistula may be indicated if tympany is a prominent sign.

Response to treatment of vagal indigestion usually is a slow process and may require several weeks. Favorable signs include a return of the normal primary and secondary contraction patterns, improvement in appetite, maintenance of normal forestomach dimensions, weight gain, and increased fecal production. Repeated development of forestomach distention, continued scant fecal output, poor ruminal motility, and recurrent bloat are indications that the animal is not responding to treatment and the prognosis is grave.

32.122.8

Fermentative Disorders

With the exception of severe acute ruminal acidosis, the disturbances of reticuloruminal fermentation generally are not fatal unless the disease is undiagnosed for a prolonged period, leading to extreme debility. Treatment of fermentation disorders centers around restoring a normal ruminal fluid environment that allows normal microbial metabolism. Identification of ruminal fluid parameters (see Table 32-16) and the nature of the forestomach ingesta directs the appropriate treatment (Box 32-7).

32.122.8.1

Box 32-7 Principles of Treatment of Fermentative Indigestions

1 Determine and resolve initiating cause; adjust feed regimen

2 Correct ruminal pH

3 Correct systemic acid-base and electrolyte abnormalities through parenteral fluid therapy (especially Ca^{++} and K^{+})

4 Remove grossly abnormal ruminal ingesta

5 Correct ruminal fill (overdistention or emptiness)

6 Transfaunate repeatedly

7 Resolve inspissation or impaction of ruminal contents when present

8 Provide oral and parenteral mineral and vitamin supplementation when indigestion or anorexia is chronic

32.122.8.2

FEEDING

The first and most important step in treatment of nutritionally related indigestions is correction of the specific causal feeding error. Because the imbalance may have gone on for weeks, especially in cases of calf indigestion, correction of the problem may also take some time. The evolutionary development of the ruminant has adapted it to be a grassland grazer. Economic pressures in the animal industry have caused managers to institute feeding practices that diverge widely from a pasture setting. Fresh green grass, however, remains one of the best means of stimulating normal forestomach digestion and motility. The second best type of diet includes a balance of palatable and digestible sources of energy, protein, fiber, and mineral nutrients. Fiber requirements should be determined by considering both the physical effectiveness of fiber and the production of fermentation acids.[529] The content of structured roughage should not fall below 10% of the ration dry matter, and a crude fiber component above 17% is desirable for any ration.

32.122.8.3

ALTERATION OF RUMINAL CONTENTS

When the viability or activity of the ruminal microflora is in question, as in the primary fermentative disorders and most cases of secondary indigestion, ruminal transfaunation is indicated.[528] This should be obtained from a healthy individual that preferably is adapted to a ration similar to the one the patient is expected to consume. The fluid can be obtained from an animal with the rumen fistulated, by removal with a stomach tube, or from a local abattoir. After the large particulate matter has been strained from the fluid (cheesecloth or large stockinette can be used), it can be administered through a stomach tube. The transfer from donor to recipient is best accomplished immediately, but fluid that contains active and healthy microflora remains viable for up to 9 hours at room temperature or 24 hours under refrigeration.[519,520] In calves inoculation with 1 L is appropriate, whereas 3 L is minimal in an adult cow, and 8 to 16 L is more desirable.

Many animals with indigestion exhibit decreased ruminal fill. As discussed, one of the primary stimuli for

active ruminal contraction is mild forestomach distention. In addition to the administration of ruminal transfaunate, it usually is beneficial in these cases to administer enough oral fluid to produce mild ruminal distention. This can be accomplished with water warmed to body temperature, and 20 to 30 L of fluid administered through a tube may be required to achieve the desired effect. The addition of salt (sodium and potassium chloride) in amounts sufficient to produce an isotonic solution (approximately 2 tsp/L) supplements deficiencies and promotes rapid turnover of the fluid from the rumen to the lower tract. Cathartic agents such as magnesium sulfate have been used and may be beneficial but do not serve to supplement the common electrolyte deficiencies.

840

841

Correction of pH abnormalities to the normal range of 6 to 7 is important when ruminal acidosis or alkalosis is detected. Alkalinizing agents such as magnesium hydroxide and sodium bicarbonate are indicated for treatment of acidosis at an initial dose of 1 g/kg. Magnesium hydroxide is commonly used by some as a routine treatment for any animals in which ruminal hypomotility has been identified. This practice is not justifiable in most cases of ruminal hypomotility because the fluid pH is commonly at or near neutral. The use of magnesium hydroxide in such settings may induce a mild systemic alkalosis, and the agent is better reserved for true cases of acidosis.[526] Ruminal alkalosis can be corrected with the infusion of acetic acid (vinegar, initial dose of 2 mL/kg, up to 12 L). All of these agents are best administered in several liters of warm water to ensure good distribution through the ruminal fluid.

Overdistention of the ruminal wall may be a primary inhibitor of forestomach motility in some cases of indigestion caused by abnormal fermentation. Treatment of free gas bloat has been discussed. When the distention is caused by accumulation of abnormal ingesta, normal contractions do not return and the ruminal tympany is not resolved until the distention is relieved. This situation is best exemplified by cases of microfloral inactivity caused by poor-quality roughage and is the underlying problem in calves with haybelly. One approach to this problem is to restrict the animal to small quantities of readily digestible feed given several times a day. Between meals the animal can be kept in an unbedded stall or muzzled. This process is continued until the accumulated ingesta have passed out of the forestomach. Repeated transfaunations during this time help reestablish a more normal microflora. This approach relies on motility and microbial activity sufficient to break down the ingesta and pass them to the lower tract. An alternative approach is to remove the accumulated ingesta by means of rumenotomy, after which the animal is transfaunated and allowed access to moderate amounts of feed until normal motility is restored. Emptying the rumen surgically is the treatment of choice when spoiled milk, putrefactive ruminal ingesta, or severe ruminal acidosis is detected. Prolonged cases of microbial inactivity or anorexia (or both) with ruminal hypomotility can result in loss of the normal stratification of forestomach ingesta. The fibrous, floating layer sinks to the ventral ruminal sac in these cases, forming a dense, firm mass. Return of normal forestomach motility will be delayed unless this accumulation of material can be eliminated. This can be accomplished during the process of microfloral reestablishment by massaging the mass through the lateral and ventral body wall. Dissolution and passage of the material can be enhanced by the administration of mineral oil (4 L) or DSS (4 to 6 oz in 2 to 3 L of water). Because DSS kills ruminal protozoa when given in amounts greater than required to saturate the fibrous matter, at least one ruminal transfaunate should be given 1 to 2 days after the last application of this agent.[530]

Animals with prolonged anorexia caused by a depressant or febrile disease that produced secondary indigestion may not return to feed or have normal ruminal motility even after normalcy of the ruminal contents has been restored. Chewing activity is one of the strongest stimulants for ruminal motility, and these individuals sometimes benefit if palatable hay or grass is placed forcefully into the mouth by hand. An alternative is to give such individuals access to pasture. Both the ruminant and its ruminal microflora have trace mineral requirements that are often not met by the type of diets that may induce microfloral inactivity.[459] The ruminal microflora is also responsible for supplying the animal with its vitamin B requirements.[423] The

The ruminal microflora is also responsible for supplying the animal with its vitamin B requirements. The stunted, poor body condition of calves affected by chronic indigestions may reflect these deficiencies, as well as protein energy malnutrition (see Chapter 9). Oral supplementation of minerals and parenteral supplementation of the B vitamins may be helpful until normal ruminal digestive function is established. Adult cattle, especially lactating animals with high metabolic demands, may also benefit from B vitamin supplementation when ruminal function is impaired.

Intraruminal administration of antibiotics has been used to kill undesirable populations of ruminal microflora. A 2- to 3-day course of treatment with a broad-spectrum antibiotic that is not readily absorbed is useful only when an overgrowth of undesirable bacterial species is present and should be followed by transfaunation. Drugs used for this effect include neomycin or tetracycline for ruminal alkalosis or urea toxicosis and chlortetracycline or erythromycin for ruminal acidosis. Feeding changes and ruminal transfaunation are also effective in inhibiting the undesirable population and inoculating the desirable population. When spoiled milk, putrefactive ingesta, or extremely acidic ruminal contents are found on ruminal fluid analysis, rumenotomy, removal of the contents, and flushing of the rumen seem the more desirable treatment.

32.122.8.4

ACUTE RUMINAL ACIDOSIS

Therapy for cases of mild to moderate or chronic ruminal acidosis can follow the guidelines outlined previously. The prognosis in these cases is usually good, although ruminal inflammation and hematogenous dissemination of infection to other organs can produce chronic problems with a poorer prognosis.

Severe grain overload requires prompt and aggressive treatment. Animals showing severe depression, an unresponsive condition, apparent blindness, and gross ruminal distention warrant a grave prognosis. Immediate slaughter should be considered for animals with similar signs that are still able to stand.

Emergency rumenotomy and removal of the acidic ruminal contents may be lifesaving if the procedure can be performed before significant amounts of ingesta have passed into the lower gastrointestinal tract. An alternative treatment in less severe cases is repeating flushing of the rumen with warm water through a large-bore stomach tube. Administration of magnesium hydroxide into the rumen and sodium bicarbonate solution (5%) IV is necessary to counter the acidosis. Intravenous fluid therapy should be continued until the animal has recovered, to provide support against hypovolemic shock. Other treatments that may be considered include NSAIDs and intraruminal antibiotics. The other therapeutic measures discussed, such as transfaunation and dietary adjustment, should be continued during the recovery phase.

32.122.8.5

SUPPORTIVE TREATMENTS

Indigestion often is accompanied by varying degrees of dehydration and electrolyte imbalance. When these abnormalities are only mild or moderate, the animal's fluid homeostasis may correct as the normal digestive processes are restored. More rapid recovery is achieved if these problems are addressed during the initial treatment, and animals must be treated if the imbalance is severe. Restoration of normal fluid balance improves attitude and appetite and normal gastrointestinal motility.

When laboratory facilities are available and the specific electrolyte imbalances can be assessed, fluid therapy can be tailored to the individual case. Empiric treatment with a balanced electrolyte solution administered IV is sufficient in most cases, because gross disturbances of the body fluid electrolytes are uncommon in most indigestions. The greatest exceptions to this are cases of severe ruminal acidosis or vagal indigestion with pyloric outflow failure and sequestration of abomasal chloride. These problems should be identified during the examination.

841
842

Hypocalcemia and hypokalemia are routinely present in many cases of indigestion. Low serum concentrations of these elements can produce muscular weakness and impair gastrointestinal motility. Both calcium and potassium should be included in the administered fluids. As an alternative, calcium salts should be administered SC if intravenous fluid administration is not elected. When anorexia has been prolonged, an additional oral dose of potassium chloride (120 g/day) may be required even after adequate hydration has been achieved and fluid therapy has been discontinued.

32.122.9 Prevention

Some of the sporadically occurring diseases of the forestomach wall such as granulomatous infections, neoplastic invasions, and diaphragmatic herniation cannot be foreseen or prevented. The most common cause of vagal indigestion syndrome is inflammation of the reticular area caused by TRP. Prevention of this disease by keeping metallic foreign bodies out of the feed or by prophylactic administration of a ruminal magnet is the best prevention of vagal indigestion as well.

The microbial-fermentative forestomach disorders are best prevented by proper feeding management. A well-balanced diet of palatable feeds with an adequate amount of well-structured roughage (not finely ground or pelleted) prevents most problems. Dietary changes should be introduced slowly (over 2 to 3 weeks) to allow adaptation of the microbial flora to the new substrate. Calves undergoing ruminal development and cattle fed high-production diets or changing between production groups are at risk of oversights in proper feeding management. Some feed additives have proved effective in preventing the overgrowth of the high-acid—producing ruminal microflora. Feed-grade buffers are widely used in both dairy and beef cattle production, in which high-concentrate diets are fed to maximize production. These buffers stabilize the ruminal pH and alter the mechanics of ruminal fluid outflow, thus decreasing the chances of overgrowth of the lactate-producing organisms. Commonly used buffers include sodium bicarbonate, sodium sesquicarbonate, sodium bentonite, magnesium oxide, and calcium-magnesium carbonate, of which only the sodium carbonates are truly buffering agents in the chemical sense. The other agents do tend to stabilize ruminal pH, however, and all of these have shown some benefit in reducing the disease problems associated with heavy grain feeding and diets that are low or marginal in effective fiber.[531] The ionophore antibiotics (e.g., lasalocid, monensin) and some other antibiotics (e.g., the sulfur-containing peptide antibiotic thiopeptin) have also proved effective in reducing lactate production in animals fed high-grain diets. The effect of these agents is to suppress the lactate-producing organisms while not appreciably affecting the lactate users. The ionophores are in common use in feedlot cattle and dairy heifer rations because the selective effects of these antibiotics on the ruminal microbes alter the ruminal metabolism in a manner that promotes increased animal weight gain.[532,533] In 2004 the FDA approved the use of the ionophore monensin for lactating cattle in the United States. Although approval was based on increases in milk production efficiency, ionophore use may also reduce the risk of ruminal acidosis and ketosis.[534]

32.123 ACUTE ABDOMEN IN RUMINANTS

David Francoz

Gilles Fecteau

André Desrochers

Abdominal emergencies in ruminants are both a therapeutic and a diagnostic challenge for the veterinary

practitioner. Some of them will require immediate surgical treatment, and others can be treated medically (see Fig. 32-96). They are associated with numerous conditions that affect the abdominal cavity and can also be mimicked by diseases of extraabdominal origin (see Fig. 32-97).

Four important questions should be addressed while dealing with an acute abdomen in ruminants: (1) Where does the pain originate? (2) Is it a medical or surgical problem? (3) Is medical treatment indicated before surgery? (4) What is the likelihood for survival and productivity? To answer these questions, the clinician should use a systematic approach based on adequate signalment and history, complete physical examination, and judicious choice of ancillary tests. Prognosis should be based on past experiences of others as well as one's own experience.

Even though a precise diagnosis facilitates the institution of appropriate treatment and helps to better predict outcome, emphasis should not be placed solely on the diagnosis. Precise information is not yet available for accurately making a prognosis on the outcome of an acute abdomen in ruminants.

32.124 A CONCISE BUT PRECISE EVALUATION OF THE ANIMAL

An animal with acute abdomen may need immediate medical assistance. Therefore the clinician should identify life-threatening problems and take appropriate action rapidly. Acute abdominal emergencies are often associated with either hypovolemic or septic shock.[535] Hypovolemic shock is characterized by increased heart rate, pale mucous membranes, slow capillary refill time, and dehydration.[535] Increased heart rate and dehydration are also observed in case of septic shock, but mucous membranes are hyperemic or bluish in color, and scleral vessels are engorged and dark.[535] Intensive fluid therapy is the treatment of choice for both hypovolemic and septic shock.[535] Consequently, an intravenous catheter should be placed and fluid therapy instituted immediately. However, a complete history and meticulous physical examination should be performed before emergency medical therapy if the condition of the patient is stable.

32.124.1 History

32.124.1.1 SIGNALMENT

Signalment may identify an animal at higher risk of particular diseases. Age, sex, breed, and production stage are important parameters to take into consideration when elaborating the differential diagnosis. For example, abomasal volvulus develops far more frequently in dairy cows than in beef cattle.[536,537] Similarly, uterine torsions are essentially observed at the time of parturition or in the last trimester.[538] Colic in a wether or a buck goat should be considered a result of urolithiasis until proven otherwise.

32.124.1.2 MANAGEMENT—FEEDING PROGRAM

Feeding management system (feeding cows with silage or a total mixed ration [TMR]), herd size (dairy farms with more than 100 cows), and high-intensity milk production are risk factors associated with the development of hemorrhagic bowel syndrome (HBS).[539] Struvite urolithiasis in cattle occurs more frequently in bulls or steers fed with high-grain diets.

32.124.1.3 HISTORY AND CLINICAL SIGNS

Previous history of surgery can be associated with the development of adhesions and colic. Recent calving and obstetric manipulations may cause a full-thickness uterine tear and subsequent peritonitis. Paralytic ileus associated with hypocalcemia may occur during estrus.[540] Pleuritis, pleuropneumonia, or rib fractures may mimic abdominal pain.[541] Previous treatments, especially those that can modify clinical signs or the interpretation of laboratory results, should also be noted. Administration of analgesics such as NSAIDs may partially control abdominal pain, attenuate signs of colic, and decrease the heart rate.

Description of the clinical signs observed by the owner and the chronologic sequence of events are of particular interest. Intussusception in cattle is characterized by an acute onset of anorexia, decreased fecal output (often with dark feces containing blood) and milk production, as well as colic. However, even though the abdominal pain eventually becomes less severe, the depression progresses.[541–544] Torsion of the mesenteric root has an acute onset with severe colic and rapid deterioration.[541,545,546] Fecal output, consistency, and appearance are relevant information. Stranguria manifested by unsuccessful micturition efforts is associated with urolithiasis.

32.124.2 Complete Physical Examination

A thorough and complete physical examination is the most important step when approaching an acute abdomen.

32.124.2.1 VISUAL EXAMINATION

The animal's abdominal profile or silhouette should be observed from the rear and both sides to detect and characterize abdominal distention.[541,547] Bilateral ventral distention is associated with small intestine disorders, whereas distention in the right paralumbar fossa is associated with cecal and/or colon disorders. In cases of abomasal volvulus, the distended abomasum can be observed caudal to the last rib in the right paralumbar fossa. Gas in the rumen causes a distended upper left abdomen, whereas some forms of vagal indigestion have a “papple” shape (pear on the right and apple on left). Lateral views of the abdomen help to determine whether the distention arises primarily from the paralumbar fossa or extends cranially under the ribs. An arched back may be observed in cases of cranial abdominal pain or laminitis (sore feet).

Evaluation of pain severity and differentiation between visceral and parietal pain can be performed using history and observation of the animal. Abdominal pain is an important criterion in deciding if surgery is necessary. Severe colics are classically associated with some surgical intestinal conditions,[548,541] although animals with severe jejunal distention secondary to acute enteritis may have a similar clinical presentation. Abdominal pain may be a consequence of excess distention of a hollow viscus (excessive intestinal distention), spasms of intestinal smooth muscles, stretching of the mesenteric supporting structure, intestinal ischemia, or chemical irritation of the visceral or parietal peritoneum.[549–551] Abdominal pain can be classified into two main categories: visceral pain (hollow viscera and solid organs) and parietal pain (parietal peritoneum, abdominal muscles, rib cage).[551] Although the task is often difficult in animals such as cattle that have unpredictable behavior in response to pain, differentiation between visceral and parietal pain should be attempted.

Pain sensation from the parietal peritoneum travels through the peripheral spinal nerves and usually localizes

over the affected area.[551] Because parietal pain is exacerbated by pressure and tension modification, the patient is reluctant to move and has a tonic reflex contraction of the abdominal muscles.[550] No active clinical signs of colic are present. This is typically observed in cases of peritonitis. The animal is reluctant to move, has a splinted abdomen, and is responsive to external palpation,[541] such as having a positive xiphoid grunt test or not dipping the back when pinched over the withers.

Some pain fiber endings are located in the submucosa and muscle layers of hollow viscera (intestines, bladder) and in the capsule of solid organs (kidney, liver). Consequently, distention, forceful contraction, or traction will produce pain in a hollow viscus. Capsule stretching will create pain in solid organs. Visceral pain is typically recognized by active manifestations of colic: kicking at the abdomen; treading with the rear feet; lying down, standing, and stretching out[541]; and grinding the teeth. Goats may also vocalize. The animal is anxious and has an apprehensive attitude. Contrary to parietal pain, visceral pain is transmitted via sensory fibers in the autonomic nerves.[549] Visceral pain is often diffuse and difficult to localize.[549]

32.124.2.2 EVALUATION OF VITAL PARAMETERS

Assessment of cardiovascular status is essential in the evaluation of an animal with an abdominal emergency. Hypovolemic and septic shock are associated with increased heart rate, pale or hyperemic mucous membranes, slow capillary refill time, and dehydration. Low heart rate and adequate hydration status are considered good prognostic indicators regarding the outcome of abomasal volvulus.[552,553] Circulatory insufficiency, secondary to hypovolemia and caudal vena cava compression, is a complication of abomasal volvulus.[553] Dehydration and acid-base abnormalities are principally caused by fluid accumulation in the abomasum and are associated with a high mortality rate.[552,554] Heart rate is increased secondary to hypovolemia, compression of the caudal vena cava, and sympathetic nervous system stimulation in response to distention and twisting of the abomasum.[552] Determination of rectal temperature, pulse or heart rate, and respiratory rate (TPR) should always be performed first, as manipulations performed during the physical examination of an abdominal emergency can elicit pain, modifying the heart rate.

The TPR and amount of pain exhibited may also be used to monitor the evolution of the condition and the response to the initiated treatment.

32.124.2.3 EXTRAABDOMINAL EXAMINATION

Once vital parameters have been evaluated and the animal appears hemodynamically stable, a thorough physical examination of the body systems should be performed. Examination of the thorax (pleuropneumia, rib fractures) and the musculoskeletal system (laminitis, myopathy) are important in eliminating diseases that mimic abdominal pain.

32.124.2.4 ABDOMINAL EXAMINATION

Abdominal examination is performed by auscultation, percussion, ballottement, and succussion of the abdomen. Pings are tympanic resonance caused by a gas-fluid interface in a distended organ and can be detected by simultaneous auscultation and percussion.[541] Because rectal palpation may create an area of increased resonance on the right dorsal part of the abdomen, detection of pings should be performed before rectal palpation.[541]

On the right side of the abdomen, many organs may be responsible for pings. Location, pitch characteristics and variability of the ping are essential to establish a differential and precise diagnosis. Pings localized from the thirteenth rib cranially to the ninth rib are typical of abomasal volvulus or a right-displaced abomasum.[541] Cecal dilatation or volvulus creates a ping in the right paralumbar fossa and caudal quadrant,[541] often extending to the hip. Abomasal volvulus will be more likely to have a high-pitched ping, whereas animals affected with peritonitis may have a bilateral low-pitched ping in the upper paralumbar fossa. Many cattle 843
have a round area of monotone pinging some 15 to 20 cm in diameter centered high on the right under the last 844
rib, which is gas in the spiral colon (see Figure 1-3). Moving or constantly contracting viscera will have changing pitch of their pings, like gas in the left-displaced abomasum, descending duodenum, or proximal colon. For this particular reason, it is important to auscultate and percuss for a certain period of time to notice ping variation.

On the left side, pings are principally associated with left abomasal displacement, ruminal collapse, and pneumoperitoneum. Left abomasal displacement typically creates variable pitch pings dorsally from the eighth to the thirteenth ribs. Pings associated with gas in the rumen, ruminal collapse, and pneumoperitoneum are localized dorsally in the left paralumbar fossa and extend cranially to the eleventh rib. Illustrations and details are presented in Chapter 1 of this textbook. Simultaneous auscultation and ballottement (succussion) of the abdomen may permit detection of fluid trapped within the intestine or in a hollow viscus like the rumen or abomasum.[541] The location of the fluid splashing sounds on auscultation-succussion may help to confirm and differentiate among auscultation-percussion findings.[541] Tense abdominal muscles, secondary to parietal peritoneum inflammation, may also be detected during succussion.

Cattle with cranial abdominal pain are reluctant to move; they stand with elbows abducted and back arched.[541] During examination, bruxism (grinding of the teeth) may be present.[541] Pain can be elicited by pinching over the withers or applying forceful movement with the knee or upward pressure with a bar or pole over the xyphoid area or anterior abdomen. In response, the animal in pain may grunt or kick and be reluctant to dip the back.[541] Sensitivity of this test may be increased by simultaneous auscultation of the trachea. Cranial peritonitis, secondary to TRP or abomasal ulcers, is an important cause of cranial abdominal pain. A complete cardiorespiratory examination may help to differentiate this from thoracic pain.

32.124.2.5 RECTAL PALPATION

Per rectum abdominal palpation of cattle is helpful in the differential diagnosis of an acute abdomen because the urogenital and digestive systems can be evaluated.

Cecal disorders are clearly diagnosed per rectal palpation. Moreover, cecal dilatation or volvulus can be differentiated by location of the apex. Based on these findings, medical treatment can be started if the caecum is only dilated and the apex is mobile.[548,555] Multiple, dilated, turgid small intestine loops and a firm mass may be palpated in cases of intussusception[543,542] or HBS.[539] Typical signs of peritonitis (adhesions between the kidneys and the rumen, and the intestinal convolutions, and decreased rectal mobility) may be palpated when the posterior aspect of the abdomen is affected.[556] Uterine wall integrity may be evaluated during rectal palpation, although examination per vagina may be necessary to confirm a full-thickness laceration in the postpartum cow. In cases of urolithiasis in bulls or steers, rectal palpation reveals a pulsatile pelvic urethra and a distended bladder. In cases of pyelonephritis, enlargement of one or both ureters may be palpated. The left kidney may be painful as well as bigger, without lobulation. Enlargement of the right kidney is sometimes

palpable. In small ruminants, urolithiasis is manifested by pulsations in the pelvic urethra that may be felt by digital rectal examination, and distended bladder or enlarged kidney can be detected by deep abdominal palpation.

Presence and macroscopic appearance of feces can be evaluated during rectal examination. A decreased volume of feces is principally associated with intestinal stasis or obstruction, which may occur secondary to a direct mechanical obstruction (requiring surgical treatment) or to gastrointestinal ileus (requiring only medical treatment).[557] However, feces may be present in the first few days after an intestinal obstruction.[557]

32.124.3 Ancillary Tests

32.124.3.1 PACKED CELL VOLUME AND TOTAL SOLIDS

Shock, sepsis, and toxemia cause hemoconcentration and dehydration and are associated with an increase of PCV and total solids. On the other hand, increased PCV and decreased total solids are observed during the formation of a third compartment filled with a protein-rich fluid such as in generalized peritonitis.[558]

32.124.3.2 BLOOD GAS ANALYSIS AND ELECTROLYTES

Blood gas analysis as well as determination of electrolyte imbalance may be useful before initiation of treatment. Most adult ruminants with acute abdominal diseases suffer from metabolic alkalosis.[559] Metabolic alkalosis is often associated with abomasal volvulus, intussusception, cecal disorders, abomasal ulcers, peritonitis, renal diseases, and reticuloperitonitis.[559] Hypochloremia and hypokalemia are frequently combined with metabolic alkalosis.[560] Metabolic acidosis may be observed if urinary tract disease, small intestinal strangulation or obstruction, or enteritis with severe diarrhea is present.[559]

Serum chloride concentration,[554,561] anion gap,[561] and base excess[562,563] have been proposed as preoperative prognostic indicators in dairy cattle suffering from abomasal volvulus. Poor short-term prognosis was associated with serum chloride concentrations less than 79 mEq/L,[554] base excess values of −0.1 or less,[562] and anion gap values of more than 30 mEq/L.[561] However, a prospective study on the outcome of abomasal volvulus reported that serum base excess and anion gap values did not differ between productive and nonproductive animals.[552] In this study, serum chloride concentration was significantly lower in nonproductive animals, but this prognostic test had numerous false-negative results.[552]

Blood gas analysis and electrolyte measurement results are helpful in the institution and monitoring of fluid therapy.

32.124.3.3 BLOOD LACTATE CONCENTRATION

Blood lactate concentration, although rarely used in ruminants, can be used to assess cardiovascular or respiratory system compromise, to monitor the response to treatment, and to establish a prognosis for survival. In cattle, high blood lactate concentrations have been associated with a poor outcome for abomasal volvulus in one study,[553] whereas Constable and co-workers did not find any association in their study.[564] In humans[565–568] and horses,[569] blood lactate concentrations are an important indicator of adequate response to treatment and reperfusion of ischemic tissues.

32.124.3.4 COMPLETE BIOCHEMICAL PROFILE

Evaluation of specific enzyme activity (e.g., hepatic enzymes, BUN, and creatinine) combined with physical examination and other ancillary tests may be useful in establishing a diagnosis and assessing progress.

32.124.3.5 WHITE BLOOD CELL COUNT AND DIFFERENTIAL

A WBC count rarely provides further information for establishing the exact cause of an acute abdomen. Hematologic findings are rarely specific to a condition and reflect the underlying inflammatory process. In most cases a minimal to moderate inflammatory process characterized by a neutrophilic leukocytosis is observed. Hematologic findings may also provide information about the acuteness of the disease and the severity of the sepsis and toxemia associated. Severe sepsis is associated with neutropenia, degenerative left shift, toxic changes of neutrophil morphology, and lymphopenia. Hematology is also an important ancillary test to monitor the response to treatment.

844

845

32.124.3.6 FIBRINOGEN

In ruminants, increased fibrinogen concentration is an early indicator of inflammation. Studies in cattle report that fibrinogen concentration may increase within 1 to 2 days after induction of inflammatory conditions.[570,571] Consequently, increased fibrinogen concentration may be observed in some cases of acute abdomen. Normal fibrinogen concentration despite severe visceral involvement should be observed only in peracute cases (within a few hours) (e.g., torsion of the root of the mesentery). Moderate to marked increased fibrinogen concentration is also the signature of an active localized inflammatory condition such as reticuloperitonitis, liver abscesses, or pyelonephritis.

32.124.3.7 URINALYSIS

Urinalysis is helpful in differentiating between colic of urogenital origin versus gastrointestinal disorders. Urinalysis can be rapidly performed using a urinary dipstick* and gross morphologic examination. Renal diseases are associated with proteinuria (>1+), glucosuria, and positive blood reaction. In case of acute urethral obstruction, hematuria and proteinuria are consistently observed. Determination of urinary specific gravity may help to characterize azotemia.[572]

* Chemstrip 9, Roche Diagnostics Corporation, Indianapolis, IN.

32.124.3.8 ABDOMINOCENTESIS

Collection and evaluation of peritoneal fluid is helpful in the diagnosis and the establishment of treatment, as well as prognosis, in many gastrointestinal disorders in cattle.[541] Abdominocentesis is considered an essential ancillary test in the approach to acute abdomen in many species.[535,573] Because of the ability of cattle to wall off and localize infections in the abdomen, a four-quadrant method of abdominocentesis is suggested by some authors.[541] Fluid can be evaluated macroscopically for color, volume, odor, and turbidity. Normal values are reported in the section of this chapter on peritonitis. Peritoneal fluid changes to cloudy yellow, then blood-tinged with fibrin, and finally to black in color as bowel necrosis and hemolysis of extravasated RBCs occur. In case of generalized peritonitis, fluid is abundant, cloudy, and sometimes foul-smelling. Occasionally,

digestive fibers can be observed macroscopically if rupture has occurred.

Biochemical variables may be evaluated in peritoneal fluid. Lactate, glucose, alkaline phosphatase, and pH of the peritoneal fluid concentrations have been reported to be indicators of intestinal ischemia and peritonitis in horses.[574] Such information is not published for ruminants.

32.124.4 Diagnostic Imaging

32.124.4.1 ULTRASONOGRAPHY

With the advance of multifrequency abdominal transducers, ultrasonography is used more frequently in ruminant medicine. Information on ultrasound of the ruminant abdomen is available in this chapter.

32.124.4.2 RADIOGRAPHS

Although the use of abdominal radiographs in adult cattle is limited to referral hospitals, and their effectiveness is limited to the cranial abdomen, they are one of the most helpful ancillary examinations for the diagnosis of reticuloperitonitis.[575,576] Abdominal radiographs may help in the diagnosis of intestinal atresia and intussusception in calves.[541]

A lateral view of the abdomen of small ruminants may assist in the diagnosis of urolithiasis because stones in the urethra or in the bladder may be detected.

32.124.5 Medical or Surgical Decision

A differential diagnosis list and a decision for surgical or medical treatment should be established based on clinical signs and ancillary tests results (Fig. 32-96). If a precise diagnosis is made, adequate treatment can be instituted. When a precise diagnosis cannot be established, attempts should be made to differentiate surgical and medical cases (Fig. 32-97). Among surgical cases, intestinal obstructions are those requiring immediate surgery. A mechanical obstruction may be suspected when there is a suspicion of intestinal or cecal torsion on rectal examination, pings indicating a right abomasal displacement or volvulus, peritoneal fluid indicating bowel devitalization, or severe signs of active colic or rapid deterioration.[557,577] If an intestinal mechanical obstruction is not suspected during the first examination, exploratory surgery may be delayed for up to 36 hours.[557] However, frequent monitoring should be performed and appropriate medical treatment provided to the animal.

32.124.5.1 SURGERY

Most abdominal surgeries in adult cattle are performed with the animal standing under sedation and local or regional anesthesia. Cattle can tolerate intestinal resection and anastomosis standing if adequate local anesthesia and systemic analgesia are provided. However, some animals with acute abdomen are reluctant to stand and may be expected to lie down. If that occurs, surgery should be performed with the animal in lateral recumbency.[578] Because a right paralumbar fossa celiotomy provides the best exposure to the intestinal tract, left lateral recumbency should be favored. Other than the general status of the animal, the suspected affected organ, presence of aggressive behavior, surgeon preferences, and facilities should be considered in the choice of doing the surgery with the animal standing or in lateral recumbency. If the animal is dehydrated and/or

manifests signs of shock, preoperative fluid therapy and analgesics are recommended.[546,557,577,579] For the prevention of surgical infection, appropriate preoperative antibiotic administration is also recommended.[577,580]

32.124.5.2 MEDICAL AND SUPPORTIVE TREATMENT

The goal of therapy in an animal with acute abdomen is to initially correct the hemodynamic and metabolic imbalances associated with hypovolemic or septic shock, to control pain, and to correct or treat the primary cause of the disease, when identified. Consequently, medical treatment is based on fluid therapy, NSAIDs, and antimicrobial drugs.

32.124.5.2.1 Fluid Therapy

Crystalloid solutions (0.9% NaCl, Ringer's solution) are indicated initially to replenish fluid loss and improve the circulating blood volume.[560,581] To resuscitate critically ill neonatal patients, recommended intravenous fluid administration rates of isoosmotic crystalloid solution are 80 to 90 mL/kg of body weight per hour.[581] However, such rates are difficult to achieve through a catheter in adult ruminants. Studies demonstrated that perfusion rates of 40 and 80 mL of an isoosmotic crystalloid solution per kilogram of body weight per hour can be used safely in adult ruminants and dehydrated calves, respectively.[582–584] If the animal is not critically ill, fluid and electrolyte deficits should be corrected over 2 to 8 hours. The maximal flow rate usually achieved through a catheter in an adult is 15 to 20 mL/kg/hr.

Hypertonic solutions (7.2% or 7.5% NaCl) are also an alternative. Intravenous administration of hypertonic saline provides rapid resuscitation in dehydrated or endotoxemic ruminants.[585] A rate of 4 to 5 mL of hypertonic solution per kilogram should be administered IV through the jugular vein over 4 to 5 minutes. Animals should be provided with a supply of fresh water immediately after the treatment, or an intravenous infusion of an isotonic crystalloid solution should be instituted. Cattle not observed to drink within 5 minutes should have 20 L of water pumped into the rumen.[585] An administration rate for a hypertonic solution of over 1 mL/kg/min should be avoided because it induces a potentially fatal hypotension coupled with a decrease in cardiac contractility.[585]

845 847

Fig. 32-96 Suggested decision tree for cattle with acute abdomen.

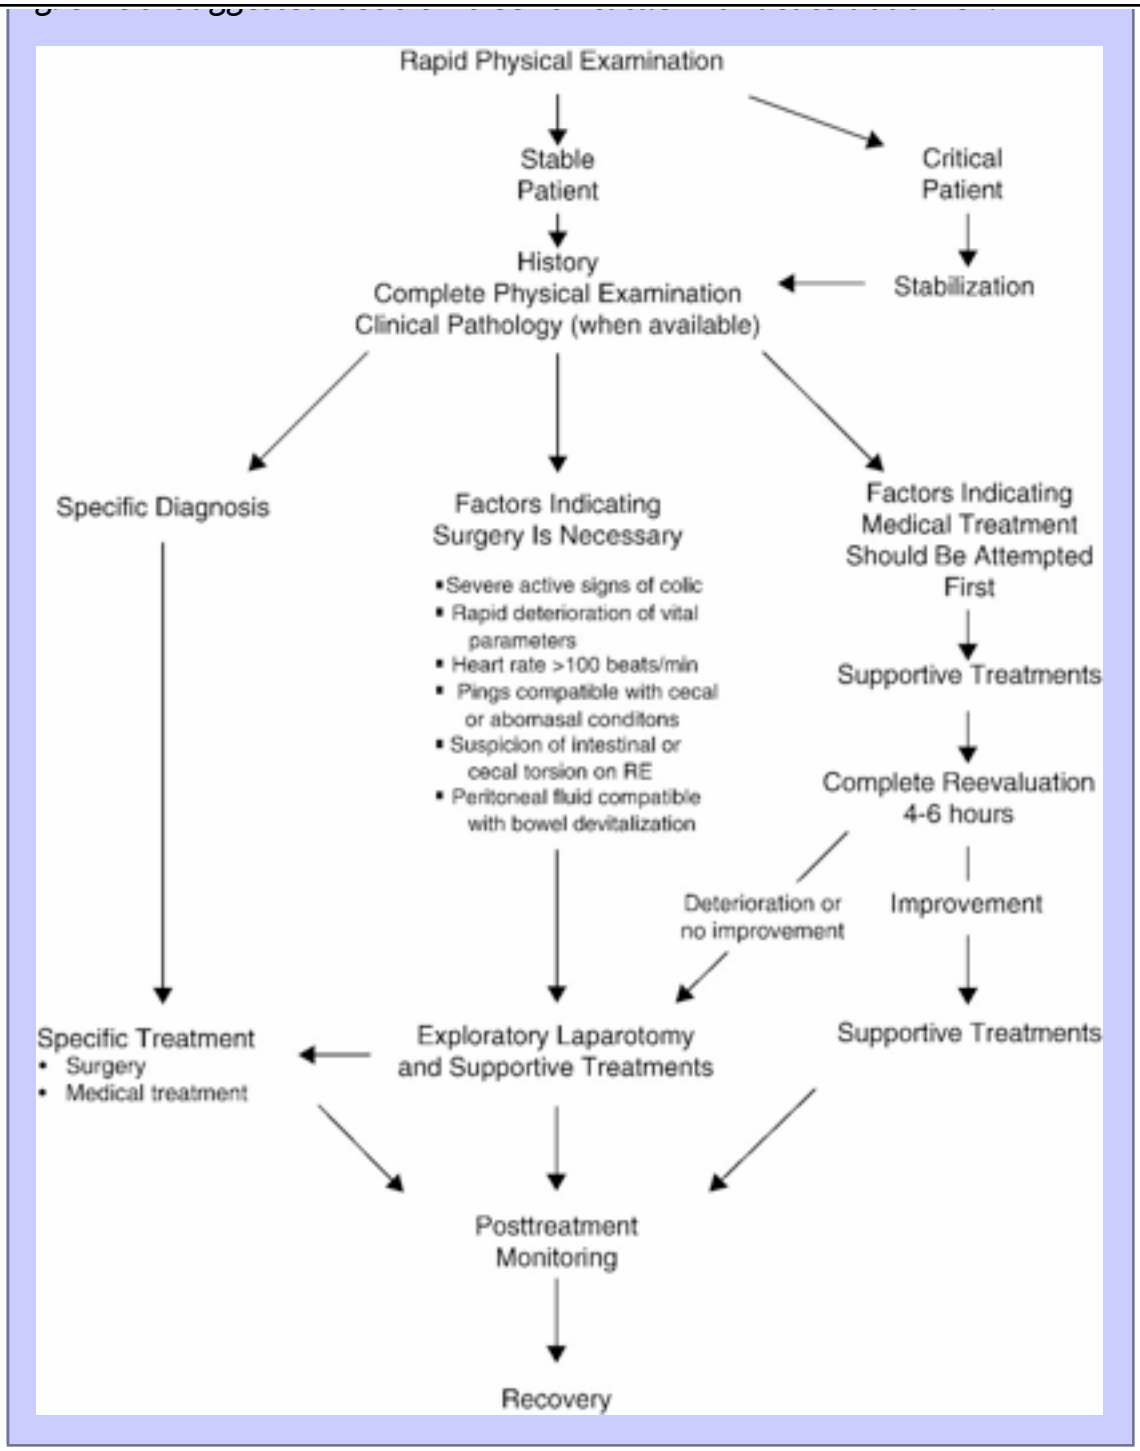


Fig. 32-97 Classification of abdominal causes based on the need for

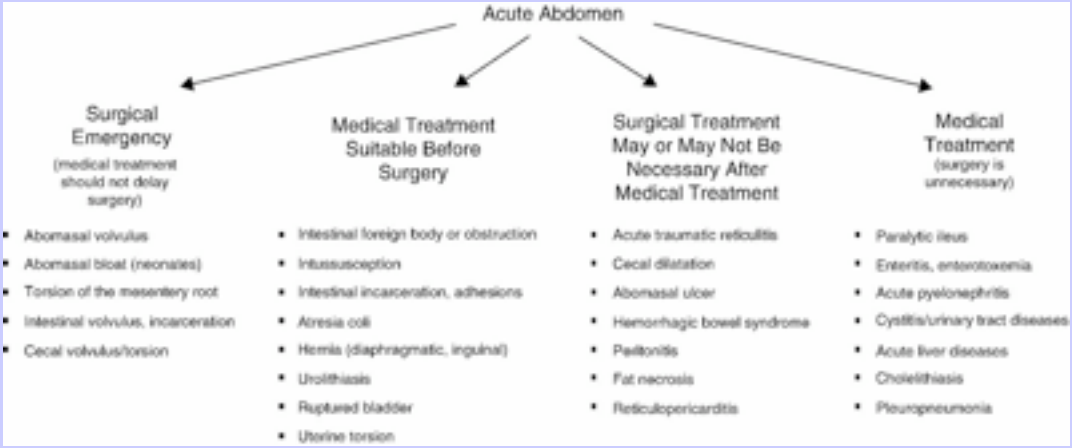
surgical exploration or medical treatment.



32.124.5.2.2

Correction of Acid-Base and Electrolyte Imbalances

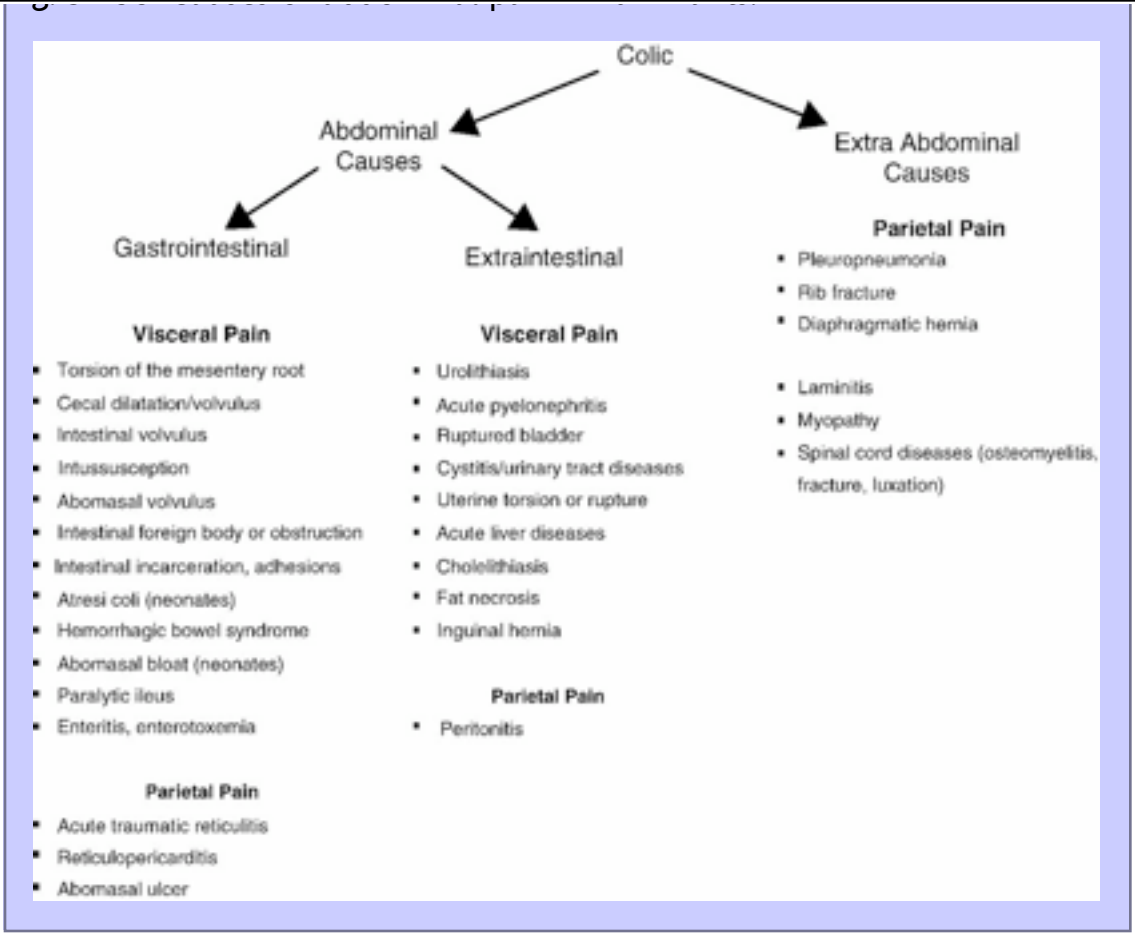
Correction of electrolyte imbalances should be based on laboratory results when available. Previous treatments should be considered (e.g., intravenous calcium, orally administered magnesium hydroxide) to initiate the most appropriate fluid therapy if no laboratory results are available.[560] Most animals with acute abdominal diseases suffer from metabolic alkalosis, hypochloremia, and hypokalemia.

Calcium homeostasis is in a precarious balance in postpartum dairy cattle. Hypocalcemia is common in anorectic ruminants or in ruminants with gastrointestinal diseases.[560,581] Moreover, metabolic alkalosis, frequently observed in cases of acute abdomen, is strongly associated with subclinical hypocalcemia.[540,586] Calcium ions are of particular importance in gastrointestinal motility. First, in the gastrointestinal smooth muscles, the channels responsible for generating action potentials are calcium-sodium channels.[551] Second, gastrointestinal smooth muscle contraction occurs in response to the entry of calcium into the muscle fiber.[551]

Based on these considerations, the intravenous solutions used for the medical treatment of acute abdomen, secondary to a suspected digestive disorder, should contain Na, Cl, K, and Ca.

The Ringer's solution containing 8.6 g of NaCl per liter, 0.3 g of KCl per liter, and 0.3 g of $CaCl_2$ per liter, yielding 147 mEq/L Na, 155 mEq/L Cl, 4 mEq/L K, and 4 mEq/L Ca, is the commercially available solution of choice. In our clinics in Quebec, we use a beneficial homemade solution composed of 7.5 g of NaCl per liter, 1.5 g of KCl per liter, and 5.75 g of Ca^{2+} per liter (25 mL of 23 % calcium borogluconate per liter), yielding 128 mEq/L Na, 148 mEq/L Cl, 20 mEq/L K, and 26 mEq/L Ca, for adult cattle. We usually begin our fluid therapy with rapid administration of a 0.9% NaCl solution (15 to 20 mL/kg/h, which is the highest rate possible through a catheter) for rapid correction of dehydration and then administer this homemade solution with an infusion rate of approximately 4 to 5 mL/kg/hr.

Fig. 32-98 Causes of abdominal pain in ruminants.



32.124.5.2.3

Control of Pain and Inflammation

Pain and inflammation are important causes of gastrointestinal hypomotility (Fig. 32-98). Gastrointestinal pain increases sympathetic tone, causing general inhibition of the gastrointestinal tract.[551,587,588] Numerous inflammatory mediators are released during disease of the gastrointestinal tract, leading to alteration of intestinal motility.[587,589] Peritoneal inflammation or irritation and associated pain are well-recognized initiating factors of ileus in multiple species.[587,589] Release of proteinases, vasoactive substances, free oxygen radicals, and endorphins secondary to ischemia and reperfusion injury, or to endotoxemia, impairs cardiovascular function and decreases gastrointestinal motility.[589] Inflammatory mediators lead to a pain response and modulate the intensity of noxious stimuli.[588,587] Consequently, analgesic and antiinflammatory drugs appear essential in the management of acute abdomen. These drugs must be used with caution. NSAIDs may induce abomasal ulcers, particularly in an anorectic patient. Analgesics may mask clinical signs (pain, fever) and compromise adequate case management by delaying surgery.

NSAIDs are the most commonly used drugs for gastrointestinal pain management in cattle. There is no information comparing the efficacy of the different NSAIDs available in food animal medicine related to their use in the management of acute abdomen. Some authors report that, based on clinical observations, flunixin provides an excellent visceral analgesia.[590] Ketoprofen and flunixin appear to have similar activities in endotoxic calves.[591] Consequently, no single NSAID can be recommended based on scientific

activities in endotoxic calves.[588] Consequently, no single NSAID can be recommended based on scientific evidence for the management of abdominal emergencies in cattle. The choice of NSAID becomes a matter of previous experience, comparative medicine, legislation, and cost. In our experience, flunixin and ketoprofen are both adequate for the management of acute abdomen in cattle. In equine gastrointestinal pain, a poor or short duration response to NSAIDs indicates a need for surgery.[588] This principle can be applied to cattle with caution because of their unpredictable behavior in response to pain.

847

848

α_2-Agonists that function as sedatives and analgesics, such as xylazine, detomidine, and medetomidine, could also be used to relieve pain in cases of acute abdomen. All are considered to be strong analgesics that can alleviate most visceral pain, at least temporarily, in equine medicine.[588] There are few data on the use of α_2-agonists for the management of acute abdomen in cattle. In a cow with a large intestinal obstruction, signs of abdominal discomfort disappear immediately after the administration of a single dose of xylazine (0.05 mg/kg IV) for at least 1 hour.[592] Different side effects must be considered before the administration of alpha-2 agonists. Xylazine is reported to have significant effects on the gastrointestinal tract in cattle, decreasing reticuloruminal and intestinal motility.[593] Because of the hemodynamic changes associated with the administration of α_2-agonists, these drugs must be used with caution in patients with arterial hypotension and/or shock.[594] α_2-agonists can mask surgical pain and delay the decision for surgery. This is particularly critical with the use of detomidine.[588] Finally, dose and administration of α_2-agonists should be used with care if standing surgery is planned.

32.124.5.2.4

Antimicrobial Drugs

Bacterial translocation from the intestines can occur in cases of mechanical or functional ileus secondary to bacterial overgrowth, inflammation, and impairment of barrier function of the intestinal wall.[555,595] A systemic broad-spectrum antibiotic treatment should be instituted when a septic process is suspected, until bacterial culture results become available. This initial antibiotic therapy should be effective against gram-negative, gram-positive, aerobic, and anaerobic pathogens. The choice of antibiotic should also take into consideration legal aspects and the cost of the treatment. β-Lactams, tetracyclines, and trimethoprim-sulfadoxine appear to be good choices. In cattle there is no accepted recommendation for the duration of treatment. In human medicine, prolonged broad-spectrum antibiotic therapy in case of surgical acute abdomen does not appear beneficial.[596] Prevention of infective complications was not affected by prolonging the course of antibiotic treatment.[596] In human medicine the current recommended dose is a single prophylactic antibiotic administration when there is no or minimal evidence of contamination, and 5 to 7 days when pus or contamination, either localized or diffuse, is present.[596]

32.124.5.2.5

Other Treatments

The use of purgatives (magnesium hydroxide, mineral oil, liquid paraffin) in cases of suspected gastrointestinal obstruction or ileus in cattle has no therapeutic basis.[557] Moreover, these treatments may exacerbate the condition. Because the intestines are already filled with gas and fluid, purgatives only impose additional distention. In human medicine, laxatives are frequently used for the treatment of postoperative ileus (POI); however, no study could demonstrate their actual benefit.[597] Braun and colleagues reported that the use of purgatives for the treatment of cecal disorders delayed the time to first defecation.[555] Moreover, magnesium hydroxide may be responsible for detrimental effects such as metabolic alkalosis,[598] sedation caused by hypermagnesemia,[598] increased ruminal pH,[599] and decreased

metabolic alkalosis,[—] sedation caused by hypermagnesemia,[—] increased ruminal pH,[—] and decreased ruminal microbial activity.[599]

Motility-modifying agents may be used in the management of gastrointestinal disorders. In most cases intestinal motility is restored when pain is relieved and electrolytic imbalances are corrected. Steiner reviewed the different prokinetics that can be used in ruminant medicine and their clinical implication.[593] For cattle, he recommends the use of bethanechol (0.07 mg/kg SC tid for 2 days; not approved for food animal use in the United States) alone or in combination with metoclopramide (0.1 mg/kg SC or IM tid for 2 days; not approved for food animal use in the United States), or erythromycin in polyethylene glycol (10 mg/kg IM bid for 2 days, Erythro-200) for the postoperative treatment of right abomasal displacement or torsion.[593] Bethanechol (0.07 mg/kg SC tid for 2 days; not approved in the United States) can be used for conservative or postoperative treatment of cecal disorders and treatment of paralytic ileus.[593] Contrary to cattle and sheep, in goats metoclopramide (0.5 mg/kg IM or IV; not approved in the United States) has been reported to significantly increase myoelectric activity of the duodenum.[593] Continuous infusion of neostigmine (87.5 mg in 10 L of sodium chloride-glucose infusion at 2 drops/sec per cow) was successfully used for the conservative and postoperative treatment of cecal disorders.[555] In this clinical report, this protocol was preferred to those previously reported (neostigmine SC every hour over 2 to 3 days in doses that gradually decreased from 12.5 mg to 2.5 mg).[555] Drug administration was easier and involved fewer disturbances for the animal.[555] However, no control group was included in this study. Also, neostigmine has been reported to have a pronounced effect on intestinal contractility, causing uncoordinated spikes to become more frequent, thereby compromising the potential beneficial effect.[600]

No prokinetic drug is reported to directly increase ruminal motility. In cases of prolonged anorexia or acute indigestion, ruminal flora can be disturbed and reduced. Transfaunation may help to rapidly reconstitute the ruminal flora and hasten return to normal function of the rumen and the digestive tract. The technique for and beneficial effects of transfaunation (reduction of ketonuria, increased feed intake, and higher milk yield) have been reported in the postsurgical treatment of left abomasal displacement.[601]

32.124.6 Follow-Up

When a definitive diagnosis cannot be made, a close monitoring of the animal may be indicated. Follow-up must also be performed secondary to surgery to ensure adequate response to surgical treatment and to allow possible adjustment of treatment. In a referral hospital the animal should be reevaluated every 4 to 6 hours. In field practice, vital parameters, rectal examination, presence and consistency of feces, and pain may be reevaluated every 6 to 12 hours. A significant reduction of heart rate was observed 4 and 6 hours after the initiation of treatment in cases of cecal dilatation.[555] Feces are passed within 4 to 6 hours after surgery in cases of intestinal volvulus[546] or cecal disorders.[555] Failure to defecate for 24 hours or more is abnormal in cattle and therefore indicates persistence of intestinal obstruction and may adversely affect the prognosis.[557] Deterioration or persistence of clinical signs despite the initiation of supportive treatment is also an indication for surgery. Surgical exploration is indicated if the following clinical signs are observed: persistence of colic, development of abdominal distention, heart rate over 100 beats/min, scant feces, typical abomasal or cecal pings, or paracentesis indicating bowel devitalization.

The decision for surgery or medical treatment remains challenging in cases of acute abdomen in ruminants.

Optimal management of acute abdomen prevents any unnecessary delay in cases requiring surgery and avoids unnecessary surgery. Knowledge of diseases associated with signs of acute abdominal pain is important, but no clinical signs are specific for a particular problem, and a specific diagnosis cannot be established postoperatively in many cases. Based on a systematic approach to clinical examination and a judicious use of ancillary tests, the clinician may be able to identify cases that require immediate or delayed surgery, avoid unnecessary surgery, and establish a cost-effective management plan.

32.125 TRAUMATIC RETICULOPERITONITIS (HARDWARE DISEASE, TRAUMATIC RETICULITIS)

David Francoz

Charles L. Guard

32.125.1 Definition and Etiology

TRP or hardware disease is a common disease of cattle but is rarely seen in small ruminants. It is the most common cause of anterior abdominal pain in cattle. The ingestive behavior of cattle predisposes them to the accidental swallowing of metal foreign objects that settle in the reticulum. Ingestion of a foreign body may also be associated with diseases that cause pica, such as phosphorus deficiency. Subsequently, the foreign object may enter the reticulum and (1) attach to a magnet without clinical diseases; (2) penetrate the reticulum wall only with intramural inflammation; (3) perforate the reticulum wall, penetrate into the peritoneal cavity, and create localized peritonitis; or (4) migrate into the peritoneal and thoracic cavities.[602] The diaphragm, pericardium, and heart muscle are located just cranial to the reticulum, with the liver positioned medially and dorsally and the spleen laterally and dorsally. These organs may sometimes be penetrated by foreign bodies and become involved in the inflammatory process.

32.125.2 Clinical Signs and Differential Diagnosis

TRP in the most severe, acute form is characterized by fever, anorexia, decreased or absent ruminal contractions, and evidence of cranial abdominal pain. Pinching of the withers or upward pressure on the xiphoid region may elicit a grunt on expiration. Affected cattle may stand with an arched back and resist ventral flexion of the back when pinched over the withers (normal cattle flex ventrally). Some cattle grunt spontaneously when forced to move or when defecating or urinating. Lactating cows show a sudden decrease in milk production.[603,604] Some cows regurgitate ruminal fluid, especially if the oropharynx is mechanically stimulated. Tachycardia, reluctance to move or lie down, mild bloat, constipation, or abducted elbows may also be seen. These typical signs often abate within the first day or two, making diagnosis more difficult. Auscultation may reveal a pounding heart or muffled heart sounds bilaterally if pericarditis with effusion has developed by the time of examination. Sudden death has occurred as a result of the laceration of a coronary blood vessel or puncture of the heart by the foreign body.

Less severe or more long-standing cases may have signs that are more subtle and confusing. Cows in early lactation may have ketosis; however, a distinguishing feature of hardware disease is the abrupt onset of anorexia and hypogalactia. Fever may be absent. Weight loss, rough hair coat, diarrhea, or generalized lameness, along with cranial abdominal pain that is difficult to localize, may be the only signs.

If the pericardial sac has been seeded with bacteria, pericarditis usually develops. There is no initial change in

heart sounds, but over a period of several weeks as septic fluid accumulates, the heart may become muffled. When there are both fluid and gas in the pericardium, sloshing sounds like a washing machine may be auscultated. Distended jugular and superficial abdominal veins and other signs of congestive right-sided heart failure are most common after pericardial effusion. Dyspnea may occur if left-sided failure is also present.

The foreign body may penetrate the liver or spleen, leading to abscess formation. These abscesses as well as reticular adhesions may be responsible for ruminoreticular outflow problems and may lead to vagal indigestion.[605] These are further discussed with vagal indigestion.

TRP must be differentiated from other causes of cranial abdominal pain. They mainly include abomasal ulcers, hepatic abscesses from other causes, and pleuritis. More informations about the differential diagnosis of abdominal pain is presented in the section on acute abdomen in cattle. When thoracic structures are involved, TRP must be differentiated from primary pneumonia or pleuritis, diaphragmatic hernia, and heart diseases such as endocarditis, lymphosarcoma of the heart, and cor pulmonale. Finally, TRP must be differentiated from others causes of ruminal distention and vagal indigestion.

32.125.3 Clinical Pathology

The WBC count and differential, as well as the determination of plasma proteins and fibrinogen, may indicate an acute or chronic inflammatory process depending on the stage of the TRP. Neutrophilia and a left shift are expected in acute cases. However, in more chronic cases changes are less pronounced, and WBC count as well as differential may be normal.[602,606] High fibrinogen concentration may be observed in acute cases (2 to 3 days after the beginning of the disease) and chronic active cases. Studies in referral centers[607,608] have demonstrated highest plasma fibrinogen concentration with TRP compared with other abdominal disorders. High total plasma proteins, primarily reflecting high globulin levels, were expected in chronic cases of TRP. Higher concentrations of total plasma proteins have been observed in cases of TRP compared with other abdominal disorders.[607–609] Plasma protein concentration cutoff points of 87 to 100 g/L have been proposed in these studies. All the results of the studies demonstrated that high values of plasma fibrinogen and plasma protein concentrations are highly suggestive of TPR. However, other disorders can induce the same modifications, and absence of these abnormalities does not rule out TRP. Consequently, other diagnostic tests (diagnostic imaging) must be performed to confirm the diagnosis. Biochemical profile and blood gas analysis are usually within normal range but may reflect hypochloremic metabolic alkalosis associated with ileus and dysfunction of the abomasum.

Radiography and ultrasonography of the reticulum are very useful for the diagnosis of TRP. Radiographs of the reticulum are limited to referral centers. They are performed on standing animals and allow the detection of a metallic foreign body and the determination of its location in or outside the reticulum. Different parameters may be observed on radiographs for the diagnosis of TPR. They include presence or absence of a foreign body, position of the foreign body, presence of focal gas shadows or gas-fluid interface near the reticulum, and the shape, size, and location of the reticulum.[610–612] Of these parameters, location of the foreign body is the most reliable indicator for the diagnosis of TPR.[610,612] Ultrasonography of the reticulum is presented elsewhere in this chapter. Ultrasonography and radiography are two complementary methods that provide different useful information for the diagnosis and the management of TPR.[613] Ultrasonography is also the most useful complementary examination for the diagnosis of pericardial effusion.

Abdominocentesis and pericardiocentesis may be performed blind or with ultrasound guidance. Abdominal fluid

analysis and its limitations in cattle are discussed in the section on peritonitis. Pericardiocentesis may be performed at the level of the point of the elbow in the fifth left intercostal space. Aseptic preparation of the skin and local anesthesia of the region to be punctured are required; pulling the left forelimb forward may be helpful. A 5- to 10-cm spinal needle or intravenous catheter can be used; the length required depends on the size of the 849
animal and the amount of subcutaneous fat. Previous ultrasonographic examination is helpful for the choice of 850
the needle. Caution is advised when advancing the needle to prevent laceration of the myocardium. Ultrasound-guided centesis prevents trauma to the myocardium. Visual inspection of the fluid obtained is usually adequate to confirm the diagnosis of pericarditis; it is cloudy and foul smelling. The fluid may be examined bacteriologically and cytologically.

If ileus occurs or vagal indigestion develops, analysis of the ruminal fluid may reveal elevated chloride ion concentration as a result of reflux from the abomasum and omasum.

32.125.4 Pathophysiology

The indiscriminant eating habits of cattle lead to accidental consumption of foreign bodies. Those that are of high specific gravity initially settle to the bottom of the ventral sac of the rumen. Subsequent contraction cycles of the forestomach move those objects from the rumen into the reticulum. If the object is large enough and sharp enough, it can be pushed, most often through the cranial wall of the reticulum, by the forceful, normal reticular contractions. Normal forestomach bacteria leak through the hole thus created and may establish infection locally along the foreign body. Infection also may spread as in the pericardium or locally during abscess formation. The pain and inflammation associated with the trauma and infection lead to decreased appetite and ruminal hypomotility or stasis. Agalactia is abrupt because of the acute anorexia and subsequent failure to absorb precursors for milk synthesis.

Rehage and colleagues[605] demonstrated that the disturbances of digesta through the forestomachs and the abomasum in cows affected with TRP develop in three phases. The first one, characterized by poorly comminuted feces, occurs secondary to virtual immobilization of the reticulum caused by pain and inflammatory adhesions. With extension of the adhesions, additional impairment of reticulum motility develops. At this time, stratification of the food particles in the reticulorumen is lost, volume of these two forestomachs is increased, and ruminal outflow is inhibited. Finally, the consistency of ruminal contents is changed to a pasty mass with high viscosity. Increase in viscosity of ruminal outflow leads to inhibition of the transpyloric outflow. At this time, abomasumal volume increases and internal vomiting occurs.

32.125.5 Epidemiology

The ingestive techniques of cattle allow sharp nonfood items to be prehended and swallowed. Ingestion of such items by sheep or goats is extremely rare. The disease affects confined cattle where mechanical processing of forages or construction activities increase the chances that wire or nails will be included in the feed. Most cases are sporadic, but outbreaks have occurred when such things as multistranded cable have been chopped up by a forage harvester and ensiled.

32.125.6 Necropsy Findings

Cattle that die peracutely may have a lacerated myocardium with resulting hemorrhage or cardiac tamponade. Diffuse peritonitis characterized by copious, foul-smelling peritoneal fluid with an obvious reticular defect may be seen in acute cases. More chronically affected animals may have extensive pericardial effusion with a thick epicardial layer of fibrin. The penetrating foreign body generally is still present in the wall of the reticulum or pericardium.

32.125.7 Treatment and Prognosis

Conservative treatment generally is attempted first and includes the administration of a forestomach magnet, parenteral antibiotic therapy, and confinement. Often the animal is confined to a stanchion or box stall. Many cattle recover after such a course of therapy with resumption of forestomach motility and appetite within 1 to 3 days. Different drugs have been used to enhance the chance of the magnet to enter the reticulum cavity. The effects of premedication with atropine, scopolamine, or xylazine and of standing the cow with its forelimbs 30 cm lower than the hindlimbs on successful administration of a magnet (i.e., adequately located in the reticulum cavity) have been evaluated in healthy cows.[614] Adequate location of the magnet was evaluated radiographically 1½ hours after the administration of the magnet. None of the procedures increased the chance of the magnet being successfully placed in the reticulum. Moreover, in all groups (treatment groups and control groups) only 57% of the magnets were adequately located in the reticulum.[614] Braun and co-workers demonstrated that foreign bodies that have penetrated the reticulum wall or that have clearly perforated the reticulum had about 54% and 32% chance, respectively, to become attached to the magnet.[615] Animals that have not significantly improved by the third day may require a rumenotomy to remove the foreign object. Ideally, radiography combined with ultrasonography is recommended at this time to verify the diagnosis and objectively assess the response to treatment, but ultrasonography alone is most feasible in most practices.[615]

During rumenotomy, abscesses that are tightly adhered to the reticulum may be drained into the lumen of the reticulum.[616] In some instances reticular abscesses may also be drained through an ultrasound-guided transcutaneous incision,[617] ultrasound-guided insertion of a chest trocar, or insertion of a trocar during ventral laparotomy.[602] Treatment of peritonitis requires systemic antibiotic therapy and possibly drainage of the affected area; surgical correction of the inciting cause is discussed in the section on peritonitis.

32.125.8 Prognosis

The prognosis of TRP depends mainly on the location of the foreign body and the other organs affected. The prognosis is fair to good when TRP is associated with localized peritonitis and when only the spleen or the liver is also affected. In most cases as inflammation diminishes, the reticular function can return to normal.[618] The prognosis is poor to guarded in TRP associated with pericarditis, pleuritis, or diffuse inflammatory adhesions in the abdomen.[602,618]

32.125.9 Prevention and Control

Eliminating sources of sharp foreign objects in the feed supply prevents TRP. Installation of large magnets on feed handling equipment and prophylactic administration of forestomach magnets to all animals at 6 to 8 months of age prevent almost all cases caused by magnetizable objects.

32.126 PERITONITIS IN THE RUMINANT

Gilles Fecteau

Despite the frequency with which peritonitis is included in a list of differential diagnoses, it remains a very frustrating disease for all food animal clinicians. A diagnosis is often based on clinical signs and history and rarely confirmed by ancillary tests. If the patient improves with treatment, the clinician may never identify the cause of the peritonitis.

32.126.1 REVIEW OF PERITONEAL CAVITY

32.126.1.1 Histology

The peritoneal cavity is lined by a serous membrane composed of two layers called the *peritoneum*. The deeper layer (subserosa) is composed of loose connective tissue containing collagen, fat cells, reticular cells, and macrophages.[619] Covering that layer is a single-surface layer of mesothelial squamous cells (serosa). On the surface of the diaphragm, special lymphatic collecting vessels are located under the mesothelial basement membrane. Small stomata are found between mesothelial cells. They act as channels for lymphatic drainage from the peritoneal cavity to the thoracic duct.[620–622]

850
851

32.126.2 Normal Peritoneal Fluid

The peritoneum is a highly permeable membrane. Most of it acts as a bidirectional semipermeable barrier to the diffusion of water and low—molecular-weight solutes between the blood and the peritoneal fluid.[620–624] Peritoneal dialysis uses this principle to treat renal failure. Normal peritoneal fluid provides lubrication for the movement of abdominal organs and apposed peritoneal surfaces.[625] It is formed and resorbed constantly. Normal fluid movement is achieved by normal movement of the viscera and contraction of the diaphragm during respiration. A normal animal has no more than 1 mL of peritoneal fluid per kilogram of body weight.[624] In acute severe peritonitis, the inflammatory process may induce a net flow of liters of proteinaceous fluid (80 mL/kg/day in humans), leading to hypoproteinemia and/or hypovolemic shock.[620]

Normal peritoneal fluid has a wide range of values.[622,626–629] It should be clear, with a specific density less than 1.016 (Table 32-17). Protein content should be less than 3 g/dL, although some authors have reported normal values up to 6.3 g/dL for cattle.[629] Normal bovine peritoneal fluid may contain some fibrinogen and may clot when exposed to air.[630] Normal fluid contains fewer than 10,000 cells with a majority of macrophages. Lymphocytes, eosinophils, and desquamated mesothelial cells may also be present, but there are normally very few neutrophils. Normal periparturient cattle have significantly more abdominal fluid with a lower protein concentration.[630] With peritonitis there may be a complete absence of collectable peritoneal fluid because of dehydration or fibrous adhesions.

Table 32-17 Normal Range for Classification of Bovine Peritoneal Fluid According to Different Authors

Parameters	Normal Values	References
Turbidity	Clear	
Total protein (g/dL)	0.1–3.1	626,629
	2.2–4	626
	1.2–6.3	633
Specific gravity	1.005–1.015	629
Total cell count (per µL)	425–2950	633
	2000–5000	629
	<10,000	626
Differential	Ratio 1:1, neutrophils to mononuclear cells	626
Neutrophils	45–2183	633
Lymphocytes	8–168	633
Mononuclear cells	36–960	633
Eosinophils	5–545	633
Comments	Eosinophils may predominate	626
	Serosa cells may predominate	629

32.127 PATHOPHYSIOLOGIC MECHANISM OF DISEASES IN THE PERITONEAL CAVITY IN RESPONSE TO INJURY

32.127.1 Healing

Peritoneal regeneration is completed within 5 to 7 days, regardless of the defect size. Healing can occur by reperitonealization or creation of an adhesion with an adjacent nearby mesothelial surface. This adherent type of healing occurs more frequently if the inflammation is severe, with presence of bacteria and/or foreign material.[620,621,624]

32.127.2 Host Defenses Against Peritoneal Infection

The first mechanism of defense is physical removal of the bacteria. In normal dogs, for example, it is possible to retrieve bacteria in the bloodstream 12 minutes after an experimental injection into the peritoneum.[624] The second mechanism of defense relates to the response to noxious stimuli. This intense acute inflammatory response includes degranulation of peritoneal mast cells with release of vasoactive substances. This creates a net influx of fluid rich in complement and serum opsonins that can bind to the bacteria.[620,621,624] Third, the

omentum contributes to the defense mechanism by adhering to an infected and/or damaged area to wall off the problem site. Finally the rapid movement of neutrophils, and later, macrophages, is also an important mechanism of control of infection.[624]

32.127.3 Adhesions

Adhesions are defined as fibrinous or fibrous bands that create an abnormal attachment of two or more surfaces that should be moving freely against each other. Formation of adhesions is part of the healing process and should be interpreted as an effort to control an injury. The omentum is often involved in adhesions and acts as a natural sealing device to control the acute phase of inflammation. Whole blood potentiates adhesion formation by providing more fibrinogen.[620] The various suture materials are approximately equal in their capacity to induce adhesions, with chromic gut perhaps inducing the most reaction.[620] Adhesion may or may not be reversible, depending on the amount of organization that takes place in the process. Adhesions that are cut or broken usually rapidly reform. As the fibrin deposition process is replaced by capillaries and fibroblasts, the adhesion becomes solid fibrous tissue. The three major elements responsible for dissolution of the fibrinous adhesions are (1) adequate oxygen and nutrient supply for the mesothelium, (2) liberation of plasminogen-activating substance by mesothelial and submesothelial cells, and (3) control of the inflammatory process.[620,621] Mechanical obstruction to the normal flow of ingesta and subsequent development of bowel obstruction are major undesirable side effects of formation of adhesions.

32.128 PERITONITIS

32.128.1 Definition and Etiology

Peritonitis is an inflammatory process involving the peritoneal cavity and its serosal surface, the peritoneum. Peritonitis is not a true synonym of intraabdominal infection because the latter is defined as an inflammatory response of the peritoneum to microorganisms and their toxins that results in purulent exudates in the abdominal cavity. Peritonitis should be considered as the localized equivalent of SIRS, whereas intraabdominal infection is the localized equivalent of sepsis. Intraabdominal abscess is an intraabdominal infection confined within the abdominal cavity. Because most often in farm animals peritonitis is caused by bacteria, the two terms are often used as synonyms. The inflammation may result from trauma, surgery, or vascular damage associated with an intestinal obstruction and/or accident or from gastrointestinal ulceration (Box 32-8). Peritonitis is a serious and complex process that is often accompanied by various degrees of abdominal pain, progressive signs of hypovolemia and septicemia, and/or endotoxemia.

851 852

32.128.2 Classification

Peritonitis may be classified according to the clinical presentation and/or the cause. Clinically relevant classifications include acute versus chronic, septic versus chemical, localized versus generalized, and primary versus secondary. Although it is useful to classify types of peritonitis, it is imperative to recognize that it is a dynamic process. An apparently localized nonseptic peritonitis can evolve toward a more diffuse septic process if the primary cause is not resolved.

32.128.3 Pathophysiology

After peritoneal injury or contamination, mesothelial cells initiate an inflammatory response, modifying the permeability of the peritoneum and its vascular supply. Several blood constituents are then able to move into the peritoneal cavity. Macrophages and polymorphonuclear cells, humoral opsonins, natural antibodies, serum complement, and a protein-rich fluid are the most important. The inflamed peritoneum also becomes more permeable to toxins, allowing them to be absorbed into the bloodstream. Although this initial response is beneficial to the organism, it induces several systemic abnormalities that the clinician must recognize and treat adequately.

32.128.3.1.5 MISCELLANEOUS

Hematogenous with systemic infection: tuberculosis, septicemia

Fat necrosis

Hypovolemia, hypoproteinemia, bacteremia or septicemia, and toxemia are commonly observed in acute diffuse septic peritonitis. The major adverse effects of peritoneal contamination are (1) rapid clearance of bacteria, producing endotoxemia and/or bacteremia, (2) rapid influx of fluid rich in protein, leading to hypovolemia and hypoproteinemia, (3) deposition of fibrin, occluding lymphatic drainage, contributing to abdominal distention, and enhancing the chance of abscess formation, (4) ileus, and (5) adhesion formation, which may lead to obstruction (Fig. 32-99).

32.128.4 Clinical Signs and Diagnosis

Clinical signs are often nonspecific but suggestive of gastrointestinal dysfunction. Severity of clinical signs ranges from mild recurrent discomfort caused by a localized abscess to an acute severe onset of toxemia and hypovolemia leading rapidly to death after the sudden rupture of a viscus. Cattle suffering from acute peritonitis tend to show more characteristic signs. As the condition becomes less acute, the ability of the bovine to seal the infection will attenuate the clinical signs. Chronic but active peritonitis remains to this day a very difficult

diagnosis to make without ancillary tests. Abdominal rigidity and tenderness, abdominal distention, scleral injection, fever, anorexia, and sudden reduction in milk production are classic but not pathognomonic findings of acute peritonitis. In the acute stage, abdominal pain and the release of catecholamines often lead to a complete gastrointestinal stasis and ileus. The rumen is then completely atonic. Feces are abnormal in quantity and quality. In the acute stage, feces are present in small amounts and often dry. In more chronic cases feces are present with a tendency to be diarrheic. Pain, decreased plasma volume, and endotoxemia often result in persistent tachycardia. Anterior abdominal pain, evaluated by the withers pinch test, may be difficult to interpret. This procedure is based on the normal reflex of the bovine to drop its back when the withers and back are pinched (ventroflexion). Cattle with anterior abdominal pain may be reluctant to ventroflex on withers pinch. You can increase the sensitivity of this test by simultaneous auscultation of the trachea during the manipulation. Production of an expiratory grunt is considered as a sign of pain during ventroflexion. Cranial ventral pressure with the fist, knee, or some other external force (transverse pole under the abdomen) just behind the xiphoid can help identify the presence of pain (expiratory grunt) and even localize it in some cases. It is my impression that one of the most reliable clinical sign of abdominal discomfort in cattle is reluctance to move. Scleral injection, fever, tachycardia, gastrointestinal stasis, and distention are the clinical signs that should be monitored to evaluate peritonitis.

32.128.5

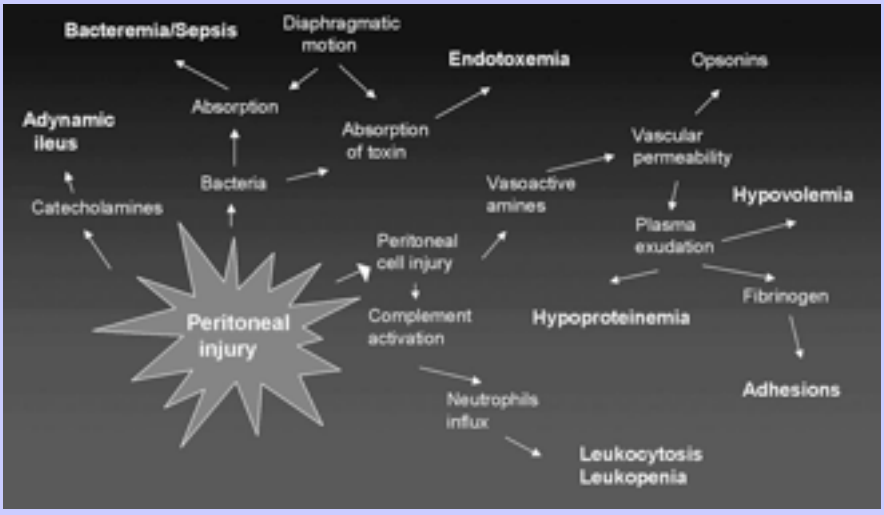
Ancillary Tests

Hematologic findings associated with peritonitis range from a completely normal hemogram to severe leukopenia with degenerative left shift and presence of toxic neutrophils, depending on the severity of the peritoneal contamination. In severe cases variations observed reflect the degree of sepsis and toxemia. PCV tends to increase as proteins decrease. In less severe cases, a neutrophilic leukocytosis and hyperfibrinogenemia are often present. Hematologic analysis has been a useful tool to monitor response to therapy after a diagnosis has been made by other ancillary tests. Immature cells in the peripheral blood and/or leukocytosis were better indicators of recurrence than body temperature in one human study.[631] Plasma fibrinogen concentration is also used to monitor the progress of a particular case.

852

853

Fig. 32-99 Pathophysiology of peritonitis.



The blood chemistry profile is rarely altered by peritonitis in a way that is diagnostically useful. Chronic

inflammation causes a marked increase in serum proteins, particularly the globulin portion. In acute severe cases, secondary findings may include increased serum urea nitrogen and creatinine, mildly increased liver enzymes, reduction in total CO_2, and strong ion difference and reduction in serum albumin. Ileus and upper gastrointestinal stasis may result in marked hypochloremia and alkalosis.

Cytologic examination of the peritoneal fluid is a useful aid in making a definitive diagnosis of peritonitis (see Table 32-17).[632] Abdominocentesis techniques have been described elsewhere.[630] The right side just cranial to the udder is the preferred site (to avoid stomach and omentum) (Fig. 32-100). A needle, a blunt teat canula, or a bitch catheter and scalpel blade may be used with success (Fig. 32-101). The heavy fascia of bulls makes a needle preferable. It is imperative to remember that failure to secure fluid is common and should be interpreted with caution (because fibrinous peritonitis with fluid loculation is common). More than one site should be attempted if no fluid is secured on the first attempt. Interpretation and classification of peritoneal fluid analyses have been reviewed by several authors.[622,626,627,630] After exploratory celiotomy and omentopexy on normal cattle, peritoneal fluid has increased specific gravity, total protein, and WBCs for at least 6 days, even without any peritonitis.[633] One should remember that because of the bovine's ability to deposit fibrin and seal areas of the peritoneal cavity, the interpretation of peritoneal fluid analysis applies only to the immediate area that was sampled. The clinician can be misled to conclude that a nonseptic process is occurring on the basis of a caudal tap, when in fact a septic process has already been sealed by the fibrin deposition in the cranial abdomen.

Abdominal radiographs using a high-power unit are extremely useful in cases in which TRP is suspected.[634] They have limited value in other causes of peritonitis. A review of radiography of the bovine cranioventral abdomen is available.[635]

Ultrasound examination is useful for assessing the size and anatomic relationships of lesions, particularly when considering drainage, aspiration, or surgical exploration of a mass surrounding vital structures. The reader should see the section on ultrasound in this chapter. Knowledge of the underlying anatomy is important to prevent misinterpretation. Clarity of the image is affected by the size of the probe and the depth of tissue being evaluated. Higher-frequency probes produce finer images but have limited tissue penetration. Images reflect the echogenicity of the tissues viewed; relative echogenicity helps to differentiate structures. Abscesses can have mixed echogenicity, varying from anechoic (absence of internal echoes) to echogenic, depending on the relative amount of fluid, fibrin, and gas. The fibrous capsule of abscesses may be identified as echogenic bands around the area in question. Ultrasound is particularly useful for evaluating the integrity of the body wall for presence of hernias resulting from traumatic injuries, secondary to abscessation or incision dehiscence. Normal and abnormal appearances of umbilical structures have been described.[636,637] Recognition of free abdominal fluid is easily accomplished by ultrasound examination, and it is also useful to guide a peritoneal tap. Areas that should be scanned include the caudal lower flank area (right and left), right perirenal area, liver, abomasum and pylorus, and right paramedian area. Normal liver and liver abscess formation have been described.[638,639] References are available to describe normal appearance of the reticulum and the small intestine in cows.[640,641] During exploratory surgery, ultrasound can be used to image an internal mass or a viscera appearing abnormal. Intraoperative ultrasound is performed by placing the probe in a sterile sleeve filled with ultrasound gel.

853 854

Fig. 32-101 Material used to perform abdominocentesis of the bovine.

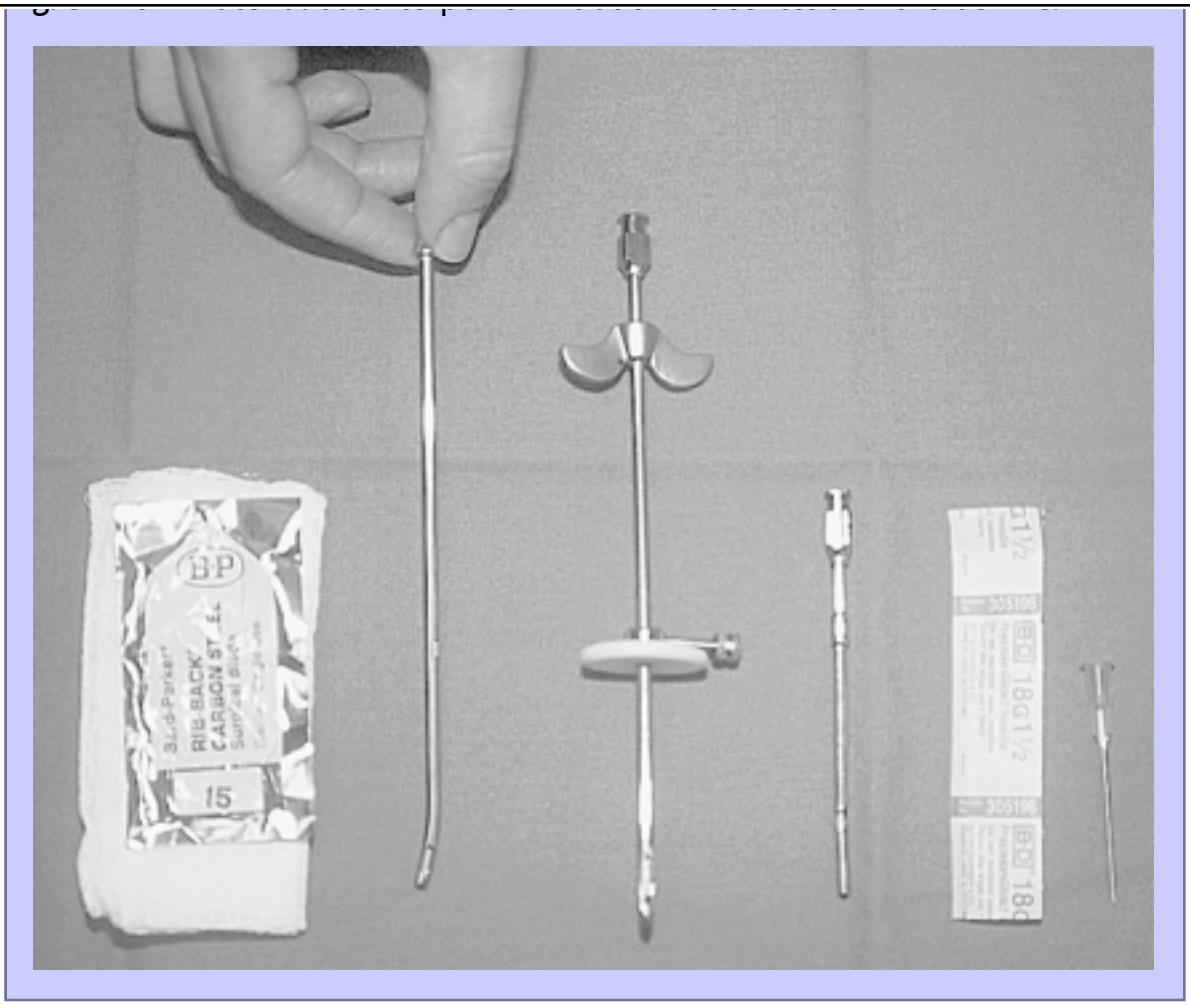


Fig. 32-100 Site of caudal abdominocentesis.

Surgical exploration is often used to confirm or rule out an intraabdominal problem.[642] Information obtained from physical examination and laboratory data is often indicative of a diagnosis but does not provide a specific cause. Cattle are particularly amenable to exploratory surgery, as the procedure is performed when they are standing and is not often associated with complications. Recent advances in minimally invasive surgical technique in cattle are promising. Laparoscopy can be used to diagnose acute and chronic peritonitis, which is otherwise difficult to identify with ultrasound or abdominocentesis. It is easier to evaluate the extent of the lesions with the organs in situ.[643]

32.128.6 Treatment

The basic elements of therapy are support, antibiotics, and surgery.

32.128.6.1 Supportive Therapy

Depending on the severity of the process, the patient may be presented in shock. Large volumes of isotonic intravenous fluids are then indicated. Correction of any acid-base deficit is indicated. Electrolyte abnormalities (hypokalemia and hypocalcemia) should be identified and corrected. If the animal is hypoproteinemic, plasma or whole blood transfusions may be beneficial. Nonsteroidal and/or steroidal antiinflammatory drugs may be of importance to prevent the synthesis of more inflammatory mediators. Pain control is also important. Transfaunation may be beneficial in cases of prolonged anorexia. In one study, ruminal transfaunation was shown to reduce ketonuria and increase feed intake and milk yield after surgical correction of left-displaced abomasum (LDA).[644]

32.128.6.1.1 Antibiotic Therapy

Systemic antibiotic therapy should be instituted as soon as a decision to treat is made. Until results of culture and antimicrobial susceptibility become available, a broad-spectrum antibiotic should be used. The choice should take into consideration the following: cost of treatment, withdrawal period in food animals, spectrum of activity, and treatment regimen (frequency and route). Tetracycline or a β-lactam antibiotic (third-generation cephalosporin or a synthetic penicillin) appears to be a good choice. Diffusion into the peritoneal cavity is not a major limiting factor, because the permeability of the peritoneum is always increased in peritonitis. However, when fibrin becomes organized and forms multiple small pockets of infected peritoneal fluid, then diffusion becomes more problematic. In human medicine, single antimicrobial therapy with a broad-spectrum agent is effective in patients suffering from secondary peritonitis.[645,646]

32.128.6.1.2 Surgical Therapy

Surgical control of peritonitis includes peritoneal debridement and irrigation and drainage. Using ultrasound guidance, it is possible to safely establish drainage from the abdominal cavity. A thoracic chest trocar can be used temporarily until all fluid has been removed.

The concept of abdominal lavage during surgery was adopted by human surgeons around the turn of the century and has been accepted as a part of the treatment of peritonitis since then with fluctuating support.[647] Although the principle of removal of any gross contamination is not in question, the level of aggression with which we should institute abdominal lavage during surgery is still open to debate in human and veterinary literature. There is evidence of negative effect of lavage on the mesothelial cells, the peritoneal defense mechanism, and the risk of spreading the infection.[647,648] The solution used to irrigate is also under debate. There is no significant advantage to adding antibiotics to the lavage solution[647,648] and controversy regarding the possible advantages of adding an antiseptic.[647] In our experience, drainage of the abdomen with Foley catheters or negative pressure drains has been consistently unsuccessful in the bovine. Large amounts of fibrin may be deposited in a short period of time; in combination with the omentum, this makes those drains plug and become rapidly ineffective.

854

855

32.128.6.1.3 Prognosis

The ultimate outcome of a bacterial peritonitis episode is determined by many factors, some of which are controlled by the clinician. The early decision on treatment (medical and surgical), correct choice of antimicrobials, and adequate supportive therapy contribute to the success or failure of a therapy. The owner's delay in seeking therapy, the primary cause of peritonitis, and the patient's age are examples of important factors beyond the clinician's control. When aggressive therapy is economically possible, survival rates will be good, but long-term sequelae may compromise a complete recovery.

32.129 MISCELLANEOUS CONDITIONS

32.129.1 Ascites

Ascites is a collection of serous fluid in the peritoneal cavity. It must be considered as a secondary sign rather than a primary diagnosis.[649] In that regard the primary cause must be identified in order to treat the patient adequately. Common causes of ascites in ruminants include severe liver disease and congestive right-sided heart failure. Young cattle with mesothelioma have remarkable ascites. Ascites remains an uncommon condition that needs to be differentiated from septic causes of peritonitis and from urine accumulation with ruptured bladder.

32.129.2 Pneumoperitoneum

Pneumoperitoneum is commonly observed postsurgically in the bovine. Presence of air in the abdomen can be recognized by simultaneous percussion and auscultation. A low-pitch resonance can be auscultated in the upper flank on both sides of the abdomen. Presence of pneumoperitoneum normally resolves in the week after surgery. No clinical signs seem associated with the presence of pneumoperitoneum, although some clinicians describe abdominal pain associated with no other cause than the presence of air in the peritoneal cavity. Pneumoperitoneum not associated with surgery is indicative of bacterial peritonitis and the presence of gas-producing bacteria (Box 32-9).

32.129.3 Retroperitoneal Abscess

Retroperitoneal abscess is a particular condition occurring in cattle after a flank laparotomy. Animals are often presented several days after surgery. They are mildly febrile, not performing adequately, and showing clinical signs compatible with peritonitis. The skin wound is often unremarkable, but some pain may be elicited while the flank area is palpated. A substantial mass may be palpated per rectum, localized in the upper quadrant of the side of the previous surgical approach. The mass will be firm, smooth, unmovable, and close to the previous flank incision. Transabdominal or rectal ultrasound examination reveals a large amount of fluid located between the peritoneum and the rectus abdominis or the internal oblique of the abdomen. More superficial abscesses can also occur. A needle aspiration allows visual inspection of a thick, opaque, foul-smelling fluid. Treatment is aimed at establishing drainage and systemic antimicrobial therapy. A large volume of purulent and fibrinous material (up to 40 L) can be removed from the abscess. Rapid decompression may provoke hypovolemic shock, and intravenous fluids should be administered before a large abscess is drained. Prognosis is good, but the recovery phase is extremely long because of the large cavity left after drainage. Early closure of the drain is often observed, necessitating reopening.

32.130 FROTHY BLOAT

Charles L. Guard

Gilles Fecteau

32.130.1 Definition and Etiology

Frothy bloat is caused by diets that lead to the formation of stable froth in the rumen. Ruminal tympany is synonymous with bloat. The condition may be fatal if the distention is extreme enough to compromise ventilation by compressing the thoracic viscera. Cattle are more susceptible than sheep, but the disease does occur in the same circumstances in small ruminants.

32.130.2 Clinical Signs and Differential Diagnosis

The degree of forestomach enlargement varies from that producing an even filling of the left paralumbar fossa to that causing a uniform, extreme abdominal enlargement when the animal is viewed from the rear. With intermediate degrees of distention, the left paralumbar fossa bulges beyond the contours of the last rib and the tuber coxae. Clinical signs of colic may be seen, including kicking at the abdomen, treading, frequent lying down and rising, and vocalizations. Some animals adopt a stretched stance with the rear feet placed far back. Sheep with heavy fleece may be significantly bloated without the changes in abdominal contour being obvious. As the forestomach enlarges and compresses the diaphragm, breathing becomes more labored. Open-mouth breathing, cyanosis of mucous membranes, and collapse leading to death may occur within a few minutes if the animal becomes frantic from the abdominal pain and dyspnea. Other conditions to consider in the diagnosis of frothy bloat in ruminants include other causes of ruminal enlargement: free gas bloat and vagal indigestion. Advanced

pregnancy, hydropic conditions of the uterus, left or right abomasal displacements, cecal dilation or volvulus, intestinal volvulus, omasal bursitis, ascites, diffuse peritonitis, and pneumoperitoneum are conditions creating abdominal enlargement that may be included in the differential diagnosis.

Many systemic conditions influence the motility of the forestomach and thus may produce mild bloat coincidentally.

32.130.3 Clinical Pathology

Clinical pathologic measurements are not required for the diagnosis and management of most cases of frothy bloat in ruminants. When no cause for forestomach enlargement is obvious, evaluation of a sample of ruminal contents may provide information useful for prescribing treatment and prevention. The presence or absence of froth and the pH are critical features relating to the cause that influence the choice of therapy. The normal pH of the rumen varies with time after feeding but should be between 5.4 and 6.8.

32.130.4 Pathophysiology

Regardless of the cause of forestomach distention, the process may become self-perpetuating because of reflex inhibition of motility. Low-threshold stretch receptors in the ruminal wall augment cyclic forestomach contractions when stimulated. However, stimulation of high-threshold stretch receptors leads to inhibition of motility. Thus, beyond a certain degree of stretching of the ruminal wall, further contractions that may relieve the distention through eructation are prevented.[650]

Frothy bloat is caused by the retention of gases of fermentation within the mass of ingesta that fail to rise and coalesce into a dorsal gaseous layer. This condition can arise from diets of lush legumes or winter wheat pasture or may be seen with high-concentrate finishing rations in the feedlot. In the case of legume-induced disease, bloat has occurred after grazing or feeding of fresh-cut forages or the feeding of alfalfa hay. The structure of stable froth in the affected ruminal contents is not a true foam. The ingesta in the septa between adjacent bubbles form a complex structure that prevents coalescence. The viscosity of the fluid may prevent gravitational flow through the septa that would lead to the bubbles' rising and coalescing. Frothy ruminal fluid is higher in chloroplast membrane fragments, soluble protein, and very fine particles than nonfrothy ruminal fluid.[651] The presence of the resulting frothy ingesta at neural receptors believed to be near the cardia prevents the reflex relaxation of the cardia during the secondary contractions of the forestomach that ordinarily lead to eructation.[652] In addition, the viscosity of the frothy ingesta is such that the cardia may become plugged during attempts to eructate.

Current research[651] supports both animal and plant characteristics as predisposing to legume bloat. Individual cattle have been classified as having either high or low susceptibility to legume bloat. Thus far, highly susceptible cattle have been shown to have larger ruminal volumes and specific salivary proteins in consistently different proportions than bloat-resistant cattle. The actual mechanisms that lead to larger forestomach volume in susceptible cattle have not been determined. There is a relationship between plant factors associated with bloat and the rapidity with which leaf structure is disrupted after ingestion.[651] Bloat-inducing plants are more readily macerated, thus providing quicker bacterial access to the inner leaf cells. Less bloat-predisposing cultivars of the main bloat-causing species, such as alfalfa *(Medicago sativa)*, red clover *(Trifolium pratense)*, and white clover *(Trifolium repens)*, have a thicker leaf cuticle, smaller stomata, and a more fibrous leaf structure. Ionophore antibiotics such as monensin inhibit ruminal protozoa that normally ingest chloroplasts, leading to a reduction in the bloat potential of some forages.[653,654]

Grain bloat occurs in a manner similar to that caused by legumes; a stable froth is produced from high-concentrate rations. Particle size and the rate of fermentation are thought to be the determining factors in the froth production. A mucoprotein slime composed of bacterial byproducts stabilizes the froth.[653,655] This material tends to be stable at a lower pH than is found in non—grain-fed ruminants, so grain feeding promotes slime accumulation by lowering ruminal pH. Genetically susceptible cattle lack adequate mucin in their saliva to disrupt the tiny gas bubbles. Animals (such as dairy cattle) that are fed grain and then legumes may be particularly susceptible to frothy bloat because all the factors leading to froth production and accumulation are present. Both legume bloat and grain bloat may resolve spontaneously if the animal stops consuming the bloat-producing feed and microbial digestion eliminates the froth-stabilizing factors.

Acute distress, often appearing as colic, is caused by overdistention of the forestomach that stimulates pain receptors in the ruminal wall. As the abdominal distention increases, the ability to achieve normal respiratory movements of the diaphragm and rib cage is impaired. Death from asphyxia ultimately results as the lungs are compressed by the cranially expanding diaphragm.

32.130.5 Epidemiology

Frothy bloat often occurs as an epidemic. Pasture bloat occurs wherever alfalfa, red clover, or white clover is grazed. Environmental conditions that produce rapid, early growth lead to a higher incidence of bloat. Frothy bloat also occurs when stocker cattle are grazed on winter wheat pastures in the southern Great Plains of the United States. Death losses at pasture range from 0.5% to 2.5% of cattle at risk on an annual basis. The incidence of feedlot bloat has been estimated at about 1%, with death losses of about 0.1%.[651]

32.130.6 Necropsy Findings

The finding of tenacious froth in the rumen along with other evidence of bloat is grounds for a presumptive diagnosis of frothy bloat. The challenge for the diagnostician is to determine if the bloat occurred before death; this may not be possible if the animal was not observed before death. The increase in intraabdominal pressure prevents venous return from the hindquarters and may lead to obvious edema in the intermuscular areas. Unfortunately this is not a consistent finding; other evidence of impaired circulation or a differential degree of edema between fore and hind parts must be used to make a diagnosis.

32.130.7 Treatment and Prognosis

Passage of a stomach tube is indicated to determine the cause of the ruminal distention and possibly initiate treatment. A sample of the ruminal contents for pH measurement should be obtained at this time. Care must be taken to exclude saliva from the tube by blowing into the rumen, flushing water through the tube, or using a ruminal sampling device that carries the tip of the stomach tube down into the liquid ingesta. If no gas can be released with a stomach tube, the tube should be withdrawn after suction has been applied and examined for the presence of froth. If the animal is not in respiratory distress or extremely colicky, surface-active agents should be administered by means of a stomach tube. Poloxalene is recommended for forage bloat,[654] and mineral oil or animal tallow for feedlot bloat.[657]

856

857

Some cattle are in violent pain with bloat but not in respiratory distress. Sedation with xylazine may be necessary

for further examination and treatment. Animals with extreme distention of the forestomach and in respiratory distress require immediate surgical intervention. A trocar introduced through the left paralumbar fossa after local anesthesia relieves bloat caused by free gas accumulation but may not be adequate for frothy bloat. An emergency rumenotomy may be necessary to evacuate frothy contents.

32.130.8 Prevention and Control

Prevention of frothy pasture bloat has historically relied on attempts to anticipate when forages were most likely to induce bloat. Cattle were fed other feeds and allowed limited access to the problem forages. Accurately predicting when forages are safe has not been reliable. As an alternative the cattle at risk have been treated with supplemental surface-active agents such as poloxalene.

In Australia and New Zealand, oils and tallows have been drenched daily, sprayed on fields, and smeared on the flanks to be later licked off, to prevent pasture bloat. Although poloxalene has proved effective, it is more expensive than oils. It can be fed in molasses blocks or individually administered. More recently ionophore antibiotics have shown promise for controlling bloat. Rumensin (1 mg/kg daily) greatly reduced the incidence of legume bloat, and lasalocid (1.32 mg/kg/daily) effectively reduced the incidence of grain bloat.[653,654] In both circumstances, beginning treatment before exposure to the bloat-inducing feed was more effective than waiting until bloat occurred. Agronomists are selecting cultivars of the bloat-producing forages for slower rates of initial fermentation. These are likely to become more widely used in the regions in which bloat is a regular occurrence.

Providing adequate fiber in feedlot rations and slowly introducing higher proportions of concentrates, particularly corn, barley, and soybean meal, permit ruminal adaptation that helps prevent bloat.

32.131 ABOMASAL DISPLACEMENT AND VOLVULUS

GILLES FECTEAU

CHARLES L. GUARD

32.131.1 Etiology

Although the precise cause of displacement of the abomasum remains unknown, general agreement exists in veterinary literature that it is a multifactorial syndrome and that abomasal hypomotility is an absolute prerequisite. Abomasal motility can be decreased in many ways. Overdistention of the rumen, reticulum, or omasum can inhibit motility of the abomasum,[658] as can ulcers and ostertagiasis.[659]

Many of these conditions occur commonly in the immediate postpartum period or are related to common disorders of postpartum dairy cattle (Table 32-18).

32.131.2 Prevalence and Incidence

Abomasal displacement occurs either to the right or to the left side of the abdomen when gas accumulates within this viscus. Left-displaced abomasum (LDA) is the more common, accounting for 85% to 95.8% of cases.[680] By far the highest incidence is in adult dairy cattle in the early postpartum period, but cases have been seen in all other classes of cattle. LDA is probably a worldwide problem, and one survey of the prevalence of disease in dairy herds indicates that 24% of herds reported at least one case of LDA during a 3-year period.[662] In one

Canadian study the lactational incidence risk of LDA was estimated to be 2%.[681] The prevalence among dairy herds is variable depending on geographic location, management practices (confinement vs. pasture), feeding practices, climate, and probably several other factors.

Table 32-18 Factors Associated with Influencing Abomasal Motility and Contributing or Possibly Contributing to Abomasal Displacements

Factor	Reference
Low pH	660,661
Particle size and fiber content	662,663
Amino acid, peptide, and fat content of duodenal fluid	658
High volatile fatty acid content	665
High ruminal histamine synthesis	666
Endotoxemia	667
Hyperinsulinemia	668
Hypokalemia	669
Epinephrine release	670,671
Histamine release	672
Metabolic alkalosis	673
Hypocalcemia	674
Prostaglandins	672,675,676
Lack of exercise	665,677
High blood gastrin concentrations	667,678
Acetonemia	679

32.131.3 Pathophysiology

After abomasal atony, distention with gas produced by microbial fermentation occurs and most likely precipitates the displacement. Diets with more grain result in an increase in the amount of gas produced in the abomasum. It has been hypothesized that the displacement will be oriented (left or right) according to the size of the rumen. A large and filled rumen will make the left displacement less likely, and the abomasum will dilate and in some cases twist to the right (Figs. 32-102, 32-103, and 32-104). If the rumen is small and empty (as in the postpartum period), the abomasum can move to the left and LDA can occur.[664]

Desrochers, from *Surgery of the abomasum in cattle*, Version 2.0, Université de Montréal.

32.131.4 Surgical Therapy

Numerous surgical techniques are used and have been described elsewhere.[680] The comparison of their advantages and disadvantages has also been studied.[682] The permanent attachment is usually created by suturing either the abomasum or the greater omentum to the abdominal wall. The techniques may be classified into three different broad categories: blind technique, surgical (open) technique, and laparoscopic technique. Multiple factors influence the decision; cost and preference of the surgeon are very important. Recently, laparoscopic technique has been described and studied.[683–686]

All techniques have been successful when performed adequately. Understanding the limitations of each of them will allow the food animal clinician to best serve the patient and client in all situations.

32.132 LEFT DISPLACEMENT OF THE ABOMASUM

32.132.1 Clinical Signs and Differential Diagnosis

Cattle with simple LDA have a reduced appetite (complete anorexia, reduced consumption of concentrates, or alternating periods of normal appetite and anorexia). Milk production is reduced. Ketosis may develop as a secondary problem. Feces are often normal to softer than normal but reduced in volume. Rectal temperature is normal, unless a concurrent infectious problem is present (metritis, mastitis). Pulse and respiration are normal or slightly above normal, unless a concurrent or secondary problem is present. Ruminal contractions are decreased to absent and difficult to hear because the abomasum interferes with transmission of the sound. The last one or two ribs on the left are sprung, but the abdomen is sunken in the paralumbar fossa. Gurgling or tinkling rather than normal scratching sounds may be heard on auscultation in the left paralumbar fossa. Simultaneous auscultation and percussion reveal a ping over the gas-filled portion of the abomasum (see Fig. 1-5). With LDA the area of ping may be anywhere from the lower third of the abdomen in the eighth intercostal space to the paralumbar fossa. Attention should also be given to the cranial and lower aspect of the flank because in some cases the ping will be audible only in this area.

On rare occasions, during rectal examination the clinician may be able to palpate the abomasum to the left of the caudodorsal blind sac of the rumen or at least perceive that the rumen is displaced medially.

Ruminal tympany, pneumoperitoneum, and collapsed rumen[687] may all produce pings on the left side of the cow. Physometra (air in the uterus) and dilation and displacement of the cecum to the left of the rumen (which is rare) may also produce left-sided pings. Having an assistant blow on the stomach tube passed into the rumen while auscultating over the left side differentiates the rumen from other structures. Percutaneous needle aspiration of fluid or gas from the suspected abomasum aids in correct identification. A pH of less than 4.5 as determined with wide-range pH paper or the odor of abomasal gas (slightly acrid or burnt almonds) confirms the presence of LDA.

32.132.2 Clinical Pathology

The most important abnormalities detected by clinical chemical evaluation usually are the serum electrolyte and acid-base levels.[688] Sequestration of the hydrochloric acid secreted into the abomasum within the abomasum or by means of reflux in the ruminoreticulum may occur and lead to metabolic alkalosis. The blood pH and bicarbonate concentration are slightly elevated, with a concomitant small decrease in the blood chloride concentration. Cattle examined on the farm usually are hypoglycemic and ketonuric. However, any important stress (e.g., transportation) may create a transient hyperglycemia. The serum calcium level may be below normal as a result of decreased intake and absorption. Hypokalemia may develop as a consequence of both the metabolic alkalosis and reduced intake and absorption.

The CBC may reveal a mild dehydration and a stress leukogram. If LDA is combined with bleeding abomasal ulcers it may produce severe anemia. The presence of a concurrent disease may lead to specific changes (e.g., left shift with acute coliform mastitis).

32.132.3 Epidemiology

Cows in early lactation are at greatest risk of developing LDA. In one prospective study of 3172 lactations in New York, 81% of 48 LDAs occurred in the first 30 days after calving.[689] The overall incidence was 1.5% of lactations. An older study reported a lower incidence rate (0.35% from 1970 to 1972), but even within that period the rate increased each year.[690] A higher incidence has been reported in late winter and early spring after the winter housing season.[691] Cows in this study had LDA in association with parturition as expected, but a preponderance of cases occurred in cows calving in February to April. Increasing parity was associated with an increased incidence of LDA in studies from Ontario, Canada, New York, and Israel.[690–692] Milk production potential is not thought to be related to the risk of LDA.[693] Most cows produce 300 to 500 kg less milk in lactations with LDA than would be expected if the disease did not occur.[694] For unknown reasons, about 80% of recovered cases produce about 400 kg less milk, and 20% produce 2000 kg less milk. Length of time a cow remains in the herd after correction of LDA is not affected. The financial consequences of LDA for an individual cow with the smaller reduction in milk production favor maintaining the cow in the herd.

858

859

Energy and protein nutrition of the prepartum dry cow were suggested to be causally related to LDA in one study.[695] On a herd basis, in cows fed levels of energy and protein above National Research Council recommendations, LDA was less likely to develop. Genetic factors may also play a role in the predisposition to LDA. In a retrospective case-control study, cows with LDA were 1½ times more likely to be sired by bulls in one group than controls.[691] Fox[696] suggested that body depth had increased in dairy cattle since 1945 and that this may provide more room for the relatively empty abdominal viscera to move about at parturition. An experimental herd composed of two groups of Holstein cows, continuously mated and selected to produce large and small body sizes, had a 4.5% incidence of LDA in the large size group and a 1% incidence in the small cows during a 14-year period.[697] Body weight was 514 kg versus 464 kg, wither height was 134 cm versus 129 cm, and fat-corrected milk production was 6163 kg versus 6135 kg for the two groups. Thus some evidence exists to support a genetic basis for predisposition to LDA, and perhaps this is mediated through body size or conformation.

32.132.4 Treatment and Prognosis

Treatment for LDA involves returning the abomasum to its normal anatomic location and preventing reoccurrence (“pexy”), treating the electrolyte and acid-base abnormalities, and providing therapy for concurrent disease conditions. Prognosis for LDA is good but is influenced by the severity of the concurrent disease. Cattle with severe hepatic lipidosis and LDA should be given a guarded prognosis, as their recovery is often slow and incomplete.

32.132.5 Prevention and Control

The incidence of LDA has been reduced in problem herds by dietary manipulation that reduces the likelihood of forestomach and abomasal atony caused by high-concentrate rations. This includes slow introduction of concentrates after calving, prepartum introduction of ensiled and concentrate feeds and increase in the particle size of the forage. Maintaining serum calcium concentration around parturition may be achieved by dietary management during the prepartum period. Dietary cation-anion difference (DCAD) is a reliable method of controlling hypocalcemia in dairy cows (see Chapter 41). Reduction in other periparturient inflammatory diseases such as mastitis and metritis also reduces the incidence of LDA.

32.133 RIGHT DISPLACEMENT OF THE ABOMASUM

Simple right displacement of the abomasum (RDA) occurs at approximately 10% to 15% the frequency of LDA. The exception to this is the reported higher incidence of RDA than LDA in Denmark.[698]

32.133.1 Clinical Signs and Differential Diagnosis

The general systemic state of the cow with a simple RDA is the same as that of the cow with LDA. On the other hand, as the simple RDA evolves toward the volvulus, the systemic changes observed in cattle with abomasal volvulus progressively appear. An area of tympanitic resonance is heard on the right side with simultaneous auscultation and percussion. The ping usually is confined to an area under the last five ribs in the upper half of the abdomen. The condition must be differentiated from other causes of right-sided pings, such as cecal distention (with or without volvulus), gas in the spiral colon, pneumorectum after rectal examination, pneumoperitoneum, physometra (gas in the uterus), and abomasal volvulus (see Fig. 1-4).[699,700] Cecal and rectal pings usually are detectable in a linear pattern just below the transverse processes of the lumbar vertebrae extending to the tuber coxae. Rectal examination identifies the gas-filled structure. Pings heard with gas in the spiral colon typically have a variable pitch, depending on the location over the cranial paralumbar fossa and last three or four ribs. Generally the spiral colon may be palpated per rectum as a laterally flattened, mildly distended viscus adjacent to the right body wall. Gas in the uterus can be detected per rectum. Pneumoperitoneum creates a ping that is distributed all along the dorsal portion of the abdominal cavity and is usually heard on both sides.

Abomasal volvulus is the most difficult to differentiate from RDA. Determination of the difference by physical diagnosis in an early case of abomasal volvulus is probably impossible. With time the cow becomes progressively more dehydrated and more severely ill with volvulus than is usual with RDA. Heart rate (above 100 beats/min), ruminal motility (totally absent), and fecal output (almost none) are clinical signs in favor of a diagnosis of abomasal volvulus. Advanced cases of volvulus also have a ping that has an arched dorsal border and a horizontal ventral border caused by the fluid level in the abomasum. This fluid is auscultable on succussion of the abomasum.

32.133.2 Treatment and Prognosis

Surgical treatment is required to correct RDA. Because of the difficulty of differentiating RDA from early volvulus, intervention should be as prompt as possible. The prognosis for a successful recovery after surgery is comparable to that for LDA if no other concurrent disease is present.

32.134 ABOMASAL VOLVULUS

Abomasal volvulus, or right torsion of the abomasum, leads to complete obstruction of the flow of ingesta into the duodenum and therefore is a surgical emergency. The condition occurs in all classes of cattle. Although RDA is thought to precede its development, unknown factors lead to abomasal volvulus.

32.134.1 Clinical Signs and Differential Diagnosis

The systemic effects of the gastrointestinal obstruction that results from abomasal volvulus progress to a much more severe degree than in LDA or RDA. Sunken eyes and loss of skin turgor accompany the dehydration that develops. The heart rate increases above 100 beats/min, and the pulse is weak and thready. Abdominal distention is marked bilaterally. Complete ruminal stasis develops, leading to bloat, and the abomasum greatly enlarges on the right. Despite the severe degree of gastric distention, colic rarely develops in abomasal volvulus; it is much more likely with cecal distention. The skin is cool to the touch. Feces are absent or watery but scant. A large area of tympanitic resonance with uniform pitch throughout is detectable on the right, extending from the eighth rib to the middle of the paralumbar fossa (see Fig. 1-5).[700] The ventral border of the ping is a horizontal line reflecting the fluid level in the greatly distended abomasum. Borborygmi are absent. Splashing fluid sounds can be heard when the abomasum is ballotted (succussed) behind the last rib.

859

860

Other causes of proximal intestinal obstruction and torsion of the intestinal mass around the root of the mesentery must be differentiated from abomasal volvulus. On rectal examination the abomasum can usually be felt with abomasal volvulus. With intestinal obstruction or intestinal volvulus, distended loops of small intestine can be palpated. Pings caused by gas in the intestines have a variable pitch over the area involved.

Cecal distention with rotation can produce a similar degree of abdominal distention high on the right, but the abdomen usually is less filled cranioventrally on the right. A ping extends to the tuber coxae, and the cecum can be palpated per rectum. Diffuse peritonitis leads to complete atony of the gastrointestinal tract, and the abdomen may become distended with gas in all parts of the tract; there is no discrete ping extending over a large area of the right side.

As abomasal volvulus progresses, cattle become recumbent and depressed. Death occurs within hours of this stage, which occurs 1 to 3 days after the development of the volvulus.

32.134.2 Clinical Pathology

The serum biochemistry profile will show much more dramatic changes with abomasal volvulus than with RDA or LDA. Clinicopathologic consequences include hypovolemia, dehydration, hemoconcentration, metabolic alkalosis, hypochloremia, hypokalemia, and paradoxic aciduria. Hyperglycemia, hypocalcemia, and hyponatremia may also be observed. Later in the condition a superimposed metabolic acidosis is also present. Anion gap gradually increases with the severity of the disease. Systemic shock eventually causes fatality. Reduced fluid intake and sequestration of large quantities of chloride-rich fluid in the stomachs (third space problem) leads to dehydration and hypovolemia.

Under the influence of carbonic anhydrase, hydrogen ions are normally pumped into the abomasal lumen. A chloride ion follows into the lumen, whereas bicarbonate and sodium remain in the blood. Under normal circumstances the HCl leaves the pylorus, where the hydrogen ions are neutralized by pancreatic and intestinal secretions and the chloride is resorbed. When abomasal volvulus occurs, the HCl is sequestered in the abomasum and regurgitated into the omasum and rumen (internal vomiting). Ruminal chlorides increase. The animal becomes alkalotic and hypochloremic. Because of shifts between intracellular and extracellular compartments, potassium moves intracellularly as hydrogen ions move extracellularly in response to the metabolic alkalosis. This, plus the total anorexia, lead to severe hypokalemia. The hallmarks of abomasal volvulus are metabolic alkalosis, hypochloremia, and hypokalemia.

Paradoxic aciduria occurs in the face of metabolic alkalosis, when the cow should be retaining hydrogen ions.

[701,702] The overwhelming renal physiologic drive appears to be sodium retention. Dehydration and reduced cardiac output result in falling blood pressure. The animal must respond by volume expansion; thus sodium is resorbed in the renal tubules. Chloride is also resorbed. Because there is hypochloremia, the electrical gradient that must be corrected is high; if 140 mEq/L of sodium is resorbed and only 60 mEq/L of chloride is available, there is a net of 80 mEq/L (140 − 60) of cations that must be secreted back into the tubules. This is normally accomplished by secretion of potassium. Because hypokalemia is severe, hydrogen ions are paradoxically secreted to retain electrical neutrality so that blood pressure can be maintained by means of maximum sodium resorption.

32.134.3 Pathophysiology

At least some of the factors predisposing to LDA or RDA probably contribute to the paths of abomasal volvulus. Whether true RDA precedes abomasal volvulus is not known. Dissection of naturally occurring cases of abomasal volvulus demonstrated that the structures involved in rotation can vary from the reticulum to the omasum at the orad end.[698,703,704] The rotation probably occurs most frequently at the reticuloomasal junction. The duodenum is looped around the omasum, regardless of the degree of volvulus. Creating the condition manually in an anesthetized calf was easier if the gas-filled fundus ascended around the cranial surface of the omasum, pulling the reticulum with it.[703] The ensuing displacement leads to a counterclockwise rotation of the abomasum and omasum as viewed from the right side and the rear. The duodenum is pulled medial to the body of the omasum and wraps around the neck of the omasum in the final configuration. The continued hydrochloric acid secretion of the abomasum and the gas produced in the omasum and abomasum further stretch and occlude the duodenum. The abomasal blood vessels and the ventral vagal trunk are compromised near the site at which the duodenum wraps around the omasum in long-standing cases. Thrombosis of vessels may occur.

The acid-base and electrolyte abnormalities of **early** abomasal volvulus are the same as those of LDA. In cases of severe distention of the abomasum and omasum with vascular compromise, systemic cardiovascular insufficiency develops. Reduced perfusion of peripheral tissues may lead to metabolic acidosis terminally. Hemoconcentration develops, although bleeding into the abomasum may occur from devitalized mucosa, leading to a low hematocrit. These changes are compounded by the developing necrosis of the abomasum. The abomasum may physically leak contents through a weakened, overstretched wall. Endogenous inflammatory mediators and bacterial toxins may diffuse from the abomasum to viable surrounding tissues, where absorption occurs. In either case, the viability of the abomasum is lost, and death follows shortly.

32.134.4 Treatment

Immediate surgical intervention usually is necessary to save the animal's life. Simultaneously fluid, electrolyte, and acid-base abnormalities need correction. For early cases of hypokalemic, hypochloremic alkalosis and dehydration, intravenous fluids consisting of 20 to 80 L of 0.9% sodium chloride with 25 to 100 mEq/L potassium chloride added are administered. Intravenous potassium should not be given at a rate greater than 1 mEq/kg/hr to prevent cardiotoxicity. For advanced cases with metabolic acidosis, balanced electrolyte solutions such as Ringer's solution are indicated. Broad-spectrum antibiotics are appropriate if the integrity of the abomasal mucosa is questionable. NSAIDs are indicated to control pain, inflammation, and shock. Both standing right-sided and recumbent right paramedian approaches have been successful for correcting abomasal volvulus.[682,705]

32.134.5 Prognosis

Establishing an accurate prognosis before surgery is optimal because at that time salvage remains a possibility and little expense has occurred. A second critical time is after surgery in cows not recovering appropriately. The decision will be whether to continue to treat (cost) or salvage, if that still is an option.

Preoperative assessment is difficult. In our experience, assessment cannot be based on a single clinical observation or serum biochemistry value. The best published studies looked at two different classifications of outcome: death versus survival and productivity versus nonproductivity. A logistic regression model,[706] looking at heart rate, base excess, and serum chloride level, was developed as a preoperative predictor of death or survival. The study by Constable and colleagues found that four presurgical variables (hydration, heart rate, duration of inappetence, and AlP level) could be used to best predict cattle as productive or nonproductive after surgery.[707]

860

861

Surgical assessment of outcome has been investigated. The overall success rate of surgery varies between 61.5% and 86.3%.[708–711] The number of forestomachs involved in the twist has been found to adversely affect survival and productivity. Wallace found only 20% success in cattle with reticulo-omasal-abomasal volvulus.[711] Another study reported success in 55% of cattle with omasal-abomasal volvulus and 87% success in cattle with only an abomasal volvulus.[707] Edema of the abomasum carries a guarded to poor prognosis.[711–713] Edema around the proximal duodenum was associated with a poor outcome in Pearson's study,[712] but Fubini and co-workers found no association with outcome.[714] Purple discoloration of the abomasal serosa tends to bode poorly for long-term outcome, as does total distention of this organ, abomasal necrosis, and thrombosis of the gastric veins.[706,711] When it has been necessary to drain the abomasum of fluid to correct the twist, the animals have usually not done well.[709] The measurement of intraluminal pressures of greater than 16 cm Hg also carries a poor prognosis because of mucosal damage.[707] A logistic regression model using some of the surgical findings did not predict outcome any better than with the preoperative model.[706]

After correction, cattle with abomasal volvulus often have diarrhea for 24 hours. Feces then firm up to normal consistency. Postoperative clinical signs associated with a poor prognosis include melena, anorexia, persistent tachycardia, and dehydration.[709,713,715] In our experience, even if appetite and general attitude are initially good (24 to 48 hours after surgery), persistence of a loose low-volume stool 72 hours after surgery may indicate complications and possible vagal indigestion.[717] Once vagal signs develop, the survival rate is only 11.5% to 20%.[711,716] Prolonged treatment seems irrelevant, because neither surgical treatment (pyloroplasty, abomasal or ruminal fistula) nor medical treatment (prokinetic drugs or laxatives) has been shown to be effective.[672,709]

32.134.6

Necropsy Findings

Cattle that die of abomasal volvulus are grossly dehydrated, and the abomasum is greatly distended or ruptured. The omasum often is also greatly distended when torsion occurs at the reticuloomasal junction. Cattle that die or are euthanized after developing postoperative complications have one or more of the following postmortem lesions: gastric compartment dilation, peritonitis, abomasal wall necrosis or ulcer, vascular thrombosis, or vagal nerve lesions.[717]

Table 32-19 Abomasal Ulcers

Type	Lesions	Clinical Signs
Nonperforating	Mucosal and some submucosal tissue loss; focal mural thickening; local serositis	Partial anorexia; decreased ruminal motility; positive fecal occult blood
Nonperforating with severe blood loss (bleeding)	Penetration of mucosa and submucosal blood vessel; hemorrhage into abomasum	Partial anorexia; decreased ruminal motility; anemia; pale mucous membranes; melena; tachycardia; cool extremities
Perforating with local peritonitis	Penetration from mucosa to serosa; leakage of abomasal contents; localized peritoneal reaction with adhesion formation	Total anorexia; low-grade fever; decreased to absent ruminal motility; localized abdominal pain; very similar to traumatic reticuloperitonitis
Perforating with diffuse peritonitis	Penetration from mucosa to serosa; widespread contamination of the peritoneal cavity with abomasal contents; significant exudate in peritoneal cavity; fibrin deposition of all serosal surfaces	Total anorexia; fever early, then hypothermia; ileus of entire gastrointestinal tract; tachycardia; shock; terminally recumbent with grunt on respiration

32.134.7 Prevention and Control

Because factors predisposing to atony of the forestomach and abomasum probably are important in the genesis of abomasal volvulus, prevention should be similar to that outlined for LDA.

32.135 ABOMASAL ULCERS

David Francoz

Charles L. Guard

32.135.1 Definition and Etiology

Abomasal ulcers occur in cattle of all ages and rarely in sheep and goats. Signs of loss of gastric epithelium may range from no clinical signs, to hemorrhage and anemia and subsequent melena, to peritonitis if the erosive processes penetrate all layers of the abomasum. The exact cause of abomasal ulcers is still obscure and may be multifactorial. In calves, development of abomasal ulcers has been proposed to be associated with mineral deficiencies (mainly copper),[718,719] stress,[720] proliferation of microorganisms (*C. perfringens* type A, fungi, or others),[720–724] and/or abrasion of the abomasal mucosa by roughage, geosediments, or trichobezoars.[725,726] However, all of these hypotheses have failed to demonstrate alone their involvement in the development of abomasal ulcers.[720,723,727] In adults the disease is associated with stress such as recent parturition, peak milk production, or presence of concurrent diseases (mainly those of the peripartum period), and with diets high in starch.[728–730] Lymphosarcoma of the abomasum also may lead to clinical signs of ulcer disease. Abomasal ulcers are also an adverse effect of NSAIDS.

32.135.2 Clinical Signs and Differential Diagnosis

Smith, Munson, and Erb[729] have classified abomasal ulcers into four types: (1) nonperforating with minimal signs, (2) nonperforating with severe blood loss, (3) perforating with local peritonitis, and (4) perforating with diffuse peritonitis (Table 32-19). These classifications are useful for describing the various clinical pictures that may be observed when examining an animal with abomasal ulceration.

The mildest form (type I) is caused by nonperforating ulcers that do not result in extensive hemorrhage. Affected animals may have mild or no clinical signs. The signs are mild abdominal pain, shown by partial anorexia, decreased ruminal motility, and mild ruminal tympany. There is usually no febrile response. Manure may be normal or reduced in amount and stale because of prolonged transit. In some cases abdominal pain may be evident on manual pressure on the right ventral abdomen. TRP or indigestion may be suspected. In one study about two thirds of such cows had a positive test finding for fecal occult blood.[731]

861
862

In cattle with ulcers that erode into major gastric blood vessels (type II), blood loss can be sufficient to cause signs of anemia and hemorrhagic shock. These animals have dark blood clots in their manure or tarry, black feces with the characteristic smell of partly digested blood. The mucous membranes may be pale, tachycardia may be pronounced, and the respiratory rate may be elevated. Total anorexia and ruminal stasis usually are present. The rumen may have a fluid consistency, and if the animal is able to stand, abdominal pain sometimes is evident. There are other possible sources of proximal gastrointestinal hemorrhage in cattle, but abomasal ulcers are by far the most common cause. Among them, bleeding abomasal ulcers must be differentiated from melena sometimes seen with intussusception or HBS (jejunal hemorrhage syndrome [JHS]). The PCV usually is increased with intussusception,[732,733] normal or increased in HBS,[734,735] and decreased with a bleeding ulcer.[736,737]

Abomasal ulcers that perforate the serosal surface lead to localized peritonitis (type III) from contamination with abomasal contents. If the lesion is small or the local inflammatory reaction sufficiently swift, localized peritonitis results. This condition is most like TRP in presenting signs. The animal may be moderately febrile and partly or totally anorectic, and milk production may decrease acutely. There is evidence of abdominal pain, usually localized to the right ventral quadrant (positive withers pinch test). Ruminal motility may be absent, and mild bloat may be present. As with hardware disease, the signs usually abate over the course of a few days if the infection is successfully contained. In some cases the infection is confined to the omental bursa, where extensive fluid and pus may accumulate. The course of omental bursitis is much more prolonged than that of simple localized peritonitis and usually results in a guarded prognosis.

Major leakage from a perforating ulcer leads to acute diffuse peritonitis (type IV). The course of the disease usually is rapid, with signs of septic shock developing within 24 hours of the onset. Total anorexia and ruminal stasis are accompanied by tachycardia with a weak, thready pulse and a heart rate over 100 beats/min. Pain may be evidenced by grinding of the teeth or groaning. The extremities are cool, and the animal generally becomes recumbent. Abdominal enlargement may be evident as a result of both ruminal tympany and the accumulation of peritoneal fluid. Dehydration is detectable by skin pinch or by observation of the position of the eye in the orbit. Septic shock from other causes may be difficult to distinguish from that caused by perforated abomasal ulcers in the terminal stages of the disease. Diffuse peritonitis from uterine, cecal, or intestinal ruptures have the same final course. Abomasal volvulus of more than a day's duration has similar characteristics but can be differentiated by the right-sided ping and fluid in the abomasum.

32.135.3 Clinical Pathology

The most useful diagnostic test for abomasal ulcer disease without visible melena is the fecal occult blood test. In an evaluation of 296 hospitalized cattle with gastrointestinal disease, this test had a sensitivity of 0.77 and a specificity of 0.97 for ulcers confirmed at surgery or necropsy.[731] The test is inexpensive and can be performed during the physical examination.

Abdominocentesis confirms diffuse peritonitis (a large quantity of abdominal fluid is obtainable); centesis fluid may contain leukocytes with phagocytosed or free bacteria, and even feed particles. In localized peritonitis the results of abdominocentesis may be normal.

Abdominal ultrasonography is also useful for the diagnosis and the evaluation of peritonitis (see section on abdominal ultrasound). Braun and colleagues reported that percutaneous ultrasound-guided abomasocentesis can be safely performed for the evaluation of abomasal fluid.[738] The presence of blood or hemoglobin is principally associated with abomasal ulcers.[738,739]

If peritonitis is present, leukocytosis usually is present, with neutrophilia predominating in many cases. The plasma fibrinogen is increased (over 700 mg/dL) in most cattle with peritonitis. This may be evaluated in the field with a glutaraldehyde coagulation test on whole blood. The hematocrit is normal or elevated with peritonitis, but plasma protein levels may be decreased as a result of protein accumulation in the peritoneal cavity or increased if dehydration is severe. If blood loss is severe, the PCV is decreased. Cattle over 5 years of age with a bleeding abomasal ulcer should be tested for bovine leukosis virus. Results of a complete biochemistry profile or blood gas analysis are nonspecific. In most cases, they reflect a digestive stasis (hypochloremic metabolic alkalosis), but in animals in shock a metabolic acidosis may be observed. BUN may be increased. This can be a result of blood degradation in the intestine or hypovolemia and prerenal azotemia. The utility of BUN in the diagnosis of abomasal ulcers by identifying digestive hemorrhage remains to be determined.

32.135.4 Pathophysiology

The specific events leading to erosion and ulceration of the abomasal mucosal epithelium are unknown but probably are similar to those in other species. Cytoprotective mechanisms include a mucous barrier, cloudy mucus containing bicarbonate ions to neutralize back-diffusing hydrogen ions, and high submucosal rates of blood flow to remove back-diffusing hydrogen ions. When these mechanisms are disturbed, gastric (abomasal) ulcers can occur. Stress, concurrent diseases, corticosteroids, and NSAIDs are among factors known to contribute.

32.135.5 Epidemiology

Abomasal ulceration occurs in cattle of all ages. At slaughter many calves are found to have clinically inapparent abomasal erosions and ulcers, with prevalence reported ranging from 32% to 76%.[740–743] In clinically affected calves, perforation with peritonitis (rather than hemorrhage) usually develops. In clinically normal slaughter cows, 20.5% had type I ulcers.[744] However, a much lower prevalence (1% to 2.6%) of abomasal ulcers in healthy adult cows has also been reported.[745,746] In adult cattle with abomasal ulcers causing illness, approximately one third of clinical cases in a referral population had significant hemorrhage.[736] Of these, half had lymphosarcoma and for the most part were older than 6 years of age. The age of the cattle with non—tumor-associated bleeding ulcers was generally younger (7 of 12 were less than 5 years old). In the remaining two

thirds of the cattle, ulcers had perforated, with about half having diffused and half having localized peritonitis.[747] Most adult cattle with abomasal ulcer disease are in the first month after calving and have a concurrent disease. Many cows have been discovered to have an abomasal ulcer at surgery for displaced abomasum. Metritis, mastitis, and ketosis are the other diseases commonly seen with abomasal ulcers. The incidence of abomasal ulcers apparently increased with the advent of heavy corn silage and high-moisture corn feeding. In the recent past, as feeding and management practices have addressed the most common abomasal displacements, the incidence of ulcer disease has also decreased.

862

863

32.135.6 Necropsy

Cattle with bleeding abomasal ulcers resulting in death are very pale and may have blood or bloody fluid throughout the distal gastrointestinal tract. The lesion in the abomasum is typically small and involves an abomasal blood vessel in the submucosa. Most bleeding and perforating ulcers were found in the fundic portion of the abomasum in the region of the proper gastric glands. The most ventral portion of the abomasum in its normal position is frequently affected.[737,745,746,748] Most animals have a single ulcer significantly bleeding, but approximately 60% have one or more additional ulcers or erosions.[737,745] Cattle with diffuse peritonitis have many liters of foul-smelling fluid in the peritoneal cavity. Fibrin usually covers the serosal surface of all abdominal organs. The defect in the serosal surface of the abomasum is usually nearly round and 3 to 6 cm in diameter. Abomasal fluid freely enters the peritoneal cavity. Omasal bursitis may be present, with the omental recess filled with purulent to fibrinous fluid. In these cases the remainder of the abdomen may not be grossly affected. Asymptomatic abomasal ulcers (often 50 to 200) may be found coincidentally in cattle that die of septic metritis or mastitis. These ulcers generally show no signs of hemorrhage and go undetected until necropsy.

32.135.7 Treatment and Prognosis

Treatment is aimed at correcting dietary problems, reducing stress, ameliorating concurrent disease problems, and initiating specific therapy for the clinical problems caused by the ulcer. Removal of high-energy feedstuffs and replacement with good-quality hay plus confinement to a stall are beneficial.[728] The buffer effect of food is very important for the control of abomasal pH. Consequently, the return to a normal appetite is the main goal of the treatment of abomasal ulcers.[749]

Blood transfusions may be necessary for cattle that have lost enough blood to lower the hematocrit to 14% or below. Usually 4 to 6 L given once is adequate, but repeated transfusions occasionally may be necessary. Cross-matching usually is not necessary for cattle unless repeat transfusions are performed over a period of more than 3 days. Broad-spectrum antibiotics are administered to cattle with signs of peritonitis. Principles and details on the treatment of peritonitis are described in the section on peritonitis in ruminants. Intravenous or oral fluids may be necessary to treat dehydration and metabolic or acid-base disturbances that occur concurrently. Animals with diffuse peritonitis must be given intravenous fluids with caution because of the risk of pulmonary edema associated with the low colloid oncotic pressure of their plasma.

Numerous recent studies have been performed to evaluate the effect of different therapeutic agents on abomasal pH of healthy calves. Results of these studies have been summarized by Constable and colleagues.[749] The therapeutic agents studied in normal calves included oral administration of an antacid agent containing aluminum hydroxide and magnesium hydroxide (25 mL and 50 mL, tid), oral administration of specific H_2-antagonists (cimetidine, 100 mg/kg and 50 mg/kg, tid; and ranitidine, 10 mg/kg and 50 mg/kg, tid), and oral administration of the proton pump inhibitor omeprazole (4 mg/kg sid). All these treatment regimens induce an increase in mean

24-hour abomasal luminal pH. Oral administrations of the antacid agent induced a dose-dependant increase in luminal pH and were more efficacious when administered postprandially. Because some deleterious effects were observed when this antacid was administered at the dose of 50 mL tid, this should be considered the maximal dosage rate in calves.[749] Cimetidine (100 mg/kg tid) was the most effective. However, ranitidine (50 mg/kg tid) was the most cost-effective in theses studies. Results of theses studies need now to be confirmed in ill calves. In adults, oral administration of these therapeutic agents is of doubtful benefit because of dilution in the rumen and slow release into the abomasum. Oral medications administered after stimuli that induce reflex esophageal groove closure would be more likely to have the desired effect. Traditional stimuli to close the esophageal groove have included copper sulfate solutions and 10% sodium bicarbonate solution. Vasopressin (0.25 IU/kg IV) was shown to induce reliable abomasal deposition of materials given by drench to adult goats.[750] Intravenous administration of H_2-antagonists at lower doses may be efficacious, but their use by this route is cost-prohibitive ($100 to $200 USD per day) or reserved for very high-value animals. In our clinic in Quebec, we use ranitidine 1 to 1.5 mg/kg IV tid for high-value animals; our clinical impression is that this is effective.

The prognosis is good for ulcers that are not bleeding and not perforated. For those animals that stop bleeding and those with localized peritonitis, survival and eventual return to normal function can be expected. Many dairy cattle stop lactating during the acute course of the illness and do not return to milk until the next lactation. Because abomasal ulcers generally occur within the first month after calving, most of these animals are salvaged for slaughter. Most cattle with diffuse peritonitis die despite aggressive specific therapy. Early recognition and immediate surgery followed by antibiotic and fluid therapy may save some valuable individuals. Cattle with ulcers that occur secondary to lymphosarcoma should be euthanized or slaughtered.

32.135.8 Prevention and Control

Because the exact cause of development of abomasal ulcers is unknown, prevention is difficult. Dietary management that reduces other abomasal diseases likewise reduces the incidence of abomasal ulcers. Avoiding abrupt changes in rations and including adequate fiber sources of sufficient particle size to facilitate normal ruminal function also promote normal abomasal function. Minimizing stress caused by overcrowding, excessive competition, and adverse environmental conditions, and minimizing mastitis and metritis should also reduce problems with abomasal ulcers. Elimination of animals infected with the bovine leukosis virus from the herd eliminates lymphosarcoma as a cause of abomasal ulcers. Judicious use of corticosteroids and NSAIDs is also important.

32.136 ABOMASAL DILATION AND EMPTYING DEFECT OF SUFFOLK SHEEP

David Francoz

Charles L. Guard

32.136.1 Definition and Etiology

A syndrome of abomasal dilation and mechanical transport failure has been described in adult Suffolk sheep.[751–754] The condition resembles but is uniquely different from abomasal impaction of cattle wintering on very-poor-quality roughage. It has been mainly reported in Suffolk sheep but a similar syndrome has been described in two Hampshire,[755] one Dorset[756] and one Texel sheep.[757] No hereditary pattern of disease has yet been found.[753,754]

32.136.2 Clinical Signs and Differential Diagnosis

The disease is primarily manifested by anorexia and weight loss. Most patients eventually die. Animals described in reports from several teaching hospitals were adults of both sexes.[751–754] Not all animals had all of these signs, but the following have been reported: watery green diarrhea or normal feces; ruminal tympany; pear-shaped abdominal distention; increased, normal, decreased, or absent ruminal contractions; a palpable firm mass in the right lower abdomen; mild abdominal pain; tachycardia; duration of observed signs from days to months; partial to total anorexia; dullness and depression; marked to undetectable weight loss; ketonuria.

Wasting diseases of sheep include malnutrition, parasitism, dental problems, Johne's disease, caseous lymphadenitis, other chronic infections, and neoplasia. Abomasal emptying defect is distinguishable by the palpable abomasum in advanced cases and the exclusion of other possible problems. Other causes of abomasal enlargement or impaction resembling those reported in cattle must also be considered. However, when a mature Suffolk from a well-nourished flock shows weight loss and a palpable abomasum, this syndrome must be considered highly likely. Confirmation should involve response to therapy but may require necropsy or exploratory surgery.

32.136.3 Clinical Pathology

Reports on cases seen in North America have found hematologic and blood chemical determinations of little benefit in the diagnosis. The hypochloremic metabolic alkalosis common in cattle with abomasal problems has not been consistently observed in affected sheep. Elevated ruminal chloride ion values have been the most consistent laboratory findings in published reports.[752,753,758] The normal ruminal chloride level in sheep is 8 to 15 mEq/L; affected sheep have had values ranging from 34 to 130 mEq/L. Mild hypocalcemia was observed in all cases in one report.[753]

32.136.4 Pathophysiology

The mechanisms underlying the dilation of the abomasum and the failure to transport ingesta to the intestines are unknown. None of the problems commonly associated with abomasal impaction and dilation in cattle have been identified in affected Suffolk sheep. Recently Pruden and colleagues advanced that abomasal emptying defect of Suffolk sheep may be an acquired form of dysautonomia.[754]

32.136.5 Epidemiology

The disease has been mainly reported in sheep of the Suffolk breed. The disease has mostly been seen in winter months in association with lambing and feeding of concentrates. Both rams and ewes have been affected. Most cases are sporadic but at least two outbreaks have been reported.[753,754] The incidence in one report was 13 of 92 mature ewes affected in the flock during one winter.[753] In the other, five ewes of the same flock (200 ewes) were submitted for necropsy the same day.[754] In both studies, pedigree analysis of affected sheep in the flock showed no hereditary pattern. One report from a diagnostic laboratory in England described abomasal impaction in a Texel ewe and in a Suffolk ram that were simultaneously diagnosed as having scrapie.[757] It remains to be seen if any causative connection exists between the two diseases. Because no antemortem tests exist for the diagnosis of scrapie, this relationship will be difficult to establish. In one study, six sheep were immunohistochemically tested

for scrapie; five were negative, and one was positive and presented equivocal microscopic lesions.[754]

32.136.6 Necropsy Findings

The abomasum is greatly distended in sheep that die of this condition. The contents are either dry or liquid but most often have resembled normal ventral ruminal sac contents. The pylorus has always been patent. Normal ingesta have been observed throughout the remainder of the intestinal tract. Incidental findings have included aspiration of ruminal contents and subsequent pneumonia, abomasal ulcer with local peritonitis, passive congestion of the liver, megaesophagus, and esophageal ulcers. Reports of histopathologic findings include no lesions other than thinning of the abomasal muscle layers[753] (presumably as a result of stretching), mononuclear cell infiltration of the main muscle layers of the abomasums,[751] and one case of myxomatous changes in the abomasal branches of the vagus nerve.[752] Chromatolytic and necrotic neurons without signs of inflammation within the celiacomesenteric ganglia were found in six of six sheep examined.[754]

32.136.7 Treatment and Prognosis

Medical therapy alone with cathartics and laxatives has been of limited benefit. Mineral oil, dioctyl sodium sulfosuccinate, and magnesium sulfate have all been used. Neostigmine and calcium gluconate were not useful.[751] Abomasotomy has led to death from complications in many affected sheep, but those that have survived more than 2 days and have been treated with metoclopramide (dosage not reported) have shown varying degrees of recovery. Metoclopramide is a dopamine antagonist that has been used in ruminants to facilitate abomasal emptying. However, experimental studies in cattle and sheep have failed to demonstrate any beneficial effect of metoclopramide on abomasal emptying.[759,760] On the other hand, erythromycin, a motilin agonist, has been shown to increase abomasal emptying rate in cattle.[759,760] Its utility in sheep remains to be determined. Despite these successes, most affected sheep die of cachexia. Because of the expense, poor response, and risks associated with abomasotomy, this treatment is reserved for valuable breeding stock.

32.136.8 Prevention and Control

Until more is known about the pathogenesis of this specific defect in abomasal function in Suffolk sheep, no useful recommendations for prevention can be made.

32.137 ABOMASAL IMPACTION

Charles L. Guard

David Francoz

32.137.1 Definition and Etiology

Abomasal impaction is the accumulation of firm ingesta in the abomasum with failure of aboral transport. Depending on the cause, abomasal impaction can be classified as primary or secondary. In primary abomasal impaction, no underlying cause can be identified and the impaction is considered idiopathic. On the other hand, secondary abomasal impaction can be the result of feeding poor-quality, coarse roughage as the sole feed. Several animals in a herd may be affected over a short period. Calves may also have impaction of the abomasum

caused by eating bedding or indigestible objects when fed low-quality milk replacers. The distended abomasum is filled with a firm mass of fibrous ingesta. Animals on low-fiber diets may consume wood or baling twine. Hairballs occasionally accumulate in the abomasum of calves. Indigestible material creates a mechanical outflow obstruction. Abomasal distention may occur with normal diets after correction of abomasal volvulus, secondary to reticuloperitonitis, or secondary to the development of adhesions between the abomasum and the rumen and or the abdomen. These conditions are referred to as vagal indigestion. Lymphoma involving the abomasum or other space-occupying lesions adjacent to the pylorus may lead to abomasal distention. Abomasal emptying defects of Suffolk sheep were addressed in the previous section.

864
865

32.137.2 Clinical Signs and Differential Diagnosis

Beef cows with abomasal impaction develop abomasal and ruminal enlargement over a period of days to weeks. Closely monitored animals have reduced feed intake and a reduced volume of firmer than normal feces. The animal may have bilateral ventral abdominal enlargement and bulging of the left paralumbar region. Ruminal contractions are of normal or increased frequency but often reduced in amplitude. In the later stages of the disease, ruminal motility often is absent. Cattle with advanced abomasal impaction may be recumbent and groan with each respiration. The consistency of the ruminal ingesta, as judged by ballottement, may be more fluid than expected on the basis of the coarse diet in some animals, whereas other animals have a uniformly firm and distended rumen. The pulse and respiration are usually normal until the animal is near death, at which time tachycardia develops. The abomasum may be palpable as a firm mass following the right coastal arch. Rectal examination reveals a distended rumen; often the ventral sac extends to the right body wall (L-shape rumen). The pyloric part of the distended abomasum may be palpable in the right ventral quadrant. Wintering beef cows usually are pregnant, and therefore the uterus prevents palpation of the abomasum. Mucus may be all that clings to the clinician's sleeve after rectal examination. Clinical signs in adult dairy cows are reported to be inconsistent, with the exception of decreased appetite.[761] In calves the abomasum may fill most of the abdomen and be doughy or firm on external palpation. The body condition of affected animals is invariably poor because negative energy balance precedes and is amplified by the impaction. If the abomasum ruptures, signs of generalized peritonitis occur. Death usually follows within hours of rupture.

In dairy cows, abomasal impaction should be considered in the differential diagnosis of nonspecific clinical signs of decreased milk production and appetite.[761] Conditions that cause dehydration and bilateral abdominal distention with absence of feces must be considered in the diagnosis. In many of these cases exploratory celiotomy is necessary to arrive at a definitive diagnosis.

32.137.3 Clinical Pathology

The hypochloremic, metabolic alkalosis typical of upper gastrointestinal obstruction in ruminants does not always develop in abomasal impaction.[761] Initially some fluid ingesta may pass through the abomasum, preventing chloride sequestration. However, some cattle have metabolic alkalosis with chloride accumulating in the rumen (internal vomiting). Terminally a metabolic acidosis from starvation may mask the metabolic alkalosis. Anemia and leukopenia can accompany the cachexia of chronic abomasal impaction in poorly fed animals. If abomasal rupture has occurred, profound hemoconcentration and leukopenia are present. Abdominocentesis generally is not useful in diagnosing abomasal impaction, because peritoneal fluid is abnormal only after abomasal rupture.

32.137.4 Pathophysiology

Animals fed roughage that is poorly digestible and incapable of meeting their energy requirements consume as much as the rumen will physically permit. The flow of ingesta from the forestomachs to the abomasum normally contains only small, finely digested particles of forage material. With chronic engorgement of highly lignified, poorly digestible forage, larger particles escape the forestomach and accumulate in the abomasum. Once a mass of fiber forms in the abomasum, further accumulation of particulate material is enhanced. With time, the mass fills the abomasum. Additional ingesta distend the abomasum to several times normal size. Also, abomasal secretion may be inhibited by the cachexia and chronic distention of the organ.

Abomasal transport failure after correction of abomasal volvulus is typical of vagal indigestion syndrome. Abomasal wall and vagal nerve damage, as well as peritonitis occurring secondary to the volvulus, prevent the return of normal abomasal muscular activity.[762] Vagal tone sometimes increases, and bradycardia is observed. Hypochloremic, metabolic alkalosis does develop frequently, with chloride accumulating in the ruminoreticular contents. The abomasum distends moderately, presumably as a result of atony.

Pyloric obstruction caused by foreign bodies or occlusion caused by lymphoma leads to mechanical outflow obstruction and must be considered. Chloride escapes back into the rumen, and metabolic alkalosis develops. The abomasum retains motility, but it is ineffective in moving ingesta into the duodenum.

32.137.5 Necropsy Findings

Emaciation and a firm, grossly enlarged abomasum are consistent with primary abomasal impaction. In Holstein cows a syndrome has also been described in which the impaction affected only the pyloric part of the abomasum.[761] The abomasal contents resemble normal, dry ruminal contents. The rumen is also enlarged but either filled with homogenous, watery ingesta that lack normal stratification or impacted with dry ingesta, similar to the abomasum. The abomasum is dilated, flaccid, and filled with fluidy ingesta if secondary to an abomasal volvulus. Intraluminal foreign body or tumor involvement of the abomasal wall is self-evident.

32.137.6 Prognosis

Because most cases of abomasal impaction are quite advanced when brought to the attention of the veterinarian, treatment usually is unrewarding. In dairy cows the short-term prognosis was reported to be good (93%) for impaction that affects only the pyloric antrum and guarded (50%) for impaction involving the entire abomasum.[761] The clinician must weigh the severity of the metabolic disturbances and the likelihood of recovery. Salvage by slaughter is often the most economic recommendation. If therapeutic measures do not resolve the impaction, death usually occurs within a few days of the onset of severe signs.

32.137.7 Treatments

Medical management includes correction of fluid and electrolyte abnormalities. Early cases may be resolved with easily digestible feeds, aggressive fluid therapy, and oral administration of laxatives such as mineral oil (4 L daily). Metoclopramide at a dose of 0.3 mg/kg given SC four to six times daily has been used to increase passage of ingesta through the pylorus. However, recent studies have failed to demonstrate any efficacy of metoclopramide on increasing abomasal motility.[763,764] Erythromycin (8.8 to 10 mg/kg IM bid) and bethanechol (0.07 mg/kg SC tid) alone or in combination with metoclopramide (0.1 mg/kg SC or IM tid) have been reported to increase abomasal emptying rate.[763,764] Pregnancy may be terminated by induction of parturition with

corticosteroids and/or prostaglandin, leading to improved comfort.

Different approaches have been proposed for a surgical treatment of abomasal impaction. Baker[765] recommended rumenotomy followed by installation of a nasogastric tube inserted into the abomasum through the omasum. Through the indwelling tube laxatives and emulsifiers may be given during the postoperative days to aid in softening and removing the abomasal contents. Mineral oil (8 mL/kg/day), dioctyl sodium sulfosuccinate (50 mg/kg/day), magnesium hydroxide (1 g/kg/day), or magnesium sulfate (2.5 g/kg/day) have all been recommended. Right flank or right paracostal approaches could also be used in order to gain direct access to the abomasum. Abomasotomy could be performed to remove the abomasal content, but it has not been reported successful in restoring abomasal function.[766] External massage may help break up the contents of the abomasum. Intraluminal administration of 5% dioctyl sulfosuccinate solution or saline could also be performed.[761]

32.137.8 Prevention and Control

Prevention of primary abomasal impaction requires proper dietary management of cattle in cold weather. Because animals outside without shelter have substantially increased maintenance energy requirements in cold, windy weather, straw or corn stover (stalks) is not adequate as the sole feed. Concentrates and better-quality forage prevent abomasal impaction. Monitoring body condition during winter weather alerts the good manager that supplemental feed is needed before abomasal impaction occurs.

32.138 OBSTRUCTIVE INTESTINAL DISEASES

David Francoz

Charles L. Guard

32.138.1 Definition and Etiology

Several conditions may lead to obstruction of the flow of ingesta through the intestinal tract. They can be divided into functional and mechanical obstructions. Functional obstructions (pseudoobstruction or ileus) are the consequence of neuromuscular perturbations of the gastrointestinal tract. Mechanical obstructions are the consequence of physical obstruction of the gastrointestinal tract secondary to digestive tract lesions (intussusception, volvulus, or congenital lesions) or extradigestive lesions (mesenteric fat necrosis, fibrous adhesions, or hernia). Each of the specific diseases is discussed in the following paragraphs and summarized in Table 32-20.

Table 32-20 Causes of Intestinal Obstruction in Ruminants

Disease	Animals Most Commonly Affected	Signs
Intestinal atresia or stenosis	Neonates	No feces; abdominal distention
Intestinal volvulus around mesenteric root	All ruminants; neonates more common	Colic; rapid abdominal distention; collapse; shock
Intussusception	All ruminants; LI or SI of neonates; SI of adults	Colic early, then chronic low-grade pain; dehydration; mucus plus blood in dark red feces; slow abdominal distention; decreased fecal output; mass palpated per rectum; distended loops of intestine per rectum
Cecal dilatation and volvulus	Adult dairy cattle in early lactation	Mild to severe colic; distended abdomen, especially upper right; ping in right paralumbar fossa; distended cecum palpated per rectum
Intestinal tumors	Sheep, rare in cattle	Progressive weight loss; cattle—may palpate mass per rectum; sheep—identify by celiotomy or necropsy
Mesenteric fat necrosis	Cattle, especially Channel Island breeds	May discover masses on routine examination; progressive weight loss; scant or no feces; dilated loops of bowel per rectum
Intestinal incarceration	All ruminants	See Intussusception
Pseudoobstruction or ileus	All ruminants	Scant or no feces; right-sided ping; succussable fluid on right; often associated with peritonitis

LI, Large intestine; *SI*, small intestine.

32.138.2 Clinical Signs and Differential Diagnosis

Acute manifestations of obstructive diseases include a reduced amount of feces or failure to pass feces, progressive abdominal enlargement with areas of tympanic resonance on the right side of the abdomen, and sometimes colic. If pain is severe, forestomach atony may occur. Mechanical obstructions may lead to circulatory shock and collapse. Electrolyte abnormalities depend on the site of the obstruction; those near the duodenum or pylorus lead to sequestration of abomasal secretions and result in hypochloremic, hypokalemic metabolic alkalosis. Obstructions of the cecum, colon, or rectum may lead to dehydration without alkalosis. If bowel necrosis or rupture occurs, acidosis may result from the circulatory collapse that accompanies peritonitis and the absorption of toxins.

32.139 INTESTINAL ATRESIA OR STENOSIS

Intestinal atresia or stenosis is a congenital anomaly reported in calves and lambs.[767–769] Clinical signs usually become evident within a few days after birth. Animals with anal or distal rectal atresia usually have the slowest onset of signs, whereas proximal obstructions lead to more rapid onset of signs. Malformations of the anus and rectum are believed to be hereditary,[770] and breeding of surgically corrected survivors should be discouraged. Jejunal atresia in the Jersey cow has been reported to be inherited as an autosomal recessive trait. The etiopathogenesis of atresia coli in calves is not well understood, but autosomal recessive inheritance has been reported[771] and Holstein calves seem to be predisposed.[772] Rectal palpation of the amniotic vesicle for early pregnancy diagnosis (<42 day of gestation) is also suggested to be a cofactor for the development of atresia coli.[772–774] If the anus or distal rectum is atretic, animals strain or pump their tails in an attempt to defecate. A fistulous connection may exist between the rectum and the urogenital tract (e.g., either the vagina or the pelvic urethra). Visual and digital exploration of the perineum reveals the absence of feces and may permit definition of the specific defect. Stenosis or atresia of the intestinal tract may occur to any degree and can be differentiated in four types according to classification in humans: narrowing, a membranous diaphragm with a perforation, or an imperforate membrane (type I); a cordlike remnant of the intestine (type II); a unique blind-ended dilation with complete separation of the intestine (type III, the most frequent); and multiple sites of atresia (type IV).[775] All have been described in cattle.[768] Affected neonates show depression and mild colic and progress to cardiovascular collapse after the intestine proximal to the obstruction becomes distended with fluid and gas. Tympany may be easily detected by percussion. If the anus and rectum are normal, a digital examination usually reveals only mucus or blood (or both). Because the rectal and descending colon walls are thin in cases of atresia coli, retrograde tubes or catheters should be used with extreme caution to avoid rupturing the bowel.[775] Complete intestinal volvulus must be considered in the differential diagnosis, but histories are often different.

866

867

Surgical repair is indicated if the animal is of high value. However, the prognosis for normal and productive life is guarded. Many affected neonates develop severe complications in the immediate postoperative period. Pneumonia, sepsis and peritonitis are among the most frequent, and the development of bowel stasis or ileus is common. When registered animals are involved, a letter should be sent to the appropriate breed registry stating that the defect has been corrected.

32.140 VOLVULUS OF THE LARGE AND SMALL INTESTINE AROUND THE MESENTERIC ROOT

Volvulus of the large and small intestine around the mesenteric root leads to severe colic and relatively rapid abdominal enlargement. Circulatory shock develops rapidly. Ruminants of any age are susceptible, but most cases are seen in preruminant neonates. Casting and rolling to correct a left-displaced abomasum may predispose to volvulus. Robertson[776] reported that 1% to 2% of surgical abomasopexies were followed by torsion of the intestinal mass around the mesenteric root. Severe colic is seen, including kicking and vocalization. Affected animals rapidly become recumbent, and hypovolemic shock develops.[777] The heart and respiratory rates increase greatly as shock develops. Variable-pitched resonant sounds may be heard bilaterally over the abdomen using simultaneous percussion and auscultation. In adult cattle the tympany is restricted to the right side. Succussion reveals splashing sounds, particularly on the right side. Rectal examination reveals distended loops of gut. Surgical correction is the only successful treatment option. The prognosis depends on the degree of devitalization of bowel. Animals surgically corrected during the early stages respond better.[777]

Volvulus of smaller portions of the intestinal tract leads to signs similar to those of complete intestinal volvulus

around the root of the mesentery but often is slower in onset. Colic with accompanying tachycardia, ruminal stasis, and anorexia is present to varying degrees. The abdomen is moderately distended on the right when the animal is viewed from the rear. Simultaneous auscultation and percussion on the right side reveal multiple-pitched resonant pings from the gas accumulated proximal to the obstruction. Rectal examination may reveal scant feces, mucus, or blood. The affected bowel usually is palpable as grossly distended with gas and some fluid. Because of their relatively long mesentery, the spiral colon (or part of it), the distal jejunum, and the proximal ileum may develop an obstructive volvulus. Therapy requires correction of acid-base and electrolyte abnormalities and rapid surgical manipulation by means of celiotomy.

32.141 INTUSSUSCEPTION

In the development of an intussusception, the oral portion of gut (intussusceptum) usually is engulfed and propelled distally by peristaltic action of the enveloping portion (intussuscipiens). Constable and colleagues reported an increased prevalence in calves less than 2 months of age compared with adults, and in Brown Swiss compared with Holstein cows.[778] The condition has also been reported in goats[779] and in sheep.[780–782] Intussusception may occur in either the large or the small intestine of calves but is almost invariably in the jejunum of adults.[778,783] Clinical signs include colic caused by the tension on the mesentery on the invaginating portion of the intestine. With time, ischemia of this portion leads to pain and eventually loss of sensation. Distention of the intestine with fluid and gas proximal to the obstruction leads to abdominal pain. Therefore a cow may show violent behavior or kicking at the abdomen in the first few hours that is eventually succeeded by treading and repeated lying and standing.[778,784,785] Over the course of several days the intussusceptum may become totally devitalized and slough. This is accompanied by severe peritonitis, and in the event of bowel rupture, toxic shock will develop. The exact cause of intussusception remains unknown. Most cases in adults were thought by one author to be associated with an intramural mass or polyp,[786] but others reports did not find such association.[778,784] The mass is propelled into the intussuscipiens by normal peristaltic contractions. In contrast, in the young animal no such mass lesion is usually associated with intussusception, but enteritis often is. *Oesophagostomum columbianum* causes nodules in the intestinal wall of sheep but has not been proved to be linked to multiple deaths from intussusception.[780]

Dehydration develops as gastrointestinal secretions accumulate in the gut lumen. In adults, hypochloremic, hypokalemic metabolic alkalosis develops gradually. The rumen becomes distended with fluid as its contents become more finely digested and abomasal reflux accumulates. The right side of the abdomen (or both sides) also enlarges as a result of the distention of the small intestine. Simultaneous auscultation and percussion of the right side of the abdomen reveals areas of variable-pitched resonance.[787] Rectal examination reveals distended loops of small intestine. The intussusception may be palpable as a firm mass. The cow may demonstrate pain when the mass is palpated. Feces are absent within hours of the onset of signs. The examiner may find mucus and blood in the descending colon. In long-standing cases the scant feces are very dark red and must be distinguished from the black feces (melena) associated with abomasal bleeding. Fluid obtained by abdominocentesis shows an increase in erythrocytes and leukocytes and an elevated protein level. Fever is often present because of peritonitis. If the condition is long-standing and bowel rupture has occurred, bacteria may be present. The CBC may reveal neutrophilia and an elevated plasma fibrinogen level.

In neonates with enteritis, fecal output decreases as appetite is lost after intussusception. A fever may develop as peritonitis occurs. Calves and other neonates may not exhibit obvious signs of colic. Abdominal palpation using both hands in an attempt to detect a mass is often successful in delineating an intussusception in a neonate. When neutrophilia, hyperfibrinogenemia, and loss of appetite develop after enteritis, intussusception should be suspected.

Treatment requires both surgical correction of the obstruction and parenteral restoration of fluid and electrolyte

balance. Because of the losses of chloride and potassium and the development of alkalosis, 0.9% sodium chloride solution with 30 mEq/L or more of added potassium chloride is recommended. Once intestinal patency has been restored, oral fluid and electrolyte supplementation usually allows the patient to achieve normal status. The prognosis is usually good if surgery is performed early in the course of disease. Complications such as peritonitis can occur and need to be controlled to maintain the chance of success. The surgical incision should be made high in the caudal right flank. A retrospective study of 336 cases of intussusception reports a postoperative survival rate of 43% and an overall survival rate of 35%.[778] The exceptions are animals with intestinal neoplasia that has metastasized.[788]

867

868

32.142 CECAL DILATATION AND VOLVULUS

Reports of hospitalized animals indicate that the postpartum interval to the development of cecal disease may be longer than that for left displacement of the abomasum; 57% of cases occurred within 2 months of parturition[789] and 46% within 4 weeks.[790] Dirksen and Doll[791] described 19 cases in calves less than 6 months old. Of these, 84% were being raised for early slaughter, and the remainder for herd replacements. This suggests that feeding or management differences may predispose to cecal disease in calves. In adult cattle, cecal dilation generally is believed to precede cecal volvulus or torsion. The cause and pathophysiology of cecal dilation and volvulus remain unknown. Increased luminal concentration of VFAs was classically believed to play a major role in the etiopathogenesis of cecal disorders.[792] However, results of studies on the impact of VFA on cecal motility have been contradictory. A recent study demonstrated that increased concentration of VFA had only minimal effect on large intestine motility and was unlikely to play an important role in the development of cecal disorders.[793] Factors that affect motility, as described for displaced abomasum, are likely similar.

Cattle with cecal dilation have a more gradual onset of illness than that noted with cecal volvulus. The time required for dilation to develop into volvulus is unknown. With simple dilation, feed intake and milk production decrease. Mild abdominal pain may be observed. The right paralumbar fossa usually is distended without the ribs being sprung. A large area of resonance is auscultable from the tuber coxae to a variable distance cranially[787] (see Fig. 1-3). Feces are usually still present, but the consistency may be loose and the amount reduced. The apex of the gas-filled cecum may be felt in the pelvic canal or nearby by rectal examination.

Cattle with cecal volvulus show an abrupt onset of anorexia, agalactia, and severe abdominal pain. Tachycardia and forestomach stasis are also present. Feces are scant or absent. The abdominal distention usually exceeds that caused by simple cecal dilation. The area of resonance in the right paralumbar fossa is larger, and fluid usually can be detected in the cecum and proximal colon by succussion. Although some cows with simple dilation have no acid-base abnormalities,[790,794] most with cecal volvulus have some degree of metabolic alkalosis with hypochloremia and hypokalemia.[790] The apex of the cecum is usually not palpable per rectum; rather, the distended body of the cecum or proximal colon impinges on the pelvic canal because the apex is directed cranially. Distended small intestine may be palpated with either cecal dilation or volvulus. Medical management of cecal dilation is usually successful with use of fluid therapy to restore normal hydration status and administration of nonsteroidal antiinflammatory drugs to control abdominal pain. In lactating cows, fluid therapy may contain calcium. Laxatives have also been recommended for the medical treatment of cecal dilation. However, Braun and co-workers[795] reported that the use of laxatives (liquid paraffin) for the treatment of cecal disorders delayed the time to first defecation. Moreover, magnesium hydroxide may be responsible for detrimental effects such as metabolic alkalosis,[796] increased ruminal pH,[797] and decreased ruminal microbial activity.[797] Prokinetic drugs that can be used in the management of cecal disorders are presented in the section on the acute abdomen in cattle. Finally, animals should be fed a high-fiber diet. Some cattle have recurrent episodes of cecal dilation, and preventive

surgery such as typhlectomy may be indicated. In two reports the recurrence rate after surgery was about 10% within a year of the first incident.[789,790] Cattle with cecal volvulus require immediate surgical intervention, fluid management to correct the hypochloremic, hypokalemic metabolic alkalosis, and administration of NSAIDs to control pain. The prognosis for surgical patients depends on the degree of ischemic injury to the cecum and other structures involved in the obstruction.

32.143 INTESTINAL TUMORS

Intestinal tumors are rare in cattle. The most commonly reported intestinal tumors in cattle are adenocarcinomas. However, lymphosarcoma, adenoma, adenomatous polyps, carcinoid, leiomyoma, leiomyosarcoma, and fibrosarcoma have also been described.[798] The incidence in sheep is relatively high in some areas of the world. An unusually high incidence of intestinal tumors was seen in cull ewes in New Zealand in the mid 1950s.[799,800] The rate of gross lesions in asymptomatic ewes going to slaughter ranged from 0.4% to 4.4%.[801,802] Breeds of British origin were observed to have a higher incidence than “fine wool” breeds. In subsequent studies in New Zealand, Australia, South Africa, and Iceland, the type of husbandry practiced was linked to a higher incidence of tumors. Details of which specific common factor or factors might be responsible await further research. No specific environmental or toxicologic exposures could be incriminated.

Affected cattle or sheep may have a protracted course of weight loss with no other observable signs until near death. Alternatively there are reports of acute gastrointestinal disturbances manifested by colic, abdominal distention, and auscultable right-sided pings.[803] Although these cases are rare, they must be differentiated from other causes of acute obstruction in cattle such as cecal volvulus, intussusception, or abomasal volvulus. In cattle in which rectal examination is possible, the lesion may be detected on routine examination as an intramural mass or annular constriction of the jejunum or ileum. In sheep, the diagnosis is usually made at necropsy. Clinical signs in affected animals might include diarrhea, abdominal distention caused by the accumulation of gas and ingesta proximal to the obstruction, or ascites. The well-characterized lesions in sheep involve local spread of the tumor through the lymphatics and intraperitoneally. Ultimately, cellular deposits occur on all visceral and parietal peritoneal surfaces, severely impairing lymphatic drainage from the abdomen.

32.144 MESENTERIC FAT NECROSIS

Mesenteric fat necrosis affect cattle of all breeds, but more commonly Aberdeen Angus and Jersey cattle.[804] It has also been reported in a pigmy goat.[805] The cause remains unknown but dietary factors have been implicated, such as consumption of feed containing long-chain, saturated fatty acids; trace element deficiency; trauma; hormonal disturbance; and ingestion of endophyte-infected fescue.[804,805] The lesions develop as an inflammatory response around degenerating adipose cells. The triglycerides in these cells are thought to undergo hydrolysis to glycerol and fatty acids. The longer the carbon skeleton and the greater the degree of saturation, the more resistant are the fatty acids to removal by normal cellular mechanisms. Remaining clumps or crystals of fatty acids serve as inflammatory foci for the subsequent necrotic masses.[804] Affected cattle have subnormal serum free cholesterol and elevated serum free fatty acids.[806] Cattle with fat necrosis may eventually develop an intestinal obstruction. The clinical signs resemble those of progressive intestinal obstruction from other causes. Weight loss, anorexia, diarrhea, bloody stool, abdominal enlargement, and right-sided ping are all possible signs. Fever, tachycardia, and signs of discomfort such as tenesmus, treading, and teeth grinding may be seen as the obstruction becomes more severe. Many affected cattle have no clinical signs, and the condition is discovered during rectal examination for other reasons. Rectal examination may be impossible because of stricture of the rectum, or dystocia may occur as a

result of the necrotic fat masses in the pelvic canal. Fat necrosis usually affects mature cattle,[804] but there is a report of a 6-month course of illness attributed to fat necrosis in a 13-month-old Black Angus heifer.[807]

Animals with fat necrosis that become clinical usually are not treated. Different treatments have been attempted over the years, but none was considered effective. Experimental therapy of subclinical fat necrosis using a compound that alters lipid metabolism in fungi was successful in one study.[806] The fungicide isoprothiolane was given at a dosage of 20 g/day PO for 8 weeks. Approximately half of the treated cows had a 50% reduction in necrotic masses by 12 weeks; at follow-up evaluation in 1 year the masses were not detectable in half the surviving cows. Cows given such unapproved drugs should not be used for food.

32.145 INTESTINAL INCARCERATION

Intestinal obstruction may occur in ruminants as a result of accidental entrapment of loops, usually of jejunum, around remnants of embryonic structures or through acquired defects in mesentery or the abdominal wall. Duodenal obstruction caused by malposition of the gallbladder was also reported in a heifer.[808] Intestinal adhesions caused by intraperitoneal injections of irritating substances may also lead to intestinal obstruction. Initial signs of colic followed by depression, anorexia, progressive abdominal distention, and absence of feces usually develop. Distended loops of small intestine usually are palpable per rectum. Remnants of the urachus,[809] the omphalomesenteric duct,[810] and the left umbilical vein[811] in cows and of the ductus deferens[812] in steers have been described as responsible for incarceration of the jejunum. The authors of one report indicated that 26% of cows examined had a persistent round ligament of the liver and falciform ligament.[811] Therefore tears in the falciform ligament leading to intestinal entrapment may be among the most common causes of the relatively rare problem of intestinal incarceration in cattle. Treatment of intestinal incarceration requires surgical intervention.

32.146 HEMORRHAGIC BOWEL SYNDROME (JEJUNAL HEMORRHAGE SYNDROME)

HBS or JHS is an acute enteric disease of cattle characterized by segmental intraluminal hemorrhage with subsequent obstruction of the small intestine. The disease seems to have been described for the first time in 1991[813] and is now considered an emerging disease in different countries.[814–817] HBS mainly affects dairy cows, but it is also reported in beef cows and a bull.[816,817] It is principally a sporadic disease, but outbreaks in dairy herds have been reported.[818,819]

The pathogeny of HBS is still unknown and may be multifactorial. *Aspergillus fumigatus* has been implicated in the disease,[820] but *C. perfringens* type A and *C. perfringens* type A with alpha 2–toxin are considered the most likely causes by many authors.[815,818,819,821] However, it is very difficult to clearly define the precise role of *C. perfringens* in the pathogenesis of HBS because *C. perfringens* type A is present in the intestine of healthy cows and is known to proliferate rapidly after death. Ewoldt and Anderson were unable to reproduce the disease by direct inoculation in the abomasum or jejunum of *C. perfringens* type A with alpha2–toxin.[822] According to the authors, this may be explained by the multifactorial pathogenesis of HBS. Different risk factors have been described in the development of HBS. They include lactation stage (being in the first 100 days of milk and in the second or higher lactation), feeding regimen (being fed with a TMR, or a high-energy diet with low fiber), and herd size (herds with more than 100 cows).[815,818,819,823] Berghaus and colleagues, in their study on risk factors associated with HBS, conclude that all management practices associated with high-producing cows may promote the occurrence of HBS.[823]

Affected animals may be found dead, but they typically demonstrated an acute decrease in milk production, anorexia, mild increase in heart rate, normal temperature and respiratory rate, and slight to moderate dehydration. These clinical signs worsen rapidly as the condition evolves. Mucous membranes are frequently pale or congested, which reflects the cardiovascular and hypovolemic shock. Animals usually have slight to moderate right abdominal distention. Clinical signs of abdominal pain may be present. Ruminal contractions are decreased or absent depending on the stage of the disease. The rumen may also be distended. In most cases, transrectal examination demonstrates intestinal distention, and scant to absent feces. An intestinal mass is rarely palpable per rectum. When present, feces contain digested and/or clotted blood. HBS must be differentiated from other cause of intestinal obstruction (intussusception, intestinal incarceration, volvulus of the intestine around the mesenteric root), dysentery (salmonellosis, coccidiosis, winter dysentery, coagulopathies), and melena from abomasal ulcers.

Signs of intestinal obstruction are observed during the transabdominal ultrasonography (distended intestinal loops, decreased or absent peristalsis). In some cases hyperechoic structures (blood clots) are observed in the lumen of the intestine.[815,817] Hematologic findings are consistent with a slight to moderate inflammatory process. Hematocrit is usually normal as a result of combined hemorrhage and hypovolemic shock. A hypochloremic, hypokalemic metabolic alkalosis is frequently observed on blood gas analysis, consistent with a proximal intestinal obstruction. Postmortem lesions consist of segmental necrohemorrhagic enteritis of the small intestine. The jejunum is the portion of the intestine most frequently involved.[815–817] An intraluminal blood clot associated with intramural hematoma and ulceration is observed. Histologic examination of the intestinal wall frequently reveals submucosal hemorrhage, edema, and neutrophilic infiltration, as well as necrosis and ulceration of the mucosa.[815–817]

The medical treatment of HBS consists mainly of fluid therapy to restore electrolyte imbalance and to correct dehydration and antimicrobial drugs and NSAIDs to control pain and inflammation. In our clinics we also found a beneficial effect of transfusion of 5 to 6 L of blood.[817] Surgical treatment consists of right flank laparotomy associated with enterectomy of the affected intestines. If the intestines do not look devitalized, the clot can be dislodged by manual massage or enterotomy.

The prognosis for animals with HBS is guarded. Mortality rates of 100%[816] and 77%[815] have been described. However, 55% of cases survived at Saint-Hyacinthe.[815] Two animals out of five that were treated medically and 18 animals out of 30 treated surgically survived.

Because the etiopathogenesis of HBS is not well understood, it is difficult to provide recommendations for the prevention of HBS. Prevention may be focus on management practices, and particularly feeding practices in order to provide adequate fiber length and quantity in the diet. There is currently no available vaccine against *C. perfringens* type A. Vaccination with the commercially available seven-way clostridial vaccines does not appear to protect against development of HBS.[823]

32.147 ILEUS (PSEUDOOBSTRUCTION)

Failure to pass feces usually is a sign of intestinal obstruction. However, in adult, lactating dairy cattle, a condition of ileus of the intestinal tract that mimics complete intestinal obstruction is commonly observed. The condition often resolves spontaneously or with medical treatment (fluids, calcium, and pain management); in rare instances surgical decompression of the affected bowel is required. In a series of 100 referred cases of intestinal obstruction, 39 were judged to be simple ileus.[824] Cows are most often in early lactation, and treatment is sought for partial anorexia. Colic sometimes is the presenting sign. Clinical examination reveals a normal temperature, a normal to elevated heart rate, and normal respiratory rate. Ruminal motility is decreased. Slight right-sided abdominal

enlargement may be seen early and may progress to extreme distention of the abdomen on the right. No borborygmi are heard on the right side, but fluid tinkling sounds may occur. Simultaneous auscultation and percussion reveal areas of variable-pitched resonance. Succussion produces sloshing sounds. On rectal examination a distended spiral colon, cecum, or small intestine may be palpated. Early in the course of the disease the distention is not extreme, and compression easily flattens the affected bowel. If abdominal distention is severe, introducing the arm into the abdominal cavity may be difficult because of the pressure of distended bowel at the pelvic inlet. No feces are passed, but the examiner's arm may be coated with sticky mucus and feces with a stale odor. Evaluation of serum electrolytes usually reveals no abnormalities or hypochloremic hypokalemic metabolic alkalosis. Serum calcium may be decreased. Differential diagnoses to consider include intussusception, intestinal incarceration, intestinal volvulus, and cecal dilation. There is no blood in the feces, and no masses are palpable per rectum with pseudoobstruction.

Because most obstructive lesions of the intestine in cattle are not immediately life-threatening, symptomatic therapy or simply close observation may be elected for 24 hours. If surgery is elected in the absence of an obstructive lesion, the bowel may be decompressed and drained. This is a laborious procedure that requires multiple punctures unless the distention is restricted to the cecum and spiral colon. Despite the lack of correction of a specific underlying defect, many cows begin passing feces soon after an exploratory celiotomy. Manipulation of the intestinal tract alone seems to have beneficial effects.[824] This response is difficult to differentiate from the spontaneous recovery that may occur without surgery in cows. Relief of distention of portions of the intestinal tract may remove reflex inhibition of motility that can occur in response to extreme stretching of mural tension and pain receptors. The cause of pseudoobstruction of the intestine is unknown, and little pathophysiologic information has been elucidated. Medical management is described in detail in the acute abdomen section. It mainly includes administration of fluids, calcium, and NSAIDs. Numerous practitioners also administer oral laxatives, but as mentioned earlier the practice of using magnesium salts may be questionable and could have deleterious effects.

32.148 DISEASES CAUSED BY *CLOSTRIDIUM PERFRINGENS* TOXINS (ENTEROTOXEMIA, YELLOW LAMB DISEASE, LAMB DYSENTERY, NECROTIC ENTERITIS)

Paul G.E. Michelsen

Bradford P. Smith

32.148.1 Definition and Etiology

C. perfringens is a toxin-producing, anaerobic, spore-forming rod. It is a variable species that causes a variety of diseases in human beings and animals. Some biotypes are normal inhabitants of soil, and some are commensal intestinal organisms of animals. A sometimes confusing nomenclature has evolved to organize the complexity of *C. perfringens* biology. Clinical isolates are assigned to one of the types (A through E) on the basis of possession of the major toxins (alpha, beta, epsilon, iota) (Table 32-21). In addition to these four major toxins, strains of *C. perfringens* may produce any of at least eight other recognized soluble antigens, some of which have pathogenic importance and could be called toxins. Beta 2–toxin may be an important toxin as well.[825] Most of these antigens are named with Greek letters.[826] The soluble *C. perfringens* toxin responsible for one type of food poisoning in humans has not received a Greek-letter name but is commonly known as enterotoxin (or CPE for *C. perfringens* enterotoxin). Enterotoxin is also the general name for toxins that affect the intestines, and many of the *C. perfringens* antigens with Greek-letter names are also enterotoxins. In this discussion the toxin that causes food poisoning in human beings is denoted CPE to distinguish it from enterotoxin as a class of toxins. CPE is not

recognized as the major component of classic *C. perfringens* disease in animals, but it may be important in some cases.[827,828]

The different biotypes of *C. perfringens* cause different diseases because they have different toxins, but a clear-cut assignment to one of the groups is not always possible, and overlap is considerable in the clinical signs caused by the various toxins. Many different diseases in many different animals have been ascribed to *C. perfringens*, but the ubiquitous nature of the organism and the fact that it rapidly overgrows into tissues after death makes the significance of its isolation questionable at times.

One additional potentially confusing bit of nomenclature concerns the term "enterotoxemia." Although this term is widely applied to various diseases caused by *C. perfringens*, it is strictly appropriate only for diseases in which the major signs are caused by systemic spread of the toxin in the blood.

One group of diseases caused by *C. perfringens* type C is commonly called "hemorrhagic enterotoxemia," even though the disease is not always hemorrhagic and, although the toxin may incidentally reach the circulation, it is produced in the intestine and exerts its major effects locally. A better descriptive name for this disease has been proposed to be necrotic enteritis.[829] It is important to realize that many of the effects of other biotypes of *C. perfringens* are systemic and that enteric clinical signs may be entirely lacking with disease caused by *C. perfringens* types A and D. Each type is discussed in the following paragraphs. Type E is only occasionally isolated from livestock and is not discussed.

32.148.2 Diagnosis of Disease Caused by Clostridium Perfringens

Meaningful diagnosis of *C. perfringens* as the cause of death or disease in an animal requires an integrative, open-minded approach. Type A is routinely isolated from soil and clinically normal animals. Types C and D are only rarely isolated from soil but can be isolated from asymptomatic individuals, especially those with neutralizing antibody to toxin. The bacterium proliferates after death, often crowding out other enteric organisms and invading tissues beyond the gut. The isolation of *C. perfringens* from a necropsied animal is not by itself sufficient basis for the diagnosis; however, if toxin is also demonstrated in gut contents and the history and lesions are compatible, a diagnosis of death from *C. perfringens* intoxication can be made.

870 871

Table 32-21 Types of *Clostridium perfringens* by Toxin Type and Diseases That

Have Been Attributed to the Type*

Group Typing Toxins					
Type	**Alpha**	**Beta**	**Epsilon**	**Iota**	**Diseases Attributed**
A	XX	—	—	—	Gas gangrene (along with other organisms) Avian necrotic enteritis Hemorrhagic enteritis in cattle Yellow lamb disease Enterotoxemia of mink Type A enterotoxemia of horses Abomasal tympany and ulcers of calves[837] Sudden infant death syndrome (crib death) Food poisoning in humans
B	X	XX	X	—	**Lamb dysentery**[829,840] Enterotoxemia of sheep and goats (Iran) Enterotoxemia of foals (Britain)
C	X	XX	—	—	**Necrotic enteritis** (neonatal hemorrhagic enterotoxemia of calves, lambs, kids, foals, piglets)[829,839] Necrotic enteritis of fowl, struck (enterotoxemia) of sheep (Britain) Necrotic enteritis of humans (pigbel, Darmbrand)[829]
D	X	—	XX	—	**Enterotoxemia** ("overeating disease," "pulpy kidney disease") of sheep, goats, and cattle
E	X	—	—	X	Enteritis in rabbits Occasionally isolated from sheep and cattle Abomasal tympany and ulceration of calves[837]

X, Toxin of minor importance; *XX*, toxin of major importance; —, not present.

* Diseases of major veterinary importance are in boldface.

Until recently, an isolate of *C. perfringens* was assigned to one of the five biotypes by demonstrating toxin production with mouse-protection assays or ELISA techniques. This has been replaced by a multiplex PCR technique that detects the genes for toxin production in a clinical isolate.[830] CPE, which causes food poisoning in human beings, can be detected with commercially available assays and is also detected by the multiplex PCR technique.[831] Meaningful samples for bacterial isolation come from freshly dead animals. Samples of gut contents should be collected into sterile containers and cooled or frozen. In addition to typing bacterial isolates, demonstration of toxin itself in gut contents may aid in diagnosis. False-negative results may occur in type C disease if proteases inactivate the beta-toxin.

In the absence of definitive microbiologic evidence, a presumptive diagnosis of type C or D disease must be based on the history, clinical signs, pathologic findings, and differential diagnoses. Administration of toxoid vaccines is cheap and effective and may be recommended without conclusive evidence for causation. This "whole herd" protection test may be as close as one gets to definitive diagnosis in field situations. Examination of gut-content smears from various levels of the gastrointestinal tract to demonstrate large numbers of bacteria resembling *C. perfringens* may be a helpful piece of information, but the significance of such a finding by itself is questionable. Glucosuria in urine obtained from the bladder at necropsy is often seen in sheep (but not other species) with type D disease.

Type D disease should be distinguished from other causes of acute death (see Chapter 14). A history of sudden

death in a rapidly growing, apparently healthy individual is characteristic. A single lamb is much more likely to have overeating disease than is a twin. Other causes of acute disease in well-fed individuals include systemic pasteurellosis (lambs), acute bloat, grain overload, polioencephalomalacia, and thromboembolic meningoencephalitis (cattle). These generally have a longer disease course than type D enterotoxemia.

32.149 *CLOSTRIDIUM PERFRINGENS* TYPE A (JEJUNAL HEMORRHAGE SYNDROME, YELLOW LAMB DISEASE, AND OTHERS)

C. perfringens type A can be found in many soils and is a normal inhabitant of the gut in many species. Although all five types of *C. perfringens* produce alpha-toxin, type A strains usually produce more than other types. The toxin is a phospholipase and causes lysis of red cells, platelets, and leukocytes (equine and caprine red cells are resistant to the hemolyzing effects of toxin). The toxin also causes vascular permeability through endothelial damage and can cause necrosis at the villous tips in the intestines.[826] There is also a report of type A having the gene to produce a beta 2–toxin.[832] The beta 2–toxin may act synergistically with alpha-toxin to cause necrotic and hemorrhagic intestinal lesions.[825]

32.150 HEMORRHAGIC BOWEL SYNDROME

HBS (JHS, hemorrhagic enteritis) is an acute often fatal condition of cattle characterized by segmental intraluminal hemorrhage in the small intestine.[833] The jejunum is the most commonly affected portion of the small intestine. The disease is considered to be an emerging disease of lactating dairy cattle in the United States, with 9.1% of herds in a 2002 National Animal Health Monitoring System (NAHMS) study reporting at least one case of HBS during the previous 5 years. It appears that high milk production is related to the condition, probably through feeding practices and management factors.[834]

871

872

Affected animals usually are anorectic, have a moderately elevated heart rate, and have a normal to subnormal temperature. Other signs consistent with small intestinal obstruction also develop, but abdominal pain is not usually observed. Feces may contain partially digested or clotted blood, and distended loops of intestine may be palpable per rectum. Transabdominal ultrasound may show an increased intestinal diameter proximal to the lesion, hyperglycemia, hyponatremia, hypochloremia, hypokalemia, and hypermagnesemia.[835]

Both medical and surgical approaches to treatment have had limited success. On postmortem examination *Clostridium* species may be seen in affected tissues. The odds of isolating *C. perfringens* type A from intestines of cows affected with HBS was 8.5 times greater than for cows with LDA.[833] Another theory is that *A. fumigatus* is the causative agent of HBS.[833]

Increasing the percentage of long stem fiber in the diet is associated with a decrease in number of cases of HBS.[834] The value of vaccination in preventing HBS has yet to be documented.[833] An attempt to reproduce the condition by inoculating either abomasa or jejuna of cows with *C. perfringens* type A failed to produce illness or lesions.[836]

Yellow lamb disease (so named because of the icteric nature of necropsied lambs) is an uncommon disease attributed to *C. perfringens* type A. Widespread hemolysis leads to anemia, weakness, hemoglobinuria, and icterus. The animals have a high temperature and usually die within 6 to 12 hours of onset. Differential diagnoses for yellow lamb disease include other causes of hemolytic disease, including leptospirosis and copper toxicosis. As with other type A infections, the diagnosis is always questionable owing to the commensal nature of the organism and its rapid invasion after death. The finding of predominantly large gram-positive rods in impression smears from

intestinal mucosa lends support to the diagnosis. No vaccine against type A disease is marketed in the United States, and types C and D toxoids are not expected to protect against type A unless they also contain alpha-toxoid.

One report implicates type A in neonatal calves with ruminal and abomasal tympany, abomasitis, and abomasal ulceration. The calves were 2 to 21 days old and died acutely or had signs of colic and depression of short duration.[837] Type A is a relatively common cause of food poisoning in human beings. Speculation links this type to human sudden infant death syndrome ("crib death") as well.[838]

32.151 *CLOSTRIDIUM PERFRINGENS* TYPE B (LAMB DYSENTERY)

Lamb dysentery is a disease of young lambs in Britain and South Africa. Type B has not been isolated in North America. Its clinical course and presentation are similar to those of necrotic enteritis caused by *C. perfringens* type C. Lambs less than 1 week of age become depressed and die. A yellowish diarrhea becomes brown from blood as the disease progresses. Morbidity may be high, and mortality approaches 100%. Necropsy findings include ulcers (rarely perforating) in the small intestines and dehydration of the carcass and tissues. Sanitation and the use of type B vaccine aid in prevention and control. Types C and D toxoid cross-protect because of the overlap in toxin types.

32.152 *CLOSTRIDIUM PERFRINGENS* TYPE C (NECROTIC ENTERITIS; NEONATAL HEMORRHAGIC ENTEROTOXEMIA; PIGBEL; STRUCK)

32.152.1 Definition and Etiology

C. perfringens type C elaborates the alpha (hemolytic)-toxin common to all types, in minor amounts, and the beta-toxin in major amounts. The amount of beta-toxin produced may determine the pathogenicity of a type C strain. In addition, type C strains produce the cytotoxic and hemolytic alpha-toxin, which is used to assign strains to group C if they have lost the ability to produce beta-toxin in culture.[839] Beta-toxin appears capable of producing all the signs of necrotic enteritis; the role of alpha-toxin or CPE in disease is unclear.[829]

Necrotic enteritis is primarily a disease of neonates and occurs in calves, lambs, foals, and piglets. A similar disease in adult sheep, known as *struck*, has a very limited geographic range in Great Britain.

32.152.2 Clinical Signs and Differential Diagnosis

Affected animals may die acutely without diarrhea, but this is rare. The diarrhea may be yellow or, in more hemorrhagic cases, brownish. Gray-red streaks of necrotic mucosa may be present in the stools. Foals with type C disease at first show acute abdominal pain, then explosive yellow diarrhea that becomes brown and hemorrhagic.[839] Animals become dehydrated, anemic, weak, and moribund, despite intensive therapy. Morbidity and mortality are high, but the disease is quite sporadic in occurrence. Salmonellosis and coccidiosis should be considered in the differential diagnosis, but necrotic enteritis is the more common disease in very young animals.

32.152.3 Pathophysiology

The causative beta-toxin is readily destroyed by proteolytic enzymes such as trypsin. The neonate is especially predisposed to beta-toxin attack by the presence of trypsin inhibitors in colostrum, the function of which is to prevent proteolytic degradation of immunoglobulins. Necrotic enteritis in humans is believed to be caused by decreased proteolytic activity arising from low-protein diets or the consumption of sweet potatoes, which contain heat-stable inhibitors of trypsin.[829] The scattered cases of necrotic enteritis in adult animals may be the result of similar dietary factors. Type C disease has been reproduced experimentally in maturing lambs by administering type C cultures and soybean flour, which contains potent protease inhibitors.[840]

Fig. 32-105 Perirectal and vulvar edema in a 3-month-old calf with acute oak bud toxicity. Acute acorn or oak poisoning causes similar lesions.

Ingestion of a protein-rich diet into a protease-deficient intestinal tract allows rapid growth of *C. perfringens* organisms. The bacteria attach to the villi, and elaboration of the cytotoxic beta-toxin results in necrosis and invasion of deeper intestinal layers. Death may result from the direct effects of the severe diarrhea or may be caused by secondary bacteremia or toxemia from the compromised gut barrier.

32.152.4 Epidemiology

Neonates that ingest type C organisms during the first few days of colostrum feeding are at risk. They pick up the organism from an environment contaminated by an asymptomatic shedder or from contaminated feed. Type C may be isolated from asymptomatic individuals on occasion, but it is not considered a normal commensal as is type A. Once established on a premises, the disease may become endemic. In foals the disease is significantly associated with housing in a stall or drylot during the first 3 days of life, previous presence of livestock on the farm, low amounts of grass hay fed postpartum, being born on dirt, and having stock horse parentage (e.g., quarter horse, Paint). Feeding smaller amounts of grain prepartum is associated with decreased incidence of the disease.[841]

872

873

32.152.5 Necropsy Findings

Necrosis of the mucosa of the small intestine, especially the jejunum, is the consistent finding in all species. The large intestine may be normal except for intraluminal blood. The peritoneal cavity often contains excessive fluid, which clots when exposed to air. The mesenteric lymph nodes may be hemorrhagic. Microscopically, affected gut shows hemorrhage throughout the mucosa and submucosa. The tips of the necrotic villi are covered with numerous, large, gram-positive rods.

32.152.6 Treatment, Prevention, and Control

Once a case becomes clinically apparent, treatment generally is unsuccessful because of the fulminant nature of the disease. Foals can be treated with supportive intravenous broad-spectrum antibiotics (to cover gram-negative bacteremia caused by loss of gut integrity), fluids, plasma (intravenous and oral), withdrawal of milk for 24 hours, oral metronidazole, and intravenous *C. perfringens* types C and D antitoxin. Metronidazole (10 mg/kg PO or IV given twice daily) can be given to at-risk foals in the face of an outbreak, beginning at 8 to 12 hours of age and continuing for 5 days.[842] Toxoid has been administered to horses[843] to control the disease on an apparently endemic property, with good results. Antitoxin* may be given to animals at risk in an outbreak, and *C. perfringens* types C and D are common components of multivalent vaccines. The primary vaccination series consists of two injections 1 month apart, with the final dose given 2 weeks before parturition, and a yearly booster thereafter. Neonates should be vaccinated at 8, 12, and 16 weeks of age on problem farms.

* Dybelon *C. perfringens* types C and D antitoxin, Bio-Ceutic, St. Joseph, MO.

32.153 *CLOSTRIDIUM PERFRINGENS* TYPE D (ENTEROTOXEMIA, OVEREATING DISEASE, PULPY KIDNEY DISEASE)

32.153.1 Definition and Etiology

Enterotoxemia caused by *C. perfringens* type D is a disease of major importance in sheep and of lesser importance in cattle and goats. It is caused by strains of the bacterium that produces the epsilon-toxin. This type is not a common soil organism, as is type A, but it may be isolated from the feces of apparently normal sheep and, less often, cattle.[844] Most clinical disease occurs in animals fed a highly nutritious diet, especially grain-fed livestock.

32.153.2 Clinical Signs and Epidemiology

The sudden death of a well-fed, rapidly growing animal is the most common presentation of enterotoxemia. The disease may run its course in 30 to 90 minutes, with affected lambs showing ataxia, trembling, stiff limbs, opisthotonus, convulsions, coma, and death. At the onset of clinical signs, the animal is hyperglycemic. At death it is glucosuric. The differential diagnoses should include other causes of neurologic signs and acute death: anthrax, botulism, black disease, leptospirosis, listeriosis, enterotoxigenic *E. coli* infection, septicemia, polioencephalomalacia, toxic indigestion (grain overload), systemic pasteurellosis, and tetanus.

Sublethal doses may result in brain damage and focal symmetric encephalomalacia (see diseases of nervous system, Chapter 35). Affected lambs are dull and unresponsive to normal environmental stimulation. The major differential diagnosis is polioencephalomalacia. Experimental intravenous injection of type D epsilon toxin into calves produced neurologic signs and severe acute pulmonary interlobular edema. The histologic lesions in the brain consisted of perivascular proteinaceous edema in the interna capsule, thalamus, and cellebellar white matter, whereas in the lung intraalveolar and interstitial edema were found. These are similar to some of the lesions found in sheep and goats with type D enterotoxemia.[845]

The disease in goats is usually confined to the intestinal tract and seldom involves system signs seen in sheep.[846]

32.153.3 Pathophysiology

In some feedlot situations the animal ingests *C. perfringens* type D on a regular basis, but the acid environment of the abomasum and continuous peristalsis, as well as low amounts of fermentable substrate, conspire to keep bacterial numbers low and moving out of the animal. The intestinal environment also influences the amount of toxin produced.

Some factor of overnutrition, often heavy grain feeding or very rich pasture, provides substrate for rapid proliferation of the type D organism, leading to elaboration of the prototoxin. Cleavage of the prototoxin by proteases yields the active toxin. Epsilon toxin increases intestinal permeability, causing edema in a variety of organs, notably the lungs, kidney (hence the name “pulpy kidney disease”), and brain (focal symmetric encephalomalacia). Excess pericardial, peritoneal, and pleural fluid (with or without fibrin) and subcapsular petechiation in the kidneys may be seen.[847] These lesions cause rapid deterioration and death. Hyperglycemia and glucosuria are the result of massive hepatic glycogen release caused by the epsilon-toxin.

32.153.4 Necropsy Findings

Postmortem lesions are inconsistent. The pulpy kidney lesion may not be seen in freshly examined specimens. The epicardium, serosa, thymus, and diaphragm may have small areas of hemorrhage. The pericardial sac often contains excess fluid. The lungs may be edematous. Glucosuria is considered a hallmark of type D enterotoxemia but is sometimes not present. Histologic lesions include pleural and interlobular and perivascular edema in the lung, as well as perivascular edema in the brain of some affected animals.[847]

32.153.5 Treatment, Prevention, and Control

If initiated at the first suspicion of overeating disease, type D antitoxin and oral antibiotics (sulfa) may have dramatic results.[848] The diet should be adjusted downward in outbreaks to try to minimize the substrate, especially starch, that reaches the bacteria. Lambs on rich pasture should be moved to poorer pasture or corralled and fed hay until they have been vaccinated twice. Lambs and calves brought into a feedlot should have the concentrate ration increased slowly to minimize microfloral disruptions.

Antitoxin can be given in an outbreak, but previous vaccination is more effective. Vaccination with type D bacterin-toxoid is effective in preventing disease. Two doses are given 14 to 56 days apart, before heavy grain feeding or exposure to rich pasture begins. The aluminum hydroxide adjuvanted vaccines may cause raised subcutaneous lumps (most noticeable on goats) that may go on to abscess. Dairy goats fed continuous high-grain rations may need to be vaccinated more often for continuous protection. One study of three commercial vaccines found that one of the vaccines provoked no antibody response in goats 14 days after vaccination and that at 28 days after vaccination, even the goats that had responded to the other two vaccines had titers no higher than unvaccinated controls.[849] The vaccine is not licensed in the United States for use in goats but is routinely used. Bummer lambs may be protected by feeding bovine colostrum from cows vaccinated several times with the sheep vaccine to provide high titers in colostrum.[850] Colostral titers from the dam are protective to 12 weeks of age, after which vaccination should be used to provide active immunity against the disease.[851]

873 874

32.154 BETA 2–TOXIGENIC *CLOSTRIDIUM PERFRINGENS* TYPHLOCOLITIS IN HORSES AND RUMINANTS

Beta 2–toxin is a newly described *C. perfringens* toxin that may play a role in intestinal diseases of ruminants and adult horses, particularly typhlocolitis. Affected animals may have a history of recent stress or antibiotic administration and show hemorrhagic, profuse, watery diarrhea, low body temperature, severe leukopenia, and hypoproteinemia.[852] The diagnosis depends on demonstration of the beta-2 gene by PCR.[853]

32.155 OAK (ACORN) TOXICOSIS

Bradford P. Smith

32.155.1 Definition and Etiology

Toxic signs can appear in ruminants[854,855] and occasionally in horses[856] that ingest large quantities of oak buds, oak leaves (green or dried), or acorns. Most species of oak (*Quercus* species) cause similar signs when ingested, although there are marked differences in the amount of toxins among the 75 oak species.[857] The metabolites of oak tannins and volatile phenols present in the buds, leaves, twigs, and acorns are responsible for causing toxicosis. The mouth, esophagus, gastrointestinal tract, and kidneys (renal tubular nephrosis) are the organs most affected. Because they are less selective in what they ingest, cattle seem to be the most frequently affected species. Signs begin shortly after ingestion of 50% or more of the diet as oak, and young cattle (under 300 kg) often appear to be more severely affected than adult cattle.

Factors leading to toxicosis include the presence of large acorn crops when forage is scarce, wind or hail that

causes large numbers of acorns to drop suddenly, or the sudden presentation of oak buds and young leaves to hungry cattle, as in spring windstorms or snowstorms that cover the grass and break branches. In the southwestern United States, range cattle regularly consume some oak species, which are apparently highly palatable and nutritious.[858] The condition has been described wherever oak grows, including most of the United States, France, Great Britain, Germany, Sweden, Australia, China, and South Africa.

Acorn calf syndrome is completely different from the oak toxicosis described in this section. Acorn calves are congenitally malformed calves born to dams that ingest large numbers of acorns under poor forage conditions during the second trimester of pregnancy. The cause appears to be a combination of poor nutrition and exposure to acorns. The calves have very short leg bones and may have abnormal hoof development and a short or long narrow head. In badly affected herds as many as 15% of calves are affected. The disease has been reproduced experimentally. Supplementation of the herd with adequate protein and energy eliminates the disease.

32.155.2 Clinical Signs and Differential Diagnosis

The course of oak toxicosis usually is 1 to 12 days, but some cattle have a protracted, debilitating disease.[854,855] In the peracute stages cattle are recumbent, weak, anorectic, and listless.[854] The rectal temperature is normal or below normal, and the heart and respiratory rates are elevated. Marked edema is present in the perineum and vulva (Fig. 32-105), and edema is obvious in the submandibular area, brisket, and ventral abdomen. Hydration appears adequate, but anuria is present. Firm, dark, mucus-covered feces usually are present. Evidence of hydrothorax, hydropericardium, and ascites may be noted on physical examination. Some cattle may simply be found dead.

A day or two after ingestion the animals appear anorectic and listless and have decreased ruminal motility. Many calves have hemorrhagic diarrhea or dark diarrhea that tests positive for fecal occult blood. The feces may have a smell of phenol. Dehydration occurs rapidly, but vital signs may be remarkably normal until hypovolemia develops. As uremia progresses, scleral vessels become dark and engorged, and the breath may take on the smell of ammonia. The major differential diagnoses are other causes of renal failure and other toxins and clostridial diseases; viral diseases that cause ulceration of the alimentary tract should also be considered. Protracted cases most often result from renal failure and uremia, although some animals have chronic oral, esophageal, or gastrointestinal ulceration or perforation with abscessation.

In horses signs usually are peracute or acute; they include sudden death or colic, tenesmus, and hemorrhagic diarrhea.[856] Acorn husks and shells may be noted in the feces. As with most colics, tachycardia, hyperpnea, and injected oral mucous membranes are seen. Increased abdominal borborygmi often are present, and hemoglobinuria may occur. Determination of serum or urinary phenolic (hydrolyzed tannin) content, based on a gallic acid standard, may be used in acute cases.[856]

32.155.3 Clinical Pathology

In cattle with peracute and acute signs, the serum urea nitrogen and creatinine are elevated, whereas other laboratory values may show considerable variation.[855,856] Initially hyponatremia, hyperkalemia, hypochloremia, hyperphosphatemia, and a marked hypocalcemia (5.1 to 6.8 mg/dL) accompany a mild metabolic acidosis with a very high anion gap (29 to 32).[854] Neutrophilia with mild hyperfibrinogenemia may be present. Although sorbitol dehydrogenase and GGT may be elevated, biopsy does not indicate that significant hepatic disease occurs with oak toxicosis. Animals may be anuric. If urine is being produced, often isosthenuria, proteinuria, and glucosuria occur. The urinary fractional excretion of sodium was elevated in one steer.[858]

874
875

In protracted cases the major findings are elevated serum urea nitrogen, creatinine, and anion gap, with variable hyponatremia, hypokalemia (versus hyperkalemia in acute stages), hypochloremia, and hyperphosphatemia. A mild metabolic alkalosis may be present. Hyperfibrinogenemia and an increase in total plasma proteins also are variable. An elevated WBC count most often reflects chronic ulceration or abscessation (neutrophilia or monocytosis or both). Liver enzymes usually are normal in protracted cases. Urinalysis results are similar to those in acute cases; in addition, hematuria often is present. By 6 weeks after exposure, a normocytic, normochromic anemia may develop as a result of chronic inflammation and uremia, and hypoalbuminemia may result from chronic renal and gastrointestinal losses. By 8 weeks after exposure, surviving cattle have largely returned to normal renal function as determined by normal serum urea nitrogen and creatinine concentrations and by the ability to concentrate urine after a 24-hour water deprivation test.[854]

Laboratory findings in horses are similar to those in ruminants, except that during the acute stages rapid hemoconcentration and marked increases in PCV occur.[856] Although protein, occult blood, and hemoglobin casts have been reported to be present in the urine, the urine specific gravity was 1.052.

32.155.4 Pathophysiology

The toxicity of oak is attributed to its high concentration of tannins, which are hydrolyzed in the rumen to gallic acid, pyrogallol, and other compounds. The tannins themselves may contribute to oral, esophageal, and gastrointestinal damage by binding to proteins, including those in epithelial cells. This results in oral, esophageal, and ruminal ulcers or perforations. Protein-bound tannins are liberated in the acidic abomasum, making them available once again to damage intestinal epithelium. Some hydrolyzed tannins are absorbed and bound to plasma proteins and endothelial proteins, resulting in hemorrhage and fluid loss from the vascular compartment into body cavities and tissues; this results in edema. The gallic acid and pyrogallols are extremely toxic to renal tubules, causing acute tubular necrosis, anuria, electrolyte abnormalities, and uremia. Ruminants are more susceptible than horses because of the hydrolysis of the gallotannins in the rumen.

32.155.5 Epidemiology

Young cattle in the 100- to 300-kg range seem to be particularly susceptible. In the southwestern United States oak toxicosis accounts for considerable economic loss in cattle.[858] The disease is seen sporadically in other ruminants and in horses. The morbidity rate in cattle varies considerably, with several to many calves in a pasture usually affected, and case fatality rates frequently exceed 80%.[855]

The disease is most often associated with ingestion of acorns in the fall and buds or young leaves in the spring. Cattle turned onto a pasture with oak trees under which acorns have accumulated may have toxicosis even when adequate forage is available.[855] In other cases windstorms have dropped numerous acorns or branches in a pasture to which cattle were already accustomed. In the early spring a heavy, unseasonable snowstorm may occur, covering the grass and bending young trees and breaking branches so that oak buds and young leaves are accessible.[854] Young leaves and acorns are more palatable than older leaves and also contain more tannins (up to 10% dry matter in acorns). The seedlings, buds, and acorns of small scrub oak may be important forages for cattle in parts of the United States.[858]

32.155.6 Necropsy Findings

In peracute and acute cases prominent edema is often the most striking lesion. Ascites, hydrothorax, hydropericardium, perirenal edema, and subcutaneous edema are found. The kidneys are normal in size with multiple diffuse hemorrhages on the surface and extending into the cortex. The liver is slightly swollen and pale or mottled. Digestive tract lesions vary from congestion to hemorrhage and deep ulceration or perforation with necrotizing inflammation. Mucosal ulceration is found in the pharynx, esophagus, rumen, abomasum, small intestine, cecum, and colon. Free blood or melena may frequently be observed.

Diffuse renal tubular damage is present. The changes include coagulation necrosis of cortical tubular epithelium and dilated tubules devoid of epithelium but with intact basement membranes. Many medullary tubules contain hyaline, granular, or cellular casts. The principal renal lesion is necrosis of the proximal convoluted tubules, but glomerular degeneration and fluid in Bowman's capsules are also seen.

By 3 to 6 weeks after exposure, the lesions include gastrointestinal ulceration, often with secondary infection; some healed ulcers; secondary bacterial bronchopneumonia; and slightly swollen, pale brown kidneys. Histologically, atrophy of the cortical tubular epithelium with a marked interstitial fibrosis and mononuclear infiltrate is seen. Evidence of tubular epithelial regeneration may be present. The liver appears normal.

32.155.7 Treatment and Prognosis

In acute stages intravenous fluid therapy aimed at promoting diuresis and correcting acid-base and electrolyte abnormalities may be lifesaving. Calcium, sodium, and chloride deficits should be replaced, and sodium bicarbonate should be given if needed to correct metabolic acidosis. In anuric animals furosemide (1 mg/kg given IV) can be administered every 12 hours, along with adequate fluid therapy. Corticosteroids and NSAIDs are not likely to have a measurable effect on the course of the disease because they are unlikely to alter the direct toxic effects of the toxic metabolites. The prognosis is guarded and must be considered poor in animals that remain anuric despite therapy. The case fatality rate undoubtedly depends more on the amount of toxic material ingested than on therapy. Antibiotics, given to prevent secondary pneumonia and abscessation, ruminal transfaunation, and readily accessible grass hay and water are recommended components of nursing care.

If the animal survives the acute stage and begins to eat voluntarily, the prognosis for recovery is good unless secondary pneumonia or gastrointestinal abscessation after perforation occurs. Renal function can return to normal by 5 to 10 weeks, and weight gains as high as 1.76 kg/day may be recorded in recovered cattle.[854]

Colicky horses can be treated as one would usually treat colic (intravenous fluids, analgesics, oral laxatives). Particular attention should be paid to diuresis, acid-base balance, and maintenance of serum calcium levels.

32.155.8 Prevention and Control

No specific antidote exists for oak toxicosis, but supplementation with calcium hydroxide (hydrated lime) immediately before anticipated exposure to oak has been effective under experimental conditions.[859] Feed containing 10% or less calcium hydroxide is palatable. Consumption of 0.9 kg/head/day of cubed or pelleted supplement containing 10% hydrated lime is effective in preventing toxic manifestations.

875

876

Supplementation of cattle suddenly exposed to oak with any feed reduces death losses, apparently by allowing

hungry cattle to consume the supplemental forage preferentially.[854,859] In an outbreak in California caused by spring snows in which 2700 cattle died of oak toxicosis, ranches where hay was immediately supplemented had minimum losses compared with ranches where feed supplementation was not offered.

32.156 WINTER DYSENTERY IN CATTLE

Charles L. Guard

Gilles Fecteau

32.156.1 Definition and Etiology

Winter dysentery is an acute, contagious diarrheal disease of cattle that occurs in epizootic fashion in a herd, usually during the colder months of the year. It is usually recognized by the clinical syndrome that occurs in herds and by exclusion of other causes of contagious diarrhea.[860] In the United States the disease is more common in the northern states; however, it has been reported in Australia, Sweden, the United Kingdom, Israel, France, Belgium, Japan, and Canada. The period of illness in an individual is brief, and within a herd the outbreak usually lasts less than 2 weeks. Recovery is spontaneous in most individuals, but in some cases supportive therapy may be indicated. The morbidity rate may be high in a herd that has not experienced winter dysentery for several years; regardless, mortality usually is rare. Although most reports indicate this to be a disease of adult cattle, in a herd outbreak mild diarrhea may be observed in animals as young as 4 months old.

There is still uncertainty regarding the precise cause of winter dysentery, but most recent attention has focused on a coronavirus that may be the same as or related to the coronavirus that causes diarrhea in neonatal calves. In Japan, France, Belgium, and the United States, investigators have identified a coronavirus or similar virus particle in the feces of cattle with winter dysentery.[861–866] The disease was reproduced by contaminating feed with untreated feces in one of two attempts.[861] By immune electron microscopy, antigenic cross-reaction has been demonstrated between the original Nebraska calf coronavirus diarrhea agent and coronavirus isolated from field outbreaks of winter dysentery.[863,865] A rise in serum antibody titer to the calf coronavirus after an outbreak of winter dysentery in adult cattle was found.[863]

32.156.2 Clinical Signs and Differential Diagnosis

Winter dysentery is an explosive diarrheal disease accompanied by some degree of anorexia and depression. In lactating cows, milk production is reduced. In rare cases mild colic may be observed; other animals may appear weak and prefer to lie down. If the diarrhea is severe or persists longer than a day, dehydration may develop. Weight loss is apparent and is caused by loss of ruminal fill and depletion of extracellular fluid. Ruminal motility usually is reduced, but intestinal borborygmi may be increased. Thirst often is increased, and polydipsia follows the diarrhea. Rectal examination may reveal dilated intestinal loops. The feces vary from light tan to dark brown; bubbles commonly form in the puddles that are deposited several feet behind the cow. Blood may be present in the feces of several animals in a group, typically in the first lactation heifers. The amount of blood may range from just visible to large clots, or it may be uniformly mixed into the feces. Some animals may have thick mucus in the feces. The odor in a barn during an outbreak of winter dysentery has been described as musty, fetid, and sweet and nasty.[867]

Fever usually is not present during the diarrheal phase of the disease but has been reported to precede it[860] or

have no consistent relationship.[868] Mild respiratory signs consisting of serous nasolacrimal discharge and a soft cough have been inconsistently observed before diarrhea. Diarrhea caused by BVDV, coccidiosis, and salmonellosis must be considered in the differential diagnosis of winter dysentery. With winter dysentery no mucosal lesions are visible on physical examination. The absence of coccidial oocysts or parasite ova in the feces helps exclude these agents as responsible for the diarrhea. However, diarrhea caused by parasites may precede the shedding of detectable organisms in feces. The rapid occurrence of multiple cases within a herd, and often within herds in a locality, suggests winter dysentery. Fecal culture for *Salmonella* yields negative results in uncomplicated cases of winter dysentery.

32.156.3 Clinical Pathology

No consistent hematologic changes that would be of diagnostic benefit have been observed. If significant dysentery persists for longer than a day, signs of anemia may develop.

32.156.4 Pathophysiology

If the current contention that a coronavirus or coronavirus-like agent is causal in winter dysentery is correct, the pathophysiologic characteristics of the disease can be attributed to lesions of the colonic mucosa.[864] Epithelial cells of colonic crypts are destroyed by viral action, leading to necrosis and hemorrhage. Even though histologic changes have been observed only in the colonic mucosa, blood was observed from the distal duodenum aborally in cattle that died of winter dysentery.[866] Loss of intestinal mucosal epithelium from colonic crypts leads to transudation of extracellular fluid and blood. The exact mechanism leading to the voluminous, watery diarrhea has not been clarified but may be related to the inflammatory nature of the disease. Mediators of inflammation may lead to hypersecretion in the small intestine and colon.

32.156.5 Epidemiology

The incubation period is thought to be 2 to 8 days. The most susceptible animals are first and most severely affected. In a small, housed herd, the typical incidence of diarrhea during an outbreak begins with the explosive appearance of signs in 10% to 15% of animals on the first day. The second day another 20% to 40% are affected. On subsequent days similar proportions become ill. By the end of a week the first affected animals are completely recovered, and only a few new cases occur. Typically within 2 weeks of the onset of diarrhea, all animals have recovered. This period is marked by significant reduction in milk production. In large herds the outbreak may be prolonged for 6 to 8 weeks. Animals in their first lactation usually are most severely affected, but other cattle recently fresh or otherwise stressed may also have a longer clinical course. This scenario is typical of a herd that had not experienced an epizootic of winter dysentery during the preceding few years. In some herds milder outbreaks occur annually, with fewer animals showing diarrhea and with less severe clinical signs.

876

877

32.156.6 Treatment and Prognosis

Most animals with winter dysentery recover spontaneously in a few days without specific treatment. Many palliative treatments have been recommended and used over the years, including intestinal astringents, protectants, and adsorbents. On the basis of 30 years of observations, Roberts[869] considered none of these treatments to alter the course of the disease. Provision of adequate fresh water, palatable feed, and free-choice salt is the most useful nonspecific therapy. The occasional animal with prolonged or severe dysentery may need

a transfusion of 4 to 8 L of whole blood.

32.157 SALMONELLOSIS IN RUMINANTS

Bradford P. Smith

32.157.1 Definition and Etiology

Salmonellosis is one of the few diseases that are increasing in prevalence. According to one study, 75% of dairies sampled in California had evidence of *Salmonella* infection.[870] A recent multistate study found that 56% of dairies sampled contained cows shedding *Salmonella* in feces.[871]*Salmonella* of concern for livestock fall mainly into one species, *Salmonella enterica*, with numerous serovars or serotypes, such as *S. enterica* serovar Typhimurium, with the words *serotypes* and *serovars* used interchangeably. We shorten it to *Salmonella* Typhimurium by convention. More than 2200 *Salmonella* serotypes (serovars) have been identified, and many are potential animal and human pathogens. Multidrug-resistant *Salmonella* Typhimurium DT104 and *Salmonella* Newport are particularly virulent to animals and human beings. The presence of identical strains of *Salmonella* Newport among bovine and human isolates indicates that zoonotic transmission is likely.[872] Fortunately 10 serotypes of *Salmonella* in serogroups B, C, D, and E are responsible for most disease in cattle; therefore control programs can be aimed at these. Table 32-22 lists the serotypes most commonly isolated from ill cattle in 2006 in the United States.[873] *Salmonella* organisms are gram-negative enteric bacteria that are facultative intracellular parasites. Most serotypes are non—host-specific, but a few are host-adapted. *Salmonella* Dublin is host-adapted to cattle, *Salmonella* Abortus ovis, and *Salmonella* Arizonae to sheep, and *Salmonella* Abortus equi to horses. Host-adapted serotypes are found most often in their host species, where true long-term carriers exist.[874] In contrast, non—host-adapted serotypes rarely achieve carrier status and usually infect an animal for a period of 3 to 16 weeks before infection is cleared,[874] although one cow with multidrug-resistant *Salmonella* Newport excreted the organisms for 190 days.[872] Infection with either host-adapted or non—host-adapted serotypes can be symptomatic or asymptomatic, depending on the dose, the virulence of the serotype, and the host's immune status. There appears to be an association between an increased incidence of *Salmonella* infections and intensive management practices such as large farms, crowded conditions, and high-protein diets. In the absence of carriers, chain infections and persistence of *Salmonella* in the environment are responsible for long-term persistence of a given strain on a given dairy.[872]

Table 32-22 Most Frequently Identified Salmonella Serotypes from U.S. Cattle

from July 2005 Through June 2006

Serotype	Serogroup
Typhimurium	B
Newport	C2
Orion var 15+34+	E1
Montevideo	C1
Agona	B
Courtesy Dr. Brenda R. Flugrad, APHIS, USDA, NVSL, Ames, IA.	

Salmonella are grouped into serogroups (A to Z and 51 to 65), depending on their cell wall antigens (somatic antigens that comprise specific oligosaccharides, often called *O antigens, LPSs*, or *endotoxin*). Thus, for example, local and regional laboratories often report that an isolate is a group D *Salmonella*. The most common group D isolate of cattle is *Salmonella* Dublin. Final confirmation that the *Salmonella* isolated is indeed *Salmonella* Dublin comes from the National Veterinary Services Laboratory in Ames, Iowa, or from some other laboratory in which antisera and facilities exist for identification of all 2200 serotypes on the basis of flagellar (H) antigens and somatic (O) antigens. Some serotypes also express capsular (Vi) antigens composed of mucopolysaccharide. Identification of the serotype is important in planning control strategies. In addition to the serotypes listed, lambs may be infected with *Salmonella* Arizonae, which comes from several different serogroups. *Salmonella* organisms are relatively easy to culture from the feces or tissues of infected animals, using common enteric agar such as XLT4 or brilliant green (BG) agar, with tetrathionate and selenite as selective enrichment media.

32.157.2 Clinical Signs and Differential Diagnosis

Salmonella infection can cause a variety of clinical signs. The most common signs are fever and diarrhea[875] after an incubation period of 1 to 4 days after exposure or a recrudescence from the carrier state. Animals of all ages may be affected, but serious illness is observed most frequently in very young animals and parturient dairy cattle.

The character of the diarrheic feces varies from watery to mucoid with fibrin and blood. Sheets of fibrin may appear to be sloughing mucosa. The feces often have a putrid, foul odor because of the presence of plasma proteins associated with severe IBD. Salmonellosis causes an acute protein-losing enteropathy. The systemic effects of endotoxins (and other toxic material) absorbed through the damaged bowel mucosa may be severe (fever, anorexia, depressed attitude, shock).

Bacteremia may occur rapidly, especially in neonates infected with *Salmonella* Dublin, *Salmonella* Typhimurium, or *Salmonella* Newport. Peracute to acute septicemia in calves may produce lesions in many organ systems. Affected calves usually are under 2 months of age (the range is 1 day to 6 months). Dyspnea, respiratory symptoms, sudden death, and occasionally diarrhea are the principal signs of *Salmonella* Dublin infection, the incidence of which usually peaks in 6-week-old calves. Blood culture results frequently are positive. Pure cultures of *Salmonella* Dublin often can be grown from specimens from the lungs of 4- to 8-week old calves with pneumonic (septicemic) salmonellosis. Calves infected with *Salmonella* Typhimurium are only 14 days of age on average (the range is 1 to 35 days) and have mainly enteric lesions, including enlarged mesenteric lymph nodes, abomasitis, fibrinonecrotic plaques in the ileum, and hemorrhage of Peyer's patches.[876]

Dry gangrene of the extremities may occur in calves after *Salmonella* infection, particularly with *Salmonella* Dublin. Legs, ears, and tails are most commonly affected, and cold agglutinins are suspected to be involved.[877]

In adult cattle, diarrhea or abortion may occur.[874] Abortion may occur by two mechanisms, because both culture-positive and culture-negative fetuses and placentae may be found in an outbreak. In the former, bacteremia in the dam results in infection of the placenta or fetus, with resulting fetal death and expulsion. Bacteremia and endotoxemia associated with diarrhea and damaged gut mucosa in cattle may result in release of $PGF_{2\alpha}$ and subsequent lysis of the corpus luteum. Abortion follows in 2 to 3 days, and the fetus and placenta will have culture-negative findings. When the fetus has a culture-negative finding, many other causes of abortion must be considered. Many infectious agents that infect only the dam can act similarly to cause luteolysis and abortion.

Differential diagnoses for the enteric form of salmonellosis in neonates include all the common enteropathogens of neonates: *E. coli*, rotaviruses and coronaviruses, clostridia, cryptosporidia, and other forms of coccidia. Concurrent infection with these agents is common. In older animals outbreaks should be differentiated from those caused by BVD, winter dysentery, and feed-induced indigestion. Pneumonic and bacteremic salmonellosis in 4- to 8-week-old calves must be differentiated by culture from pneumonic pasteurellosis; in goats, from mycoplasmal infection; and in lambs from septicemic pasteurellosis.

32.157.3 Clinical Pathology

Salmonella enteritis often results in changes in the hemogram,[878] as effects of endotoxin manifest.[879] Plasma fibrinogen frequently is elevated because of the inflammatory nature of the disease, and either neutrophilia or neutropenia may be seen. In severe cases a left shift may be present. Initial dehydration may result in an elevated PCV and plasma protein level. The plasma protein level often drops over a period of days as protein is lost into the bowel lumen. Many other nonspecific abnormalities in clinical chemistry values are often seen, including elevated liver enzymes, decreased plasma calcium, and indications of prerenal azotemia if dehydration occurs.

Definitive diagnosis of salmonellosis requires culture of the organism from feces, blood, or tissues. PCR is also available. Serologic evaluation to confirm the development of anti-*Salmonella* antibodies is useful[881] but is not commonly performed and is not currently available in most laboratories.

32.157.4 Pathophysiology

Salmonellae are invasive organisms that may penetrate ocular, nasal, oral, or intestinal mucous membranes. *Salmonella* infection is most often transmitted by fecal-oral contamination from livestock or rodents, or by feeding of contaminated protein source animal byproducts (e.g., fish meal, meat meal, bone meal, or feather meal, 40% of which are contaminated in the United States) or contaminated forages or plant proteins such as soybean or cottonseed.

Once eaten, salmonellae attach to mucosal cells, probably by means of a nonfimbrial adhesion.[881] Attachment is increased if gastrointestinal stasis is present or the normal competitive flora has been disturbed. Salmonellae cause degeneration of nearby cells and penetrate both through microvilli and through tight junctions between cells.[882] The bacteria pass through the enterocytes to the lamina propria, where they stimulate an inflammatory response and are engulfed by macrophages and neutrophils.[883] Intracellular bacteria reach regional mesenteric lymph nodes or beyond. The organism has a predilection for lymphoid tissues and is found in highest numbers in

Peyer's patches and mesenteric lymph nodes.[884] Thrombi form in vessels, and tissue damage can be severe. Virulent salmonellae are capable of surviving in host tissues and multiplying, often as facultative intracellular parasites in macrophages and reticuloendothelial cells.[885] In the case of carrier animals, salmonellae survive in cells in the presence of high titers of specific extracellular (i.e., serum) immunoglobulins. Intracellular salmonellae can also avoid many antimicrobial drugs and complement. Stress may cause a latent infection to recrudesce, resulting in fecal or mammary gland shedding or clinical disease.

The cell wall of all gram-negative bacteria contains LPS as a component. LPSs are also called *endotoxins*, and they are extremely biologically active, setting off an immunologic cascade of events that can lead to leukopenia, fever, anorexia, and eventually shock and death.[879]

32.157.5

Epidemiology and Control

A study of calves in California found that 18% of 1-day-old calves shed *Salmonella*, but this percentage declined rapidly over the first 11 weeks of life. Farms that received calves from other sources were 35 times more likely to have calves that were shedding *Salmonella* in feces than were closed herds.[886] Infection with host-adapted *Salmonella* serotypes may occur as a cyclic endemic disease, especially in calves when *Salmonella* Dublin is involved. *Salmonella* infections on a farm are maintained by (1) carrier animals shedding *Salmonella* Dublin in the feces[874] or milk,[880] (2) chain infections in infected calves and cows, (3) rodents, and (4) environmental contamination. *Salmonella* carriers infected with a host-adapted serotype such as *Salmonella* Dublin may shed constantly or intermittently. Cattle with the highest risk of becoming *Salmonella* Dublin carriers are heifers infected between 1 year of age and first calving and cows infected in the parturient period,[887] but calves surviving *Salmonella* Dublin infection and illness may also become carriers. Infected carriers that are not shedding are called *latent carriers;* stress may cause shedding in feces or milk to recrudesce. A single infected, asymptomatic fecal shedder may produce one billion *Salmonella* Dublin organisms per day to contaminate the environment (one million organisms per gram of feces). Unlike other serotypes, *Salmonella* Dublin may be carried as a chronic gut and mesenteric lymph node infection and passed in feces or carried as an intramammary infection and passed in contaminated milk.

Calving areas must be constantly cleaned and disinfected between calvings. Raw milk feeding to calves may be a source of *Salmonella* (100 to 100,000 organisms per milliliter of milk).[880] Infected calves constantly amplify the number of organisms in the environment, causing exposure of other calves. Calves with clinical signs may shed billions of *Salmonella* into the environment daily.

Environmental contamination can be difficult to eliminate, because salmonellae survive for months in moist areas out of direct sunlight and in lagoons and drainage areas. *Salmonella* Dublin was recovered from feces dried for 41 months.[888] Freezing feces at −20° C (−4° F) kills 85% of salmonellae in 2 days and over 95% by 1 month.[889] Direct sunlight and drying in hot weather are effective at eliminating salmonellae.

Research has documented contaminated irrigation water as an important source of *Salmonella* organisms. In some cases municipal sewage treatment plant effluents had contaminated water.[890] On one dairy farm, river water used to sprinkler irrigate green chop contaminated the green chop, which was fed to cows. On another farm, *Salmonella*-contaminated river water was used to irrigate cotton. When the cottonseed from that gin was used as feed, cattle became infected. On a third dairy, contaminated irrigation water resulted in haylage containing *Salmonella* organisms.[891]

878
879

Feedlot cattle colonized by *Salmonella* organisms could pose a public health risk when meat is contaminated at slaughter. In a study by NAHMS, 7.5% of cattle on feed the longest shed salmonellae, whereas 3.5% of cattle that had recently entered the feedlot were shedding salmonellae in the feces.[892] Contamination of the animals before entry can cause the entering cattle to have a higher rate of shedding than was found in cattle that had been in the feedlot for several months[893] Standing water contaminated with feces is frequently highly contaminated with *Salmonella*; culture of temporary shallow lakes (called *playas* in the southwestern United States) yielded numerous *Salmonella* serotypes.[894] In one study 1.4% of cattle, mostly from dairies, shed salmonellae when in a veterinary clinic,[895] whereas I have found an average of 7% of cattle (mainly dairy cows) in our large animal clinic are shedding *Salmonella*.

Control of *Salmonella* infection requires an integrated herd approach. Sick pens were found to be 7.4 times more likely to yield *Salmonella* as were pens of preweaned calves.[896] Management interventions that were found effective in helping control *Salmonella* on dairy farms include separation of sick and parturient cattle into hospital and maternity pens respectively (considered the most important and effective intervention), switching from a phenolic disinfectant to a peroxygen biocide such as Virkon S for equipment disinfection, use of separate footwear or footbaths for personnel in the hospital and maternity pen sections, strict protocols for disinfection of hands and equipment between handling each sick or periparturient cow, strict separation of feeds used in the hospital and maternity pens, and use of clean bedding in the hospital and maternity pens.[872] To detect herds infected with *Salmonella* Typhimurium or other serotype except *Salmonella* Dublin, a herd serologic profile based on ELISA can be used.[897] Rectal swab sampling and culture of cull dairy cows was found not to be a satisfactory method of detecting *Salmonella*-infected herds.[898] To control *Salmonella* Dublin, carrier cows and calves over 6 months of age are identified by serologic testing (ELISA) for anti-*Salmonella* antibody.[880,899–901] Suspect animals are culled or tested further by serologic means or by multiple fecal cultures and milk cultures (five samples at weekly intervals). Animals with positive test results are culled. In infected herds, *Salmonella* Dublin carriers (fecal or mammary) usually make up 0.4% to 3% of a dairy herd. Animals that remain seropositive over a 2-month period should be considered carriers, even if a culture result is negative on five samples.[880] A Danish study[902] found that only 14 of 31 persistently seropositive animals were culture positive for *Salmonella* Dublin at postmortem examination, and one seronegative animal was culture positive. One study found that ELISA serology had a good negative predictive value for cattle 100 to 300 days of age, whereas fecal culture had a poor predictive value.[903]

To control all non—host-adapted and host-adapted serotypes of *Salmonella*, calves and cows are promptly treated when signs of illness occur, and strict procedures to prevent the spread of infection are instituted. A study of 14 farms infected with *Salmonella* Typhimurium DT104 showed that clinical disease ceased by 4 months, but widespread infection and contamination continued. Over time the number of infected farms gradually declined, and vaccination correlated positively with a herd remaining free of clinical illness from DT104.[904] Control measures include the use of separate feeding utensils for each calf, washing of boots and hands by calf raisers between calves, isolation of ill calves to noncontact pens, and thorough disinfection of pens between calves. Decontamination of pens is most effectively accomplished if an all-in, all-out system is used. Pens are divided into four groups, with each group of pens used for calves born during a given week. When 3- to 4-week-old calves leave their pens as a group, these pens are cleaned and disinfected with a chlorine product such as bleach, a peroxygen product such as Virkon S, or a phenylphenolic disinfectant. This helps prevent continuous recycling of bacteria to each group of new calves. Environmental monitoring by frequent swab cultures of pens is the best way to check the effectiveness of the sanitation and disinfection program. Infection with *Salmonella* Typhimurium and other non—host-adapted serotypes most often occurs as an epidemic after the organisms enter

the farm by means of purchased cattle, rodents,[905] rendering trucks, or feedstuffs. Even *Salmonella* Dublin may be maintained on a farm by mice.[905] A case control study of farms infected with *Salmonella* Typhimurium DT104 found that the most effective interventions included purchasing cattle directly rather than through a sales yard, quarantining purchased cattle for 4 weeks, housing sick cattle in dedicated isolation areas, and preventing wild bird access to feed storage areas.[906] Feeds may be contaminated by irrigation water,[891] in manufacturing when byproduct ingredients contain *Salmonella* organisms, on the farm, or in shipment by birds or rodents or contaminated trucks. When an epidemic involving an exotic serotype occurs, feedstuffs should be examined as a likely source. Exotic serotypes are *Salmonella* from serogroups other than B, C, D1, and E1; that is, all those groups not listed inTable 32-22. Feedstuff contamination with the serotypes not considered exotic may also occur. High-protein supplements, rumen bypass protein, or calcium-phosphorus supplements of animal origin are sources of epidemics of various *Salmonella* serotypes in livestock. Forty percent of all animal byproduct feedstuffs in the United States are contaminated with *Salmonella* organisms. Once a *Salmonella* serotype enters a herd, the bacteria are rapidly spread among livestock and into the environment, where they may cause a prolonged course of herd illness and can be difficult to eliminate. Such appeared to be the case with *Salmonella* Newport and *Salmonella* Montevideo in dairy cattle in California in the past (Table 32-23). These and other group C *Salmonella* species tend to become endemic and persist for years on a dairy farm once it has become infected. Culture of feeds before use on a farm currently is the only means of preventing the introduction of exotic *Salmonella* serotypes, because national and international controls currently appear to be inadequate.

32.157.6

Vaccination

Control by vaccination of dams using killed bacterins may be somewhat beneficial in protecting neonates under 3 weeks of age through colostral and milk immunoglobulin. Because most dairy calves are taken from their dam and fed milk replacer after day one to day 3 of age, the potential benefit of intraluminal milk antibody from the dam is lost. This may account in part for the fact that vaccination of cows by itself often is insufficient to protect calves from salmonellosis. In neonates over 3 weeks of age, colostral immunity appears to play only a small role in protecting against salmonellosis. Because both humoral and cell-mediated immunity are important in protecting against salmonellosis,[907–909] active immunity is superior to passive. Modified live, genetically altered vaccines that stimulate humoral and cell-mediated immunity offer better protection for calves.[909,910] Modified live vaccines have been available in Europe for years. Such a vaccine recently became available in the United States.* The role of increased nonspecific immunity to gram-negative core antigens (through immunization with rough mutants of *E. coli* and salmonellae lacking complete cell walls) is being investigated. Some studies have been able to demonstrate an increased survival rate for salmonellosis after vaccination with a mutant stain of *E. coli* (J5),[912] designed to produce antibodies to the common core antigens of gram-negative bacteria. Endovac-Bovi (Re mutant *Salmonella*) is marketed with the same goal.

879

880

Table 32-23 Changing Incidence of *Salmonella* Serotypes on California Dairy

Farms as Illustrated by the Percentage of Farms from Which each Serotype was Isolated in 1985 to 1986 Compared with 1987 to 1988

Serotype	1985–1986 Percentage of Farms (No.)	1987–1988 Percentage of Farms (No.)
Dublin	78 (29)	53 (49)
Newport	19 (7)	36 (33)
Typhimurium	3 (1)	7.6 (7)
Montevideo	0	6.5 (6)
Infantis	0	2.2 (2)
Anatum	0	1.1 (1)
Arkansas	0	1.1 (1)

Blanchard P, Anderson M: Unpublished data based on calves brought for necropsy from Tulare area farms, 1988.

Available commercial *Salmonella* vaccines are killed whole cell bacterins for use in cattle, and a new genetically altered modified live *Salmonella* Dublin vaccine for calves.* Some practitioners report that they have used the live vaccine orally and found it to be effective but with fewer adverse reactions than when used parenterally. The only products that are solely *Salmonella* vaccines contain *Salmonella* Typhimurium or *Salmonella* Typhimurium and *Salmonella* Dublin or live *Salmonella* Dublin organisms (see Chapter 48). Autogenous bacterins can be made for serotypes not commercially available when they are isolated from animals on a farm and believed to be the causative agent of disease. A new subunit vaccine with siderophore receptor protein (SRP vaccine) is being marketed by AgriLabs under conditional USDA license. Siderophores are iron chelating proteins produced by all *Salmonella*, so producing antibodies against SRPs from *Salmonella* Newport should theoretically be effective for all serotypes of *Salmonella*, and because they are a subunit, they should be less toxic.

A major problem associated with *Salmonella* bacterins and modified live *Salmonella* vaccines is adverse reactions. Adverse reactions vary from fever, depression, and anorexia to collapse and death after vaccination. Animals may have severe reactions after the first, second, or third dose. The apparent cause of these severe reactions is a high degree of sensitivity to the presence of gram-negative endotoxin, which results in a rapid immune cascade leading to shock.[879] This sensitivity is genetically controlled, possibly accounting for the high frequency of adverse reactions in one herd and their absence in a neighboring herd. High ambient temperatures also increase sensitivity to the adverse effects of endotoxin. Adverse reactions usually can be reversed by using epinephrine (1 mL of 1:1000 [1 mg/mL] for every 50 kg of body weight given IM or IV) as soon as evidence of polypnea, dyspnea, or weakness appears.

Lack of efficacy of killed *Salmonella* bacterins in calves is evident in experimental studies. Commercial bacterin vaccines in aluminum hydroxide administered directly to calves at 2 and 4 weeks of age failed to protect the calves when they were orally challenged at 6 weeks of age.[912] Other research has demonstrated protection in older vaccinated calves that were challenged intravenously.[913] Calves under 12 weeks of age do not serologically respond with anti-LPS antibodies after vaccination with two or three doses of killed bacterins in aluminum hydroxide.[914] On the other hand, calves over 12 weeks of age and cows do respond serologically to two doses of the same vaccine.[915] The ELISA titer in cows is short-lived (2 to 4 weeks); therefore the timing of

two doses of the same vaccine.[915] The ELISA titer in cows is short-lived (2 to 4 weeks), therefore the timing of vaccination before parturition is critical if the aim is to increase the anti-*Salmonella* colostral immunoglobulin G titer.[915] Under experimental conditions, calves fed colostrum from vaccinated dams were not protected against oral challenge at 3 weeks of age.[878] One report suggests that vaccination with killed *Salmonella* Typhimurium vaccine prevented reinfection and recrudescence of clinical signs after an outbreak of DT104 and helped in eliminating the organism from the farm.[906] As mentioned previously, these differences may in part be explained by whether or not a calf continues to receive milk from its dam and thus has or does not have intraluminal antibodies. Other live vaccines have been found effective in calves and capable of cross-protection against other serotypes, including a DNA adenine methylase—deficient *Salmonella* Typhimurium[916] and an avirulent live *Salmonella* Choleraesuis strain 54,[917] but neither was licensed for cattle in the United States as of 2007.

* EnterVene-D, Fort Dodge Animal Health, Fort Dodge, IA.

32.157.7 Necropsy Findings

32.157.7.1 ENTERIC FORM

Calves often are emaciated and have serous atrophy of fat. Especially with *Salmonella* Typhimurium, the ileal, cecal, or colonic mucosae may be thickened and hemorrhagic with adherent fibrinonecrotic plaques. Fibrin may be found in sheets, especially pronounced in the areas of Peyer's patches. The abomasum, duodenum, and jejunum are often involved but less severely. The abomasum usually contains brown, fetid liquid. Bowel contents often are watery and may contain fibrin or blood or both.[876] The mesenteric lymph nodes frequently are enlarged and dark. Chronically affected cows or calves may have discrete areas of necrosis in the cecum or colon that may involve the entire thickness of the wall.[876]

32.157.7.2 SEPTICEMIC FORM

Gross lesions of bacteremic *Salmonella* infection are acute and usually subtle. Serosal and subcutaneous petechiae are widespread. The spleen usually is enlarged. The lungs are edematous and fail to collapse and have random foci of hemorrhage or congestion.[876] The wall of the gallbladder is thickened and may contain hemorrhages.[876] The bile frequently is inspissated into a firm coagulum.[876] Less common lesions include jaundice, cystitis, meningitis, osteomyelitis, arthritis, and dry gangrene of ears, tail, or feet. Gastrointestinal lesions may or may not be present.

32.157.8 Treatment

The keys to successful treatment of bacteremia caused by gram-negative bacteria are (1) antimicrobial drugs, (2) fluids and electrolytes, and (3) NSAIDs. *Salmonella* Typhimurium antiserum is available commercially. Adverse reactions by cattle to horse serum are common; care should be taken. 880 881

Early in the course of disease in calves, appropriate antimicrobial therapy often increases the survival rate markedly, because bacteremia frequently occurs. Appropriate antimicrobial therapy depends on culture and antimicrobial sensitivity patterns. Many of the most virulent *Salmonella* types are now multidrug-resistant, but isolates of relatively nonpathogenic *Salmonella* on dairies and feedlots found on surveys are usually sensitive to most antimicrobials.[886,918] In general, most *Salmonella* organisms are sensitive to florphenicol, ceftiofur (and

other third-generation cephalosporins), TMS, gentamicin, amikacin, and fluoroquinolones such as enrofloxacin.[885,886] Higher than label doses of ceftiofur used in calves with experimentally induced *Salmonella* Typhimurium infections did not alter mortality but did reduce fecal shedding and promote more rapid clearance.[919] Sulfas and fluoroquinolones may not be used extralabel in food animals in the United States. Aminoglycosides such as neomycin, gentamicin, and amikacin produce long-term tissue residues and should be avoided in animals intended for use as food. Susceptibility to ampicillin, amoxicillin, sulfas, and tetracycline varies considerably, whereas resistance to penicillin, streptomycin, erythromycin, and tylosin is anticipated. TMS combinations are relatively inexpensive, especially when given orally, but oral TMS should be used only in calves younger than 3 weeks of age. In calves over 3 weeks of age, trimethoprim should be given IV because it is destroyed in the rumen and not absorbed. Antimicrobial drugs such as fluoroquinolones, florphenicol, or TMS that achieve good intracellular levels and have a large volume of distribution appear to be more effective than those that do not achieve good intracellular levels (e.g., gentamicin and amikacin). Florphenicol or cephalosporins such as ceftiofur are good choices for therapy against many *Salmonella* isolates depending on susceptibility testing results. Antimicrobial drugs may not be effective at altering the clinical course of strictly enteric infections without bacteremia, but because bacteremia frequently accompanies salmonellosis, systemic antimicrobial therapy often is chosen.

The effects of endotoxins can be partially dampened or controlled by the judicious use of NSAIDs. The cascade of events caused by bacterial endotoxin (LPS from the cell wall) must be brought under control early and rapidly, by the use of drugs such as flunixin (Banamine) at a dose of 1.1 to 2.2 mg/kg every 12 hours. Once the animal is stabilized, NSAIDs should be discontinued, as continued administration can lead to adverse side effects such as abomasal ulceration.

Intravenous fluid therapy to maintain blood volume and pressure and correct acid-base or electrolyte abnormalities is important in any animal that is dehydrated or in shock (see Chapter 20, Neonatal Diarrhea, Chapter 32, Equine Fluid Therapy, for adult equine, and Chapter 44 on critical care). Measurement of blood gases and electrolyte values is useful to assist in fluid therapy formulations. Fluids containing sodium, with supplementation of glucose, should be administered intravenously as needed. Metabolic acidosis with mixed water by electrolyte losses is most often seen. Oral fluids and electrolytes may also be effective supplements. The prognosis is good if animals are treated aggressively and early in the course of illness.

32.157.9 Control of Infectious Disease in a Veterinary Hospital

Veterinarians must also be aware of preventing the spread of *Salmonella* and other nosocomial diseases within an animal hospital and should have an effective written infectious disease control program in place.[920] See Chapter 46.

32.158 JOHNE's DISEASE

Robert H. Whitlock

32.158.1 Definition and Etiology

Johne's disease is an insidious chronic infection of primarily ruminants but also includes rabbits,[921–923] foxes, stoats, weasels, Eurasian badgers, bears, wild boar, brown hare, brown rat, crow, rook, jackdaw, and long-tailed field mouse, among other species. It is caused by *Mycobacterium avium* subsp. *paratuberculosis*.[924–932] Despite having 99% DNA homology,[933,934] *M. avium* subsp. *paratuberculosis* can be differentiated phenotypically from *M. avium* subsp. *avium* by its dependence on mycobactin[935] and genotypically by the presence of multiple copies of an insertion element, IS900,[936] or a single copy of heat shock protein (HSx), among other DNA markers.[937] The two major strains of *M. avium* subsp. *paratuberculosis* identified by DNA strain typing are the cattle strain (c) and the sheep strain.[938] Other strains of *M. avium* subsp. *paratuberculosis*, with the exception of the Bison strain, have less species specificity.[939–942]

After ingestion of *M. avium* subsp. *paratuberculosis* during the perinatal period, the bacteria are absorbed by the M cells of the small intestine and gradually spread to regional lymph nodes.[943] Given adequate time, *M. avium* subsp. *paratuberculosis* infection becomes systemic, spreading to other body organs including the liver, mammary gland, uterus, pulmonary lymph nodes, and peripheral lymph nodes such as the popliteal and superficial cervical nodes. The term *Johne's disease* typically refers to the clinical disease condition with weight loss and diarrhea, whereas the term *paratuberculosis* refers to the condition of being infected with the causative organism, *M. avium* subsp. *paratuberculosis*, but not necessarily having clinical signs.

32.158.2 Clinical Signs

The great majority of infected animals appear clinically normal when compared with herdmates. Only after a prolonged incubation period, typically longer than 2 years and up to 10 years, do infected animals begin to develop subtle clinical signs including gradual weight loss despite a normal appetite and usually decreased milk production. Over a period of several weeks, concurrent with the weight loss, the manure consistency changes to become softer then loose and usually progresses to a pipestream diarrhea without tenesmus. The diarrhea is initially intermittent, with periods of normal manure consistency. Other than the loose consistency, the manure appears normal; blood, excess mucus, and tenesmus are not present during this time, and the animal continues to lose weight despite a normal appetite. In rare cases diarrhea begins suddenly as a persistent loose manure or watery scours. Other than the loose consistency, the manure appears normal. As the disease progresses, affected animals become increasingly lethargic and emaciated. Intermandibular edema and possibly ventral sternal edema caused by hypoproteinemia typify advanced stages of the disease. Cachexia and “waterhose” diarrhea characterize the terminal stages of the disease. Most animals are culled from the herd before this time because of decreased milk production and/or severe weight loss.

32.158.3 Stages of Infection and Disease

32.158.3.1 STAGE I: “SILENT” INFECTION (CALVES, HEIFERS, YOUNG STOCK, AND ADULT CATTLE)

Most cattle with Johne's disease are infected as young calves in the perinatal period. Recent evidence suggests horizontal transmission may occur among older heifers and even adult cattle. Once infected the organism proliferates slowly in the jejunal and ileal mucosa then gradually spreads to the regional lymph nodes. Animals in stage 1 of infection are rarely detected with even the most sensitive laboratory tests, including a fecal culture. At postmortem examination the organisms in the tissues may not be visible on microscopic

examination of tissues but may be detectable by culture of the tissues, because culture is a much more sensitive test than histopathology. This silent or eclipse phase of infection usually lasts for a minimum of 2 years and possibly for 10 years or more. However, in herds with a high prevalence of Johne's disease, cattle in stage I may proceed to stage II or even stage IV (clinical Johne's disease) by 1 year of age. Clearly the rate of progression of Johne's disease is *M. avium* subsp. *paratuberculosis*–dose-dependent and to a lesser degree dependent on age when infected. Cattle infected in the perinatal period typically progress to stages III and IV over a period of 1 to 3 years before being culled from the herd.

32.158.3.2 STAGE II: INAPPARENT CARRIER ADULTS

Inapparent carrier adults do not have weight loss or diarrhea but may have an altered immune response with increased IFN-γ response by sensitized T cells to specific mitogens and or increased antibody response to *M. avium* subsp. *paratuberculosis*. Some animals in stage II may have a positive fecal culture, shedding *M. avium* subsp. *paratuberculosis* in the manure, contaminating the environment, and serving as sources of infection to other animals on the farm. Animals may remain in stage II for several years depending on the age at the time of infection, the dose of organisms, and the immune response of the host.

Adult exposure to *M. avium* subsp. *paratuberculosis* occurs commonly in larger herds fed TMR that has been contaminated by *M. avium* subsp. *paratuberculosis*–infected manure from a super-shedder. These super-shedder cattle shed up to 10,000,000 colony-forming units (CFU) of *M. avium* subsp. *paratuberculosis* per gram of manure. Ingestion of less than 1 gram of manure from these super-shedder cattle may result in infection of the naive adult cow and/or a positive fecal culture. These periodic passive shedders should be suspected if the environmental *M. avium* subsp. *paratuberculosis* concentrations are high (equivalent to heavy shedders), suggesting the presence of a super-shedder in the herd. Subsequent fecal cultures over many months or years from these passively infected cattle should be negative, and the serum ELISA results should also be negative.

32.158.3.3 STAGE III: CLINICAL DISEASE

Animals at this stage have gradual weight loss and chronic diarrhea. The appetite remains normal. Intermittent diarrhea is often present for weeks. The vital signs, heart rate, respiratory rate, and temperature are normal. Emaciation and cachexia develop gradually with a decrease in milk production. Most animals at stage III are fecal culture positive and have increased antibody, usually detectable by a commercial Johne's ELISA and AGID test. Cattle at this stage of infection rarely remain in the herd longer than a few weeks and are culled for weight loss and unresponsive diarrhea.

32.158.3.4 STAGE IV: ADVANCED CLINICAL DISEASE

Animals in the advanced stages of the disease are weak and emaciated and usually have a profuse pipestream diarrhea. Intermandibular edema or bottle jaw is characteristic of this phase of the disease. Animals can progress quickly from stage II to stage IV, sometimes within a few weeks. Once the diarrhea is profuse and hypoproteinemia (bottle jaw) occurs, the animal's condition deteriorates rapidly, often in a matter of days. Most animals are sent to slaughter for salvage at this point. Otherwise, death occurs as a result of dehydration and cachexia.

For every cow with advanced Johne's disease born on the farm, it is likely that 15 to 25 others are infected.[944]

Only 25% to 30% of these infected animals will be detected with even the most sensitive testing techniques, fecal culture. The animal with advanced clinical signs is the "tip of the iceberg." As an example, consider a herd with 100 adult cattle and 100 young stock replacements. One cow born on the farm several years earlier develops clinical signs with weight loss and diarrhea. It is likely that 15 to 25 other cattle are infected, but less than 30% of these will be detectable by fecal culture (Box 32-10). It is also reasonable to conclude that if 25 to 30 of the adult cattle in a herd of 100 adult cattle are positive on a single herd fecal culture, most of the herd is probably infected.

32.158.3.4.1

Box 32-10 "The Iceberg Effect" in a Cow Herd

Stage IV	Advanced clinical disease	1 animal
Stage III	Clinical disease	1–2 animals
Stage II	Inapparent carrier adults	6–8 animals
Stage I	Silent infection of calves—young stock	10–15 animals
Total		15–25 animals

32.158.4

Clinical Pathology

Early stages of infection are not associated with any characteristic biochemical or hematologic changes. Animals with clinical signs are typically hypoproteinemic (TPP <5.5 g/dL) with reductions in albumin (<2 g/dL) and all classes of immunoglobulin. The marked muscle loss may be associated with elevated plasma phosphorous levels (up to 10 mg/dL), which is attributed to the catabolic state with phosphorus release resulting from muscle wasting. The animals are often mildly anemic (PCV <25%) with concurrent hypocalcemia (caused in part by the hypoalbuminemia), hyponatremia, and hypokalemia.

32.158.4.1

ANTIBODY-BASED DIAGNOSTIC TESTS

32.158.4.1.1

Agar Gel Immunodiffusion

The AGID test or rapid Johne's test (RJT) has diagnostic value only if the tested animal is showing weight loss and/or diarrhea. A positive test result in an animal with clinical signs has high specificity (>95%) for Johne's disease.[945] Lack of sensitivity and failure to detect animals that are fecal culture positive but not showing clinical signs are the major drawbacks of the AGID test.[946] The test should be reserved for the individual cow with clinical signs that are compatible with Johne's disease. One major advantage of the AGID test compared with serum ELISA is the near 100% specificity of the AGID; ELISA specificity ranges from 95% to 99%.[947] A small proportion (10% to 15%) of cattle with clinical signs will have a positive AGID test result but a negative result on the Johne's ELISA, seemingly a paradox, because the ELISA test will detect fewer antibodies than the AGID test.

32.158.4.2

ENZYME-LINKED IMMUNOSORBENT ASSAY

The ELISA detects and quantitates the host's serum antibody response to an antigen derived from *M. avium* subsp. *paratuberculosis*. The sensitivity and specificity of the ELISA are 25% to 45% and 95% to 99%, respectively.[948,949]

Animals with higher ELISA antibody titers or sample/positive (S/P) ratios are more likely to be infected with *M. avium* subsp. *paratuberculosis*.[950,951] The ELISA may be used to screen cattle to identify those at highest risk for Johne's disease. Those high-risk animals should have a fecal culture, considered the current gold standard test on live animals, to determine true infection status. If the culture test is negative, then the cow should remain in the herd. Advantages of serum ELISA are rapid turnaround time (2 to 4 days), low unit cost, and the large number of samples that can be processed each day. This screening process would permit a much higher number of cattle to participate in a Johne's disease control and/or certification program. An ELISA result should *not* be accepted as a definitive diagnostic test for the individual animal, nor should cattle be culled on the basis of an ELISA result. With less than 100% (range 94% to 99%) specificity,[952–960] any ELISA will identify some noninfected cattle as ELISA positive, especially in low-prevalence herds, a major disadvantage of the serum ELISA.

882

883

32.158.4.2.1

Milk ELISA

Early reports found that milk ELISA testing was not considered adequate for routine diagnostic use in the United States.[961,962] Then in 2001 a company in Michigan introduced a more sensitive and specific milk ELISA based on existing serum ELISA for Johne's disease. Two reports on this commercial milk ELISA found the sensitivity and specificity to be similar to those of serum ELISA.[947,963] The 2002 NAHMS dairy study indicated both the sensitivity and specificity of the milk ELISA to be similar to those of serum ELISA.[964] Studies in Denmark indicated that cows in early and late lactation had higher levels of antibody than midlactation cows.[965–968] There are two major advantages of the milk ELISA over blood ELISA. The first is that milk samples are taken at monthly intervals for routine Dairy Herd Improvement Association (DHIA) testing, which saves labor costs of having the cows restrained to take a blood sample as well as the cost of taking the sample. The second advantage is that because the samples are routinely available at monthly intervals, dairy operators may choose which cows to test at what times, thus providing the opportunity of “target testing” such as at time of dry-off or when cows are checked for pregnancy. As with any ELISA test, blood or milk, some infected cows (as determined by fecal culture) will test ELISA negative. Elisa tests do not detect as positive about 15% to 20% of culture positive heavy shedders, 50% of culture positive moderate shedders, and 75% of culture positive low shedders. The use and validation of milk ELISAs is increasing, with more sensitive milk ELISAs on the horizon. Some countries are pursuing bulk tank milk tests as a herd detection test for Johne's disease.[969]

32.158.4.2.2

Complement Fixation Test

The CF test may be required for export purposes but is not recommended for diagnostic purposes. The test is plagued with major faults, including false-positive results and lack of sensitivity to detect infected cattle.[970,971]

32.158.4.3

ANTIGEN OR ORGANISM DETECTION TESTS

PCR tests to identify specific DNA segments (IS900 or HSx protein) in *M. avium* subsp. *paratuberculosis* represent state-of-the-art technology to detect this fastidious pathogen.[972–976] Until recently most PCR methods were less sensitive than fecal culture.[977–979] The PCR approach potentially has the greatest sensitivity and exquisite specificity to detect *M. avium* subsp. *paratuberculosis*. A recently approved USDA-licensed real-time PCR (qRT-PCR) test detects *M. avium* subsp. *paratuberculosis* in fecal samples at low concentrations and may be more sensitive than the standard culture method. Not only is the qRT-PCR test sensitive and 100% specific, but it quantifies the mycobacterial concentration in the manure and has a high correlation with fecal culture colony counts when serially diluted.[980]

32.158.4.4

HISTOPATHOLOGY

Microscopic examination of the intestinal tissues and adjacent lymph nodes after acid-fast staining with Ziehl-Neelsen stain, Kinyoun's method, or Auramine-O stain provides an accurate assessment of infection status if clinical signs of weight loss and diarrhea are present.[981,982] Finding acid-fast organisms in clumps within macrophages helps declare the biopsy positive for Johne's disease. Infected cattle with clinical signs should have a positive biopsy result. A negative biopsy report suggests that other causes for the weight loss and diarrhea should be explored. However, failure to demonstrate acid-fast organisms or to identify Langhans giant cells especially in the stages I and II of the disease does not necessarily imply the absence of infection. Other tissue sites may be infected but not selected for examination. Currently qRT-PCR on a fecal sample offers a more rapid and more sensitive test than histopathology of tissues. Histopathologic examination of tissues for Johne's disease should be reserved for cattle with clinical signs and is not appropriate for subclinical Johne's disease.

32.158.4.5

FECAL CULTURE

Isolation of *M. paratuberculosis* from feces remains the gold standard for routine detection of individual infected animals in a herd suspected of having cattle infected with *M. avium* subsp. *paratuberculosis*.[983,984] Fecal culture techniques employing both centrifugation and double incubation are able to detect 10 to 50 organisms per gram of manure[985] and identify two to three times as many infected animals as the current ELISA tests.[986] *M. avium* subsp. *paratuberculosis* can be detected in fecal samples of most infected cattle 1 year or more before the development of clinical signs. The major disadvantage of fecal culture is the prolonged incubation period of 12 to 16 weeks and higher cost than the ELISA.

Implementation of liquid culture systems for *M. avium* subsp. *paratuberculosis* has reduced the incubation time to 35 days or less.[987,988] Another advantage of liquid culture is the correlation of time to detection (TTD) to *M. avium* subsp. *paratuberculosis* concentration in the sample. However, the liquid culture detects *M. avium* subsp. *paratuberculosis* indirectly based on pressure changes in the culture vial or fluorescence of the sensor within the tube. This indirect detection necessitates more rigorous confirmation testing to verify that *M. avium* subsp. *paratuberculosis* rather than another organism or chemical reaction is causing the tube to flag positive. Liquid culture methods have been successfully developed to culture the sheep strain, which does not grow readily on culture media designed for cattle strains.[989]

Occasionally a positive fecal culture will be followed by several negative fecal cultures from the same cow.

This may be a result of passive excretion after consumption of contaminated feed materials.[990] With the recent description of super-shedders or cows shedding up to 5 million CFU per gram of manure, a small amount of manure in the TMR could easily result in a positive fecal culture owing to passive shedding or "pass-through" *M. avium* subsp. *paratuberculosis*. In some herds the rate of positive fecal cultures attributable to passive shedding could exceed 50% of positive cultures. Passive shedding usually results in low *M. avium* subsp. *paratuberculosis* CFU or low shedders, but on occasion moderate shedders may be the result of pass-through from super-shedders in the herd. Typically, low shedders constitute approximately 50% of positive cultures, whereas mid-level shedders represent about 20% and heavy shedders about 30% of all positive cultures over a period of time.[991] Herd owners need to focus on culling heavy shedders and super-shedders to reduce the herd bioburden of *M. avium* subsp. *paratuberculosis* and be less concerned about the detection of low shedders.

32.158.4.6

CELLULAR IMMUNITY TESTS

An ELISA to measure IFN-γ, a mediator released by sensitized T lymphocytes in response to stimulation by specific mitogens, may be a useful diagnostic tool in the future. Current studies suggest that the IFN-γ test may be more sensitive than other currently available serologic tests.[992–994] At this time a commercially available IFN-γ test is available, but the kit does not include an antigen for *M. avium* subsp. *paratuberculosis* and the laboratory has to provide an antigen. Research suggests that IFN-γ has promise, if a well-characterized and reproducible antigen can be consistently manufactured.

883 884

32.158.4.7

DIAGNOSTIC TESTS FOR THE INDIVIDUAL ANIMAL WITHOUT CLINICAL SIGNS

The usual reason for a request to test an animal without clinical signs is to determine if the animal is free of *M. avium* subsp. *paratuberculosis* infection before it is introduced into a herd. Confirming the absence of infection in an animal without clinical signs remains a challenge for even the seasoned clinician. A negative AGID test or ELISA result does not prove the absence of *M. avium* subsp. *paratuberculosis* infection. Many animals in the early stages (I or II) of Johne's disease are nearly impossible to detect with any currently available diagnostic test. The clinician should obtain a complete history to determine if Johne's disease was present in the herd at any time during the previous 5 to 10 years. If both the herd owner and the herd veterinarian of record are willing to sign a statement to the effect that it was not, then the risk of purchasing an infected animal from this herd will be lower. Further evidence for the absence of Johne's disease may be obtained by finding negative ELISA test results on a group of 30 second-lactation or older cattle in the herd. qRT-PCR testing of composite environmental manure samples (four to six samples) that represents all cow groups within the herd offers rapid turnaround and high sensitivity to detect herd infection. Pooled (composite) environmental manure samples should include manure samples from five or six sites within the area where the cattle are grouped. Negative environmental samples from the herd of origin as well as a negative herd history increase the confidence that an animal is at low risk for *M. avium* subsp. *paratuberculosis* infection.

32.158.4.8

DIAGNOSTIC TESTS FOR THE HERD

The recommended herd test is an ELISA; performed on cattle in the herd, it is an excellent screening tool to determine the presence of *M. avium* subsp. *paratuberculosis* infection within the herd. Although the ELISA test is relatively specific, the sensitivity to detect lightly infected cattle is less than 20%.[948] If the commercial ELISA test detects one ELISA-positive animal, which is then confirmed positive by fecal culture, it is likely there are many more infected animals in the herd, perhaps as many as three times the number of ELISA- and

culture-positive cattle. If paratuberculosis is to be eliminated from the herd, annual whole herd fecal cultures are required to identify and cull those animals that may be spreading the disease to other animals, along with implementation of a strict biosecurity program.

32.158.4.9 ENVIRONMENTAL AND POOLED FECAL SAMPLES

Johne's disease continues to be considered a herd disease, with some diagnostic efforts designed to detect infection at the herd level as efficiently as possible. Initially, serum ELISA tests on 30 second-lactation cows or older were designed to address this need because this sample subset was relatively inexpensive with a rapid turnaround time. Over time, less expensive and more sensitive alternatives were sought, especially for sheep. An Australian report showed that one positive fecal sample from a sheep with multibacillary paratuberculosis could be readily detected when combined with fecal pellets of 49 uninfected sheep.[995] Later this approach to testing sheep flocks became the standard approach as a sensitive, efficient means to detect *M. avium* subsp. *paratuberculosis* infection.[995] Subsequently reports from the United States with cattle manure samples showed that culture of pools of five samples was sensitive to detect infected cows and could be done at a fraction of the cost of whole herd cultures on all adult cattle.[996] In this experimental study, 1:5 and 1:10 pools were tested. The sensitivity of pooled cultures ranged from 30% to 100% and was strongly dependent on pool size and the shedding level of the positive sample (low shedder compared with a heavy shedder). Occasionally culture of the pooled sample will be positive while each individual sample is found to be culture negative.[997,998] Evaluation of pooled fecal samples (1:5) in a range of Johne's disease—infected dairy herds detected at least 88% of samples that contained at least one animal shedding moderate (>10 CFU/tube) to high colonies per tube.[999] Later studies with pools of 10 fecal samples in low-prevalence herds proved cost-effective for herd screening and may provide an estimate of *M. avium* subsp. *paratuberculosis*–infected dairy cows within large herds.[1000] Optimal pool size depends on both prevalence and herd size, which has varied from three samples per pool for a 500-cow herd with low prevalence to five samples per pool for a 1000-cow herd with high prevalence.[1001]

Composite environmental manure samples (a combination of three or four manure samples from a specific area) from high—cow traffic areas in 64 herds known to be infected with *M. avium* subsp. *paratuberculosis* detected 50 of the 64 herds (78%) with positive fecal pools, thus providing evidence that environmental manure samples serve as an excellent proxy to detect herd infection.[998] With refinement of the environmental manure samples—composite or pooled manure samples within high—cow traffic areas, manure storage areas, and pens or lots representing all cow groups within the herd—the diagnostic sensitivity to detect herd infection is further increased.[1002] Additional investigations have shown that composite environmental manure samples from high—dairy cow traffic sites and manure storage areas have a greater sensitivity and would be less expensive for detection of herd *M. avium* subsp. *paratuberculosis* infection than 30 serum ELISAs of second-lactation and older cattle.[998,1003] Samples of lagoon water from larger herds (350 to 2500 cows) were significantly more likely to give positive results than composite manure samples from high—cow traffic areas.[1002] Because composite environmental samples are collected from high—cow traffic areas where cows defecate daily, the weather or season of collection should not affect the ability to isolate *M. avium* subsp. *paratuberculosis*. In addition, *M. avium* subsp. *paratuberculosis* has been shown to remain viable for long periods in the environment.[1004–1007]

32.158.5 Pathophysiology

M. avium subsp. *paratuberculosis* enters the intestinal tract typically by fecal-oral contamination and is taken up preferentially by the M cells, specialized absorptive cells in Peyer's patches,[943] where the organisms are resistant to intracellular degradation and eventually phagocytosed by subepithelial macrophages.[1008] However, recent work would suggest that these organisms may be taken up by absorptive cells throughout the entire length of the small intestine. Typically the organisms proliferate slowly within macrophages in the intestinal mucosa then spread to regional lymph nodes. In the regional lymph nodes the bacteria stimulate inflammatory and immunologic responses.[1009,1010] The elicited response is similar to that to other mycobacterial infections, most importantly T lymphocytes with cytokines from T helper cells. IFN-γ, one of these cytokines, is an important component of the protective host response and may be an early indication of *M. avium* subsp. *paratuberculosis* infection.[1011] In some infected cows the cellular response is able to control infection, with the animal never developing clinical signs but remaining subclinically infected for life.[992,1010] Poor nutrition, stress related to transport, lactation, and parturition have been proposed as accelerating or precipitating the onset of the clinical phase of infection.[992]

884

885

The minimum time from infection to the onset of clinical signs requires at least 12 months of heavy and repeated doses of *M. avium* subsp. *paratuberculosis*, and small doses of organism may require more than 10 years before clinical signs appear. In heavily infected herds with many clinical cases, yearling heifers may show evidence of ill thrift and loose manure because of Johne's disease, but this is rare. Typically the first evidence of weight loss and diarrhea occurs within several months of calving or another period of stress. On some occasions noninfected adult cattle become infected as adults when introduced to a heavily infected herd and then develop clinical signs several years later. The infected animal responds to the mycobacterial organism with the recruitment of macrophages and development of giant cells.[1012] As the organism multiplies over weeks and months, the thickened intestine is less able to absorb nutrients and the animal loses weight despite a normal appetite. The thickened intestinal wall begins to gradually leak protein, mainly albumin, from the blood into the intestine, resulting in a direct nutrient loss from the bloodstream and hypoproteinemia.

32.158.6 Transmission

Fecal-oral transmission is the primary mode of transmission from an infected adult to the neonate. Most infections with *M. avium* subsp. *paratuberculosis* occur in the early neonatal period, often associated with the calf sucking the manure-contaminated teat and udder when ingesting colostrum.[1013] Multiple-use maternity pens serve as focal points to spread the infection. An uninfected cow may lie on manure from a moderate or high shedder and contaminate her udder with the organisms. Approximately 25% of calves born to cattle with clinical signs will be infected in utero, but only 18% of calves born to asymptomatic cows are infected in utero.[1014,1015] *M. avium* subsp. *paratuberculosis* has been isolated from uterine flush fluids of infected cattle.[1016]

M. avium subsp. *paratuberculosis* may be passed through the colostrum and milk from cattle in the later stages of infection.[1017,1018] Feeding pooled colostrum or pooled waste milk from several cows will serve to spread the infection from adults to calves during their most susceptible stage of life. Physical separation to calf hutches or better yet to another property such as a commercial heifer-raising facility decreases the risk of transmission to young calves. Although calves are most susceptible, older heifers and adult cattle can become infected from the ingestion of contaminated feed material. Feeding manger sweepings from the adult cows to older heifers has been shown to be a risk factor for spread of Johne's disease. Semen from bulls kept in commercial bull studs represents a very low risk because these animals are tested twice yearly for Johne's disease and must test negative. Although several species of wild animals may become infected with *M. avium* subsp. *paratuberculosis*,

they represent a very low risk to spread the disease to calves.[1019]

32.158.6.1 GRASSLAND PASTURE

Some dairy herds use intensive grassland grazing of their adult milk cows. This system relies on moving milk cows to a new fresh growth of lush pasture each 12 or 24 hours on a rotational basis for 15 to 30 days. Typically heifers or steers follow the milking cows to graze the pasture closer to the ground, so the pasture will not need to be clipped or mowed mechanically. This leader-follower system has been used in New Zealand for many years and is an excellent way to provide less expensive lush pasture to the milking herd, negating mechanical harvest and greatly reducing the need to feed expensive concentrate rations. However, in herds that have Johne's disease, the follower heifers or steers also are consuming *M. avium* subsp. *paratuberculosis* along with the lush grass left by the milk cows. Thus the follower cattle have a rather continuous uniform exposure to *M. avium* subsp. *paratuberculosis* over the months they follow the milking herd. Veterinarians need to be aware of this high-risk feeding practice, which perpetuates the transmission of *M. avium* subsp. *paratuberculosis* to younger cattle in the herd.

32.158.7 Prevalence

Johne's disease is widely distributed throughout the world in many ruminant species. Reports suggest 7% to 18% of cattle from slaughterhouse surveys are infected.[1020–1022] In Holland the true prevalence at cow and herd levels, based on an ELISA test sensitivity of 0.3 to 0.4 and a specificity that ranged from 0.985 and 0.995, was estimated to be 2.7% to 6.9% for cows and 31% to 71% for herds.[1023] Herd prevalence based on bulk tank milk antibody showed that 70% of dairy herds in Denmark were positive.[1024] A recent prevalence estimate, based on culture of ileocecal lymph nodes and ileum from dairy cows at slaughter in New Brunswick, Canada found 16.1% of cows positive, whereas 21.7% of cows from Maine were positive.[1025] In 1998 the NAHMS survey indicated the dairy herd prevalence to be 30% to 50%.[1026] More recent estimates of prevalence suggest 65% to 75% of dairy herds are infected in the major dairy states. Beef cattle have lower infection rates than dairy cattle.[1027] Paratuberculosis is extensively distributed among other ruminants including sheep, goats, deer, bison, and many exotic ruminant species kept in zoologic gardens. The apparent prevalence seems to be increasing, but this phenomenon may be a result of an increased awareness by producers and veterinarians.

32.158.8 Treatment

No practical therapy for Johne's disease is available. However, for cattle with significant genetic or sentimental value, several therapeutic agents have been used to effect remission of clinical signs. Isoniazid* given orally at 10 mg/lb daily, rifampin† at 10 mg/lb daily, and clofazimine‡ orally at 5 mg/lb daily have resulted in the amelioration of clinical signs facilitating collection of embryos and semen over an extended period of time.[1028–1029] The drugs must be given daily, and if therapy is stopped clinical signs may reappear within a few weeks. No drug or combination of therapeutic agents has been shown to eliminate the infection. Treated animals continue to shed *M. avium* subsp. *paratuberculosis* in the manure, contaminating the environment, and have viable organisms in their tissues, indicating the possibility that semen and embryos from treated animals may be infected. If animals with Johne's disease are treated with chemotherapeutic agents, the owners should agree with the prescribing veterinarian that milk or meat from that animal will never be used for human consumption. Drugs used to treat Johne's disease are being used in an “extralabel” manner with an appropriate client-patient relationship but without any data regarding appropriate withdrawal times. For further information, refer to

articles by Hoffsis and colleagues[1028] and St-Jean and Jernigan.[1029]

Brumbaugh and colleagues[1030] demonstrated a reduction in the number of CFU of *M. avium* subsp. *paratuberculosis* from the livers of experimentally infected mice treated with monensin compared with nontreated controls. Later, monensin was shown to either halt the progression of lesions or reverse the lesions in cattle with clinical signs of Johne's disease.[1031] Sections of tissues including liver, ileum, and adjacent mesenteric lymph node and a rectal mucosal biopsy were compared histologically with similar tissues obtained at necropsy after feeding 450 mg of monensin for 120 days. Taken together, the results of these two studies suggest that monensin may play a useful role both in the prevention of *M. avium* subsp. *paratuberculosis* infection in young cattle and in the treatment of established infection in adults.

Neonatal calves fed 70 mg of monensin twice daily in their milk replacer suggested in a proof-of-concept study that monensin is efficacious in controlling *M. avium* subsp. *paratuberculosis* infection in the neonatal calf. The amount of monensin (70 mg) administered per day to calves in this study is higher than the amount that would normally be consumed by a neonatal calf in a calf starter formula. In experimental dairy calves, monensin greatly reduced (>60%) both the passive fecal shedding and systemic tissue uptake.[1032] Monensin added to cattle rations at all phases of life, coupled with stringent implementation of biosecurity management practices at the farm level, offers new hope to help reduce the unyielding spread of this disease among the nation's cattle herds. Monensin seems to offer cattle producers another potent weapon in their management armamentarium to reduce the spread of Johne's disease within their herds. The costs are modest compared with many other management tools designed to reduce *M. avium* subsp. *paratuberculosis* bioburden within cattle herds. No other management technique evaluated to date has been shown to reduce *M. avium* subsp. *paratuberculosis* shed in manure of cattle and to reduce the tissue uptake of the organism to this extent.

* Available from multiple companies including Henry Schein, Inc., Port Washington, NY; Barr Labs, Inc., Northvale, NY; and Eli Lilly & Co, Indianapolis, IN.

† Rifadin, Merrell Dow, Cincinnati, Ohio.

† Lamprene, Geigy Pharmaceuticals, Summit, NJ.

32.158.9 Economic Losses Attributed to Paratuberculosis

Economic losses associated with Johne's disease have been attributed to many factors, including decreased milk production, decreased fat and protein yield, increased susceptibility to other diseases, loss of genetic potential, loss of export market, increased medical costs, reduced weight at slaughter, premature culling, poor feed conversion, increased calving interval, and financial loss at auction sales if animals are designated “exposed to Johne's disease.”[1033–1042] In dairy herds where 10% or more of cull cows have clinical Johne's disease, the estimated loss per cow exceeds $220 for each adult cow in the herd.[1043]

32.158.10 Biosecurity Practices and Herd Management Plans

The key to preventing, controlling, and eliminating Johne's disease in a herd is by implementation of a rigorous herd management plan designed to reduce *M. avium* subsp. *paratuberculosis* exposure to young calves.[1044] Factors such as finances, movement of cattle on the farm, maternity and sick cow pen locations, feed delivery to adult cattle, location and structure of feed bunks, and personnel issues are but a few of the specific issues that need to be reviewed with the final focus on how to best limit transmission of *M. avium* subsp. *paratuberculosis* to young calves. Farm managers should adopt two fundamental control principles: (1) prevent highly susceptible

newborn calves and young animals from ingesting manure from infected adults, and (2) reduce total farm environmental contamination of *M. avium* subsp. *paratuberculosis* by culling infected animals shedding the highest concentrations of *M. avium* subsp. *paratuberculosis*. Calves should be separated from their dams at birth and fed single source colostrum from culture-negative and/or ELISA-negative cows. The same management factors that reduce the risk for Johne's disease also reduce the risk of other fecal-oral diseases such as *Salmonella, Cryptosporidium, E. coli*, and *Campylobacter* infection.[1045]

Fecal culture testing of the whole herd followed by aggressive culling of infected animals is very effective in reducing the prevalence of paratuberculosis in the herd.[1044] The risks of transmission of *M. avium* subsp. *paratuberculosis* within both dairy and beef herds have been compiled into three major documents, entitled "How to Do Risk Assessments for Johne's Disease," "Handbook for Veterinarians and Dairy Producers," and "Handbook for Veterinarians and Beef Producers." These documents are available at the national office of United States Animal Health Association (USAHA) and the National Institute for Animal Agriculture (NIAA) website.[1046] A companion document entitled "U.S. Voluntary Johne's Disease Herd Status Program for Cattle" is also available from the USDA website.[1047–1049]

In herds with low to moderate infection levels (1% or fewer clinical cases per year), wise use of a combination of testing, culling, and biosecurity measures may eliminate clinical disease within 1 to 3 years and most infected adults in 5 to 7 years, as the adult cattle are culled over time. Complete elimination of infected cattle is likely to take many years after clinical Johne's disease is no longer apparent. Biosecurity measures should remain in place, or Johne's disease is likely to recur. Herds at low risk for Johne's disease need to be reminded that a major risk factor for Johne's disease is the purchase of replacement cattle from herds of unknown Johne's status. As herd owners continue to expand herd size with the acquisition of purchased animals, Johne's disease is often included in the purchased cattle.[1050]

Herds with more severe, widespread infection require aggressive control programs and many years to eliminate clinical Johne's disease. These herds should consider Johne's vaccination as one serious alternative to control Johne's disease. However, a practical control program and sound herd management can eliminate clinical disease in these herds and reduce the economic impact of Johne's disease to a minimum. Feeding monensin to heifers and all adult cows should reduce the *M. avium* subsp. *paratuberculosis* bioburden on the farm and therefore reduce transmission to young susceptible calves.[1032] Rather than focused attention to detect all *M. avium* subsp. *paratuberculosis* shedders, the diagnostic efforts should focus on elimination of those cattle shedding the highest concentration of *M. avium* subsp. *paratuberculosis*, that is super-shedders.[980]

In addition to the United States, with its well defined voluntary Johne's disease herd status program,[1049] Australia was one of the first countries to implement a national Johne's disease control program. The National Johne's Disease Market Assurance Program for Cattle was launched in 1996.[1050,1051] Subsequently both Denmark and Holland[1052] and more recently Canada have implemented voluntary Johne's disease programs.[1053]

32.158.11

Vaccination

A killed Johne's vaccine is available in several states through an accredited veterinarian with the approval of the state veterinarian required. The vaccine is effective at reducing the prevalence and delays the onset of clinical signs,[1054,1055] but does not eliminate infection. Investigations with Johne's vaccines in sheep and cattle provide the following insights: (1) most Johne's disease vaccines reduce fecal *M. avium* subsp. *paratuberculosis* shedding by approximately 90% compared with nonvaccinated controls; (2) onset of fecal shedding is delayed

approximately 1 year postvaccination in sheep; (3) Johne's disease—vaccinated sheep have reduced mortality compared with nonvaccinates; (4) Johne's disease vaccines stimulate both a humoral and a cellular immune response in the host, but the site of vaccination may progress to develop granulomas or draining abscesses; and (5) massive *M. avium* subsp. *paratuberculosis* challenge may overcome the protective immunity of the vaccine, resulting in clinical Johne's disease in animals.[1056–1062] On occasion in some flocks a vaccinated sheep will develop multibacillary lesions and excrete millions of *M. avium* subsp. *paratuberculosis* CFU per gram of manure and thus expose all other sheep in the flock. Thus some vaccinated sheep may serve as vectors if moved to flocks at low risk for Johne's disease.[1063]

Animals must be younger than 35 days old when vaccinated. Reasons some oppose the use of vaccination for Johne's disease include the following: (1) vaccinated animals will often have a positive skin test for tuberculosis; (2) injection site lesions may develop into granulomas, even abscesses that break and drain; (3) accidental injection of humans is a risk that has resulted in severe painful granulomas[1064]; (4) vaccination interferes with immunologic tests for Johne's disease; and (5) some producers rely on the vaccine as the sole management tool for Johne's disease and neglect herd management changes to reduce the risk of transmission.

32.158.12 Paratuberculosis and Crohn's Disease

An increasing body of literature implicates mycobacteria as one of the causes of Crohn's disease, a chronic smoldering inflammatory disease of the gastrointestinal tract of people.[1065,1066] Abundant evidence suggests human exposure to *M. avium* subsp. *paratuberculosis* may occur from the milk or meat of infected cows and/or the water supply.[1067] Many research publications suggest *M. avium* subsp. *paratuberculosis* is killed by pasteurization, whereas others provide evidence that *M. avium* subsp. *paratuberculosis* does survive pasteurization but in decreased numbers.[1067–1072] More recently, retail pasteurized milk from three states was shown to harbor viable *M. avium* subsp. *paratuberculosis* in 2.9% of samples tested, with *M. avium* subsp. *paratuberculosis* genetic material detected in 64% of the 702 samples of milk tested.[1073] Later the same group found *M. avium* subsp. *paratuberculosis* in samples of soft cheeses.[1074] Because most metropolitan water is not filtered and is collected from rural areas, drinking water may also represent a major potential source of the pathogen. Intestinal cohabitation may change parasitism to clinical disease after a long latency period. Numerous cofactors such as genetic susceptibility, coexistence of other enteric diseases, hormonal factors, and other, poorly understood stress factors may enhance the likelihood of clinical disease after a long incubation period.[1075–1078] An association between Crohn's disease and paratuberculosis has been shown, but a causal relationship remains to be demonstrated. *M. avium* subsp. *paratuberculosis* isolates from humans with Crohn's disease have been shown to be genetically similar to isolates from cattle with Johne's disease.[1079] Recent reports indicate an increasing number of patients with Crohn's disease in whom *M. avium* subsp. *paratuberculosis* has been isolated from breast milk and from the peripheral blood.[1080] One critical report defines the characteristics of Crohn's disease that differentiate it from Johne's disease, suggesting the two syndromes are in fact different disease processes.[1081] For an unbiased review of a possible connection between Johne's disease and Crohn's disease, see the report entitled “The Diagnosis and Control of Johne's disease” by the National Academies of Science.[1082]

32.159 COPPER DEFICIENCY IN RUMINANTS

John Maas

Bradford P. Smith

32.159.1 Definition and Etiology

Copper deficiency occurs when the diet contains an abnormally low amount of copper (primary copper deficiency) or when copper absorption or metabolism is adversely affected (secondary copper deficiency). If inadequate amounts of copper are available to tissues in the form of essential metalloenzymes, the signs of copper deficiency (hypocuprosis) may occur. Clinical signs in ruminants include diarrhea, decreased weight gain, unthrifty appearance, anemia, changes in coat color (achromotrichia) or wool quality, anemia, spontaneous fractures, lameness (epiphysitis), and demyelinization (enzootic ataxia of sheep and goats, or swayback). One of these syndromes usually predominates in a given herd.

The minimum recommended dietary copper concentration (dry matter basis [DMB]) is 4 to 10 ppm (mg/kg) for cattle,[1083,1084] 5 ppm for sheep,[1085] and 7 ppm for merino sheep.[1085] Young animals and fetuses are more susceptible to copper deficiency than mature animals, and cattle are more susceptible than sheep. Secondary copper deficiency is associated with high dietary levels of molybdenum, sulfates, zinc, iron, or other compounds. Secondary copper deficiency often manifests with clinical signs of diarrhea and weight loss or unthriftiness. It has been called *teart, peat scours, renguerra, pine*, and *salt lick disease*.[1086] Salt sickness in Florida appears to be the result of combined copper and cobalt deficiencies. The cause of copper deficiency in clinical cases is often multifactorial and can be difficult to quantify. In addition, unknown factors cause clinical expression of copper deficiency in ruminants to be manifested as a variety of syndromes.

32.159.2 Clinical Syndromes and Differential Diagnosis
